Typical use of flexible metallic tubing: up-to-6-ft length for fixture whip in ceiling, containing two No. 18 Type fixture wires (for 6-amp fixture load, see 402.5) or two No. 16 Type fixture wires (for 8-amp fixture load). 240.5 permits No. 16 and No. 18 fixture wire to be protected at 20 amps.

IMPORTANT!! Flex tubing is equipment grounding conductor because fittings are listed for grounding, and the fixture wires in flex tubing are tapped from circuit protected at not over 20 amps, as permitted in 250.118.

Fig. 360-1. Flexible metallic tubing has limited application. (Sec. 360.12.)

360.20. Size. FMT is only available for general purposes in the metric designator 16 and 21 (trade size $\frac{1}{2}$ and $\frac{3}{4}$) sizes, with the metric designator 12 (trade size $\frac{3}{8}$) available for ductwork connections [300.22(B)], connections in other spaces for environmental air [300.22(C)], for luminaire connections, especially in accessible ceilings, and as part of listed assemblies.

360.24. Bends. The allowable bend radius for this product varies significantly based on whether it will be flexed, which should only be infrequently, after the initial installation. There are two tables that provide the required data.

ARTICLE 362. ELECTRICAL NONMETALLIC TUBING: TYPE ENT

362.2. Definition. One type of plastic raceway defined in the Code (Fig. 362.1) is *ENT* (electrical nonmetallic tubing), which is “a pliable corrugated raceway of circular cross section with integral or associated couplings, connectors, and fittings listed for the installation of electrical conductors. It is composed of a material that is resistant to moisture [and] chemical atmospheres and

is flame retardant.” ENT can be bent by hand, when being installed, to establish direction and lengths of runs.

Fig. 362-1. ENT is a pliable, bendable plastic raceway for general-purpose use for feeders and branch circuits.

362.10. Uses Permitted. Electrical nonmetallic tubing is permitted to be used as a general-purpose, flexible-type conduit in any type of occupancy ([Fig. 362.2](#)). ENT is not limited to use in buildings up to three stories high. But, where the building does *not* exceed three stories above grade, ENT may be used in “exposed” locations. Where concealed throughout (and not just above the first three stories), ENT may be used in a building of any height—subject to conditions given in 362.10 and 362.12. ENT may be used:

Fig. 362-2. ENT may be used in residential and nonresidential buildings. (Sec. 362.10.)

1. Concealed in walls, floors, and ceilings that provide a thermal barrier with at least a 15-min fire rating from listings of fire-rated assemblies. In the case of walls, this is fairly easy to arrange, since most $\frac{1}{2}$ -in. drywall used in commercial construction carries this rating. The same holds true above a drywall ceiling. However, if there is a suspended ceiling (common in commercial occupancies), check with the building inspector. The support grid and the ceiling panels need to be identified as a combination for this duty. For example, having 15-min panels would do no good if the T-bars dumped those panels onto the floor after 11 min of fire exposure. Note that although this is an “exposed” use not normally permitted in high-rise construction, there is specific permission to use this procedure in 362.10(5).

As previously indicated, ENT may be used *exposed* without these limitations in a building that is not over three floors above grade. The first floor is defined as the one with at least half its exterior wall area at or above grade level; one additional floor level at the base is allowed for vehicle parking or storage, provided it is not designed for human habitation. This is limited permission that recognizes ENT for exposed use under the same limitations that were placed on use of Romex in the past, provided the building finish has a 15-min fire rating. In addition, where sprinklers are provided on all floors so as to provide complete occupancy protection, not just the areas in which the ENT is proposed, ENT may be used even if exposed.

2. In severe corrosive locations where suited to resist the particular atmosphere (but not “exposed”).
3. In concealed, dry, and damp locations not prohibited by 362.12.

4. Above suspended ceilings with at least a 15-min fire rating (see commentary above).
5. Embedded in poured concrete with fittings that are listed or otherwise identified for that use.
6. In indoor wet locations, or in slab on or below grade, with fittings listed for this application.
7. Metric designator 16 through 27 (trade sizes $\frac{1}{2}$ through 1) sizes are authorized to be prewired as a listed manufactured assembly. Even if installed prewired, it is still a raceway and not a cable and must observe the four quarter bend rule, etc.
8. High-temperature wiring must not be used unless it is certain to be operating, due to limited loading, at temperatures below the rating of the ENT.

362.12. Uses Not Permitted. ENT may not be used in *exposed* locations, except above suspended ceilings of 15-min fire-rated material in buildings of any height above grade. This section excludes ENT from hazardous locations—except for intrinsically safe circuits per Art. 504—from supporting fixtures or equipment, from use where the ambient temperature exceeds that for which the ENT is rated, from direct burial, and from exposed use, with exceptions as noted.

362.20. Size. ENT is Code-recognized in metric designator 16 to 53 (trade size $\frac{1}{2}$ to 2) sizes. A full line of plastic couplings, box connectors, and fittings is available, which are attached to the ENT by mechanical method or cement adhesive ([Fig. 362.3](#)).

Fig. 362-3. Available in $\frac{1}{2}$ -, $\frac{3}{4}$ -, and 1-in. sizes, ENT has a full line of couplings and box

connectors. (Sec. 362.2.)

362.26. Bends—Number in One Run. ENT runs between “pull points”—boxes, enclosures, and conduit bodies—must not contain more than the equivalent of four quarter-bends (360°).

362.30. Securing and Supporting. ENT has enhanced support requirements, with the basic requirement of being securely fastened every 900 mm (3 ft). There is the usual 1.8 m (6 ft) allowance for luminaire and equipment whips above suspended ceilings, and it can also be fished in finished buildings as necessary. Horizontal runs through framing members are also recognized as sufficient provided, as in the case of many other wiring methods, the ends of a run are actually secured and not just supported. Appropriately listed cable ties also make an appearance as being eligible for use with this wiring method.

ARTICLE 366. AUXILIARY GUTTERS

366.1. Scope. Auxiliary gutters differ from wireways only by the way they are applied in the field; they are usually listed for both purposes as they leave a manufacturer. They are available in both sheet metal and nonmetallic forms. They have hinged or removable covers that allow for conductors to be laid in place after the system is complete. Their function is to supplement wiring spaces at meter centers, distribution centers, switchboards, and similar locations in a wiring system (Fig. 366.1). Note that a careful review of the definitions in Sec. 2 shows that auxiliary gutters are not classified as raceways for the reasons discussed at length in [Chap. 1](#) as part of the analysis of the changes associated with the revision to the raceway definition, and as covered in this commentary.

Fig. 366-1. Typical applications of auxiliary gutters provide the necessary space to make taps, splices, and other conductor connections involved where a number of switches or CBs are fed by a feeder (top) or for multiple-circuit routing, as at top of a motor control center (right) shown with a ground bus in gutter (arrow). (Sec. 366.1.)

They are not wireways, which are unlimited in length and intended as a circuit wiring method that connects a line and a load. An auxiliary gutter with a rectangular opening cut to match a similar opening cut in a panelboard, and used to contribute to the wire bending space in the panelboard would be an excellent example. This concept is why the auxiliary gutter article has current-carrying limitations for busbars placed in the enclosure, but the wireway article does not address the topic. If

a conductor needs to be pulled from the gutter through a nipple to a panel or switchboard, the use may be crossing over into the wireway article. That said, the basic field installation rules for conductor fill, derating thresholds, use as pull boxes, and distinctions between metallic and nonmetallic versions are similar. Refer to wireway topics in Arts. 376 and 378 for more information.

Auxiliary gutters are available in both metal and nonmetallic forms, but only the nonmetallic form requires listing, with specific listing requirements given that differ based on whether the use will be outdoors or not.

366.12. Uses Not Permitted. Auxiliary gutters are not intended to be a type of general raceway and are not permitted to extend more than 30 ft (9.0 m) beyond the equipment which they supplement, except in elevator work. Where an extension beyond 30 ft (9.0 m) is necessary, Arts. 376 or 378 for wireways must be complied with. The label of Underwriters Laboratories Inc. on each length of trough bears the legend “Wireways or Auxiliary Gutters,” which indicates that they may be identical troughs but are distinguished one from the other by their use. See comments following 376.2 in this handbook.

366.20. Conductors Connected in Parallel. Refer to the commentary at 376.20. The same new provision was made in both articles, along with Art. 378.

366.22. Number of Conductors. The rules on permitted conductor fill for auxiliary gutters are basically the same as those for wireways. Refer to 376.22. Note that part rule permits more than 30 current-carrying conductors—including neutrals in some cases, as described under 310.15(B)(5); but where over 30 such wires are installed, the correction factors specified in 310.15(B)(3)(a) must be applied to all the wires. One of the key differences between metallic and nonmetallic gutters is the fact that the 30-conductor allowance before derating is imposed does not apply to nonmetallic gutters. For nonmetallic auxiliary gutters the derating factors apply after the first three current-carrying conductors, just like any tubular raceway. Metal gutters are much better at providing a heat sink and a surface that easily radiates heat away from itself.

No limit is placed on the size of conductors that may be installed in an auxiliary gutter.

Figure 366-2 shows a typical gutter application where the conductor sizes and fill must be calculated to determine the acceptable csa of the gutter. There are several factors involved in sizing auxiliary gutters that often lead to selecting the wrong size. The two main factors are how conductors enter the gutter and the contained conductors at any cross section. The minimum required width of a gutter is determined by the csa occupied by the conductors and splices and the space necessary for bending conductors entering or leaving the gutter. The total csa occupied by the conductors at any cross section of the gutter must not be greater than 20 percent of the gutter interior csa at that point (366.22). The total csa occupied by the mass of conductors and splices at any cross section of the gutter must not be greater than 75 percent of the gutter interior csa at that point [366.56(A)].

Fig. 366-2. Minimum acceptable gutter cross section and depth must be calculated. (Sec. 366.22.)

In the gutter installation shown in Fig. 366-2, assume that staggering of the splices has been done to minimize the area taken up at any cross section—to keep the mass of splices from all adding up at the same cross section. The greatest conductor concentration is therefore either at section *x*, where there are three 300-kcmil and one 4/0 THW conductors, or at section *y*, where there are eight 3/0 THW conductors. To determine at which of these two cross sections the fill is greater, apply the appropriate csas of THW conductors as given in Table 5, Chap. 9:

1. The total conductor csa at section *x* is 3×0.5281 sq in. plus 1×0.3718 , or 1.9561 sq in.
2. The total conductor csa at section *y* is 8×0.3117 sq in. or 2.4936 sq in.

Section *y* is, therefore, the determining consideration. Because that fill of 2.4936 sq in. can at most be 20 percent of the gutter csa, the total gutter area must be at least 5 times this conductor fill area, or 12.468 sq in.

Assuming the gutter has a square cross section (all sides of equal width) and the sides have an integral number of inches, the nearest square value would be 16 sq in., indicating a 4- by 4-in. gutter, and that would be suitable if the 300-kcmil conductors entered the end of the gutter instead of the top. But because those conductors are deflected entering and leaving the gutter, the first two columns of Table 312.6(A) must also be applied to determine whether the width of 4 in. affords sufficient space for bending the conductors. That consideration is required by 366.58. The worst condition (largest conductors) is where the supply conductors enter; therefore the 300-kcmil cable will determine the required space.

Table 312.6(A) shows that a circuit of one 300 kcmil per phase leg (or wire per terminal) requires a bending space at least 5 in. deep (in the direction of the entry of the 300-kcmil conductors), calling for a standard 6- by 6-in. gutter for this application.

In Fig. 366-2, if the 300-kcmil conductors entered at the left-hand end of the gutter instead of at the top, 366.58 would require Table 312.6(A) to be applied only to the deflection of the No. 3/0 conductors. The table shows, under one wire per terminal, a minimum depth of 4 in. is required. In that case, a 4- by 4-in. (102- by 102-mm) gutter would satisfy.

366.56. Splices and Taps. Part (A) is discussed under 366.22.

Part (B) covers cases where bare busbar conductors are used in gutters. The insulation might be cut by resting on the sharp edge of the bar or the bar might become hot enough to damage the insulation. When taps are made to bare conductors in a gutter, care should be taken so as to place and form the wires in such a manner that they will remain permanently separated from the bare bars.

Part (C) requires that identification be provided wherever it is not clearly evident what apparatus is supplied by the tap. Thus if a single set of tap conductors is carried through a short length of conduit from a gutter to a switch and the conduit is in plain view, the tap is fully identified and needs no special marking; but if two or more sets of taps are carried in a single conduit to two or more different pieces of apparatus, each tap should be identified by some marking such as a small tag secured to each wire.

ARTICLE 368. BUSWAYS

368.2. Definition. Busways consist of metal enclosures containing insulator-supported busbars. Varieties are so extensive that possibilities for 600-V distribution purposes are practically unlimited. Busways are available for either indoor or outdoor use as point-to-point feeders or as plug-in takeoff routes for power. Progressive improvements in busway designs have enhanced their electrical and mechanical characteristics, reduced their physical size, and simplified the methods used to connect and support them. These developments have in turn reduced installation labor to the extent that busways are most favorably considered when it is required to move large blocks of power to loadcenters (via low-impedance feeder busway), to distribute current to closely spaced power utilization points (via plug-in busways), or to energize rows of lighting fixtures or power tools (via trolley busways).

Busways classed as indoor low-reactance assemblies can be obtained in small incremental steps up to 6000 A for copper busbars and 5000 A for aluminum. Enclosed outdoor busways are similarly rated. In the plug-in category, special assemblies are available up to 5000 A, although normal 600-V ac requirements generally are satisfied by standard busways in the 225- to 1000-A range. Where power requirements are limited, small compact busways are available with ratings from 250 down to 20 A.

Plug-in and clamp-on devices include fused and nonfusible switches and plug-in circuit breakers (CBs) rated up to about 800 A. Other plug-in devices include ground detectors, temperature indicators, capacitors, and transformers designed to mount directly on the busway.

Busways are listed by UL with the following general information:

This category covers busways and associated fittings, rated 600 V or less, 6000 A or less. Busways are grounded metal enclosures containing factory-mounted bare or insulated conductors, which are usually copper or aluminum bars, rods, or tubes. These enclosures and, in some cases an additional ground bus, are intended for use as equipment grounding conductors.

Some busways are not intended for use ahead of service equipment and are marked with the maximum rating of overcurrent protection to be used on the supply side of the busway.

Busways may be of one of the following designs:

Lighting Busway—Busway intended to supply and support industrial and commercial luminaires. Lighting busway is limited to a maximum current rating of 50 A.

Trolley Busway—Busway having provision for continuous contact with a trolley by means of a slot in the enclosure. Trolley busway may be additionally marked “Lighting Busway” if intended to supply and support industrial and commercial luminaires.

Continuous Plug-In Busway—Busway provided with provision for the insertion of plug-in devices at any point along the length of the busway. Continuous plug-in busway is intended for general use and may be installed within reach of persons. Busways of this design are limited to a maximum current rating of 225 A.

Short-Run Busway—Unventilated busway intended for a maximum run of 30 ft horizontally, 10 ft vertically and are primarily used to supply switchboards. Except for transformer stubs, short-run busway is not intended to have intermediate taps.

368.10. Uses Permitted. [Figure 368-1](#) shows the most common way in which busways are installed—in the open. Note that the former use of the term “concealed” in (B), as was the case for many Code cycles and as can be seen from context, squarely violated the definition of this term in Art. 100. This faulty terminology was corrected in the 2011 **NEC**, now correctly reading “Behind Access Panels.”

Fig. 368-1. Ventilated-type (with open grills for ventilation) busways may be used only “in the open” and must be “visible.” Only the totally enclosed, nonventilating type may be used above a suspended ceiling. (Sec. 368.10.)

Wiring methods above lift-out ceiling panels are considered to be “exposed”—because the definition of that word includes reference to “behind panels designed to allow access.” This section calls for busways to be “located in the open and visible” and therefore does not allow them above suspended ceilings, except with the limitations given in (B). In such locations, the busway is permitted provided means of access are provided, the joints and fittings can be reached for maintenance, and the ceiling is either not air-handling, or if air-handling, the busway conductors are insulated and there are no provisions for plug-in connections. [Figure 368-2](#) shows how other Code rules tie into this section. Note that the wording of 368.10(B)(2) directly correlates to the permission

for such busway use in spaces used for environmental air—as stated in 300.22(C).

When busway is visible –

When busway is in non-air-handling ceiling space

Fig. 368-2. Use of busways involves **NEC** rules on accessibility of overcurrent devices. (Sec. 368.10.)

Special rules govern the routing of busways through floor slabs. [Figure 368-3](#) illustrates the prohibition against the use of ventilated busways on the pass-through and up at least 1.8 m (6 ft) above the slab, as covered in 368.10(C)(2)(a). [Figure 368-4](#) shows a close-up of a floor slab penetration. Depending on the occupancy, curbing is frequently required by 368.10(C)(2)(b).

VIOLATION !

Fig. 368-3. Ventilated busways may not be used through a floor slab and for 6 ft (1.8 m) above the floor. [Sec. 368.10(C)(2)(a).]

Fig. 368-4. Opening for a busway riser through a slab must be curbed in most cases, and fire-stopped if the floor is part of a required fire separation, as required by 300.21. [Sec. 368.10(C).]

Other data limiting applications of busways are contained in the UL regulations on listed busways—all of which information becomes mandatory Code rules because of **NEC 110.3(B)**. Such UL data are as follows:

Busways are intended for installation in accordance with Art. 368 of **ANSI/NFPA 70**, “**National Electrical Code**” (**NEC**), and the manufacturer’s installation instructions.

Busways investigated to determine their suitability for

- installation in a specified position,
- for use in a vertical run, or for support at intervals greater than 5 ft,

- for outdoor use

are so marked. This marking is on or contiguous with the nameplate incorporating the manufacturer's name and electrical rating.

A busway or fitting containing a vapor seal is so marked, but unless marked otherwise, the busway or fitting has not been investigated for passage through a fire-rated wall.

Busway marked "Lighting Busway" and protected by overcurrent devices rated in excess of 20 A is intended for use only with luminaires employing heavy-duty lampholders unless additional overcurrent protection is provided for the luminaire in accordance with the **NEC**. [See [Fig. 368-5](#) for examples; refer in this handbook to the discussion at 210.21(A) and 210.23 with which this provision correlates for more information.]

Fig. 368-5. These applications involve UL data and several Code sections. [Sec. 368.17(A).]

Trolley busway should be installed out of the reach of persons or be otherwise installed to prevent accidental contact with exposed conductors.

Some busways have a number of short stubs and are marked for use with certain compatible equipment.

Busways and fittings covered under this category are intended for use with copper conductors unless marked to indicate which terminals are suitable for use with aluminum conductors. Such marking is independent of any marking on the terminal connectors and is on a wiring diagram or other readily visible location.

Unless the equipment is marked to indicate otherwise, the termination provisions are based on the use of 60°C ampacities for wire sizes 14 to 1 AWG, and 75°C ampacities for wire sizes 1/0 AWG and larger as specified in Table 310.15(B)(16) of the **NEC**. Termination provisions are determined based on values provided in Table 310.15(B)(16) or Section 310.15(B)(7), with no adjustment made for correction factors.

Some fittings are suitable for use as service equipment and are so marked.

Note that fluorescent lighting fixtures can be fed by a 50-A lighting busway with each fixture individually fused at a few amps to protect its nonheavy-duty lampholders using the fuse in each fixture or in its attachment plug, as is permitted in the UL application information as well as by **NEC** 368.17(C), Exception Nos. 2 or 3. In that case, the lighting busway for Code purposes is halfway between a feeder and a branch circuit. Each fixture tap might be understood to be a branch circuit, and the wording “overcurrent device” is intended to require protection that will qualify as a “branch circuit overcurrent device” as defined in Art. 100. If it so qualifies, then the arrangement fully complies with 210.23(C).

368.17. Overcurrent Protection. As given in part (A), Rating of Overcurrent Protection—Feeders, the rated ampacity of a busway is fixed by the allowable temperature rise of the conductors. The ampacity can be determined in the field only by reference to the nameplate.

The rule of part (B) covers Reduction in Ampacity Size of Busway. Overcurrent protection—either a fused-switch or CB—is usually required in each busway subfeeder tapping power from a busway feeder of higher ampacity, protected at the higher ampacity. This is necessary to protect the lower current-carrying capacity of the subfeeder and should be placed at the point at which the subfeeder connects into the feeder. However, the exception to this section provides that overcurrent protection may be omitted where busways are reduced in size, if the smaller busway does not extend more than 50 ft and has a current rating at least equal to one-third the rating or setting of the overcurrent device protecting the main busway feeder (Figs. 368-6 and 368-7), but only at an “industrial establishment.” For all other installations, the basic rule for overcurrent protection at the point where the busway is reduced in size must be satisfied.

Example:

Fig. 368-6. A busway subfeeder may sometimes be used without protection. [Sec. 368.17(B).]

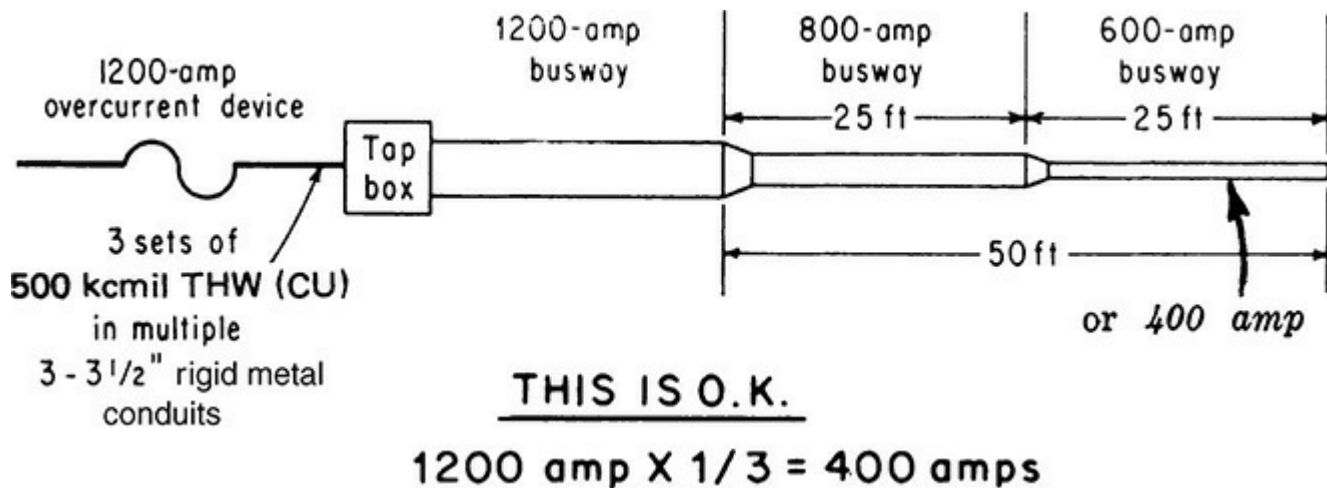

Fig. 368-7. Total length of a reduced busway is not over 50 ft (15.24 m). [Sec. 368.17(B).]

Where the smaller busway is kept within the limits specified, the hazards involved at industrial installations are very slight and the additional cost of providing overcurrent protection at the point where the size is changed is not considered as being warranted.

The rules of part (C) are interrelated with those of 240.24 and 404.8. The basic rule of this section makes it clear that branch circuits or subfeeders tapped from a busway must have overcurrent

protection on the busway at the point of tap. And if they are out of reach from the floor, all fused switches and CBs must be provided with some means for a person to operate the handle of the device from the floor (hookstick, chain operator, rope-pull operator, etc.).

Although no definition is given for “out of reach” from the floor, the wording of 404.8(A) can logically be taken to indicate that a switch or CB *is* “out of reach” if the center of its operating handle, when in its highest position, is more than 2.0 m (6 ft 7 in.) above the floor or platform on which the operator would be standing. Thus, a busway over 2.0 m (6 ft 7 in.) above the floor would require some means (hookstick, etc.) to operate the handles of any switches or CBs on the busway.

Figure 368-8 relates the rules of 240.24 and Exception No. 1 to 368.17(C)—with the rule of 240.24 *permitting* overcurrent devices to be “not readily accessible” when used up on a high-mounted busway and 368.17 *requiring* such protection to be mounted on the busway. To get at overcurrent protection in either case, personnel might have to use a portable ladder or chair or some other climbing technique. Again, 6 ft 7 in. (2.0 m) could be taken as the height above which the overcurrent protection is not “readily accessible”—or the height above which the Code considers that some type of climbing technique (ladder, chair, etc.) may be needed by some persons to reach the protective device.

NE Code 368.17 — Plug-in connection for tapping-off branch circuit shall contain overcurrent protection, which does not have to be within reach of person standing on floor.

Plug-in connection for tapping-off a feeder or subfeeder shall contain overcurrent protection, which does not have to be within reach of person standing on floor.

Fig. 368-8. Protection must always be used on busway for these taps—regardless of busway mounting height. (Sec. 368.17.)

Then, where the plug-in switch or CB on the busway is “out of reach” from the floor (i.e., over 6 ft 7 in. [2.0 m] above the floor), provision must be made for operating such switches or CBs from the floor, as shown in Figs. 368-9 and 368-10. The plug-in switch or CB unit must be able to be operated by a hookstick or chain or rope operator if the unit is mounted out of reach up on a busway. Section 404.8 says all busway switches and CBs must be operable from the floor. Refer to 404.8(A) Exception No. 1. Figure 368-10 shows a typical application of hookstick-operated disconnects.

Fig. 368-9. Busway plug-in devices must be operable from the floor or platform where operator stands. (Sec. 368.17.)

Fig. 368-10. Disconnects mounted up on the busway (top arrow) are out of reach from the floor but do have hook-eye lever operators to provide operation by person standing in front of machines. Although the **NEC** does not literally require ready availability of a hookstick, it is certainly the intent of the Code that one be handy (lower arrow). (Sec. 368.17.)

Figure 368-11 shows an application that has caused controversy because 368.17 says that any busway used as a feeder must have overcurrent protection on the busway for any subfeeder or branch circuit tapped from the busway. Therefore, use of a cable-tap box on busway without overcurrent protection could be ruled a Code violation. It can be argued that the installation shown—a 10- or 25-ft (3.0- or 7.5-m) tap without overcurrent protection on the busway—is covered by Exception No. 1 of that section, which recognizes taps as permitted in 240.21—including 10- and 25-ft (3.0- or 7.5-m) taps. But, as is now clearly spelled out in Exception No. 1 to 368.17(C), busways may be tapped as would any feeder. It is to be viewed simply as a conductor. Then, the rules given in the referenced parts of 240.21 must be satisfied. Therefore, the application shown in Fig. 368-11 does satisfy the Code.

Fig. 368-11. This use of unprotected tap from busway does not conflict with 368.17 as long as the tap meets the applicable requirements in 240.21(B) and thereby satisfies 368.17(C) Exception No. 1. (Sec. 368.17.)

The 2017NEC added a fourth exception to (C) providing still further relief. If the branch-circuit overcurrent device directly supplies a readily accessible disconnect, it is not necessary to provide for operation of that branch-circuit device from the floor. Note that Exception No. 1 already provides relief where the installation meets a tap rule in 240.21. This exception must not become a vehicle for violating the tap rules when Exception No. 1 calls for them to be applied. On the contrary, this is simply an allowance to mount the disconnect remote from the busway. The overcurrent device will stay on the busway, but a hookstick need not be provided.

368.17(D). Rating of Overcurrent Protection—Branch Circuits. Refer to data on busways on lighting branch circuits in 368.10 and Fig. 368-5.

368.30. Support. As shown in Fig. 368-12, busway risers may be supported by a variety of spring-loaded hangers, wall brackets, or channel arrangements where busways pierce floor slabs or are supported on masonry walls or columns. Fig. 368-4 shows an example of spring mounts for vertical busways which may be located at successive floor-slab levels or, as indicated in Fig. 368-12, supported by wall brackets located at intermediate elevations. Springs provide floating cradles for absorbing transient vibrations or physical shocks. Fire-resistant material is packed into space between the busway and the edges of slab-piercing throat.

Fig. 368-12. Vertical busway runs should be supported at least every 5 ft, unless designed and marked for another support interval. (Sec. 368.30.)

368.56. Branches from Busways. Busway branches can be made into a wide variety of [Chap. 3](#) wiring methods. For cord connections, the rule here requires that a cord connecting to a plug-in switch or CB on a busway must be supported by a “tension take-up support device” with the swag not longer than 1.8 m (6 ft). Industrial occupancies can extend that limit indefinitely, provided the cord is supported at 2.5 m (8 ft) or shorter intervals. “Bus Drop Cable” has its own coverage in UL (ZIMX) apart from most flexible cords. It is not covered in Art. 400, because it is comprised of either three or four finely stranded building wires of one of seven insulation types (TW, THW, THHN, THWN, XHHW, RHW, or RHH) together with a grounding conductor, all cabled within an overall jacket. [Fig. 368-13](#) shows a number of details regarding branches from busways, and [Fig. 368-14](#) shows a busway lineup, using bus-drop cable connections.

Fig. 368-13. Wiring details at busway connections must be carefully observed. (Sec. 368.56.) Circuits fed from busways may be run in any conventional wiring method—such as EMT or rigid conduit (left) or as “suitable cord,” such as “bus-drop” cable down to machines. And cable-tap boxes may be used (arrow at right) to connect feeder conductors that supply power to busway. SOME

TYPE of tension-relief device must be used on bus-drop cable or other suitable cord where it connects to a plug-in switch or CB on busway, per 368.56(B)(4). Photo shows strain relief connector with mesh grip (arrow) on cord to bus-tap CB, which is equipped with hook-eye lever mechanism to provide operation of the CB by a hookstick from floor level—as required by 404.8(A), Ex. No. 1 and 368.17(C).

Fig. 368-14. Bus-drop power cables are flexible cables listed by UL for feeding power down from busway to supply machines. Cables here have connector bodies on their ends for machine cord caps to plug into. [Sec. 368.56(B).]

368.320. Marking. Busway is also available for medium-voltage distribution, as covered in Part IV of Art. 368. The UL data that apply to this category follow:

This category covers metal-enclosed busways of the nonsegregated phase type, for use in accordance with Art. 368 of ANSI/NFPA 70, “**National Electrical Code.**” Nonsegregated phase busway is one in which all phase conductors are in a common metal enclosure without barriers between the phases.

These are assemblies of metal-enclosed conductors, together with associated interconnections, enclosures, and supporting structures.

These assemblies are intended for use on systems with nominal rated voltages from 601 V to 38 kV ac. Current ratings are from 600 to 10,000 A.

These assemblies may be intended for either indoor or outdoor applications. An assembly that has been investigated to determine that it is rainproof is marked “Rainproof,” “Outdoor,” or “3R.”

Enclosures are of the ventilated or nonventilated type. A ventilated enclosure is provided with

means to permit circulation of sufficient air to remove excess heat.

A nonventilated enclosure is constructed to provide no intentional circulation of external air through the enclosure.

These products are marked with the following electrical ratings: rated voltage, rated continuous current, insulation (BIL) level, frequency, rated frequency withstand voltage (dry), and rated short-circuit withstand current (momentary current). When shipped in sections, each section is marked.

ARTICLE 370. CABLEBUS

Cablebus is an approved assembly of insulated conductors mounted in “spaced” relationship in a *ventilated* metal-protective supporting structure, including fittings and conductor terminations. In general, cablebus is assembled at the point of installation from components furnished by the manufacturer.

The definition was revised in the 2014 **NEC** to increase the emphasis on the role of the cablebus structure as a means to “securely fasten or support conductors” and as such to separate it from most raceways.

Field-assembly details are shown in [Fig. 370-1](#). First, the cablebus framework is installed in a manner similar to continuous rigid cable support systems. Next, insulated conductors are pulled into the cablebus framework. Then the conductors are supported on special insulating blocks at specified intervals. And finally, a removable (ventilated) top is installed. Refer to the discussion at 215.2(A) (1)(a) Ex. 2 for an approach to meeting **NEC** termination rules.

Fig. 370-1. Cablebus systems are field assembled from manufactured components. (Sec. 370.2.)

ARTICLE 372. CELLULAR CONCRETE FLOOR RACEWAYS

372.1. Scope. The term *Precast cellular concrete floor*, as mentioned in 372.2, refers to a type of floor construction designed for use in steel frame, concrete frame, and wall-bearing construction, in which the monolithically precast reinforced concrete floor members form the structural floor and are supported by beams or bearing walls. The floor members are precast with hollow voids that form smooth round cells. The cells are of various sizes depending on the size of floor member used.

The cells form raceways which by means of suitable fittings can be adapted for use as underfloor raceways. A precast cellular concrete floor is fire-resistant and requires no additional fireproofing.

372.18. Cellular Concrete Floor Raceways Installation. The 2017 NEC reorganized this article almost completely, without substantive change. Five former sections became lettered subsections under this title.

(A) Header. Connections to the cells are made by means of *headers* secured to the precast concrete floor, extending from cabinets and across the cells. A header connects only those cells that are used as raceways for conductors. Two or three separate headers, connected to different sets of cells, may be used for different systems (e.g., for light and power, signaling, and telephones).

Figure 372-1 shows three headers installed, each header connecting a cabinet with separate groups of cells. Special elbows extend the header to the cabinet.

Fig. 372-1. Headers, flush with finished concrete pour, carry wiring to cells. (Sec. 372.5.)

(B) Connection to Cabinets and Other Enclosures. The require listed raceways and fittings.

(C) Junction Boxes. Figure 372-2 shows how a JB must be arranged where a header connects to a cell.

Fig. 372-2. Junction box is used to provide conductor installation from header to cell. (Sec. 372.7.)

(D) Inserts. A $1\frac{7}{8}$ -in. diameter hole is cut through the floor and into the center of a cell with a concrete drill bit. A plug is driven into the hole and a nipple is screwed into the plug. The nipple is designed to receive an outlet with a duplex electrical receptacle or an outlet designed for a telephone or signal system.

(E) Markers. Markers used with this system are special flat-head brass screws which are installed level with the finished floor. One type of marker marks the location of an access point between a header and a spare cell reserved for, but not connected to, the header. A junction box can be installed at the point located by the marker if the spare cell is needed in the future. The screw for this type of marker is installed in the center of a special knockout provided in the top of the header at the access point. The second type of marker is installed over the center of cells at various points on the floor to locate and identify the cells below. Screws with specially designed heads identify the type of service in the cell.

372.23. Ampacity of Conductors. This section makes clear that the rules given in 310.15(B) (3) requiring derating of conductors where there are more than three current-carrying conductors within a raceway, cable, or trench apply to conductors installed within cellar concrete floor raceways. Note the comments on discontinued outlets, Sec. 58.

372.58. Discontinued Outlets. When an outlet is discontinued, the conductors supplying the outlet shall be removed from the raceway. The general practice is to loop wire intermediate receptacles between the header and the end of the run. This requirement assures that reinsulated conductors will not be resting in the raceway below an abandoned outlet. This in turn prevents a fish wire inserted afterward from a downstream location from getting caught on a reinsulated conductor, with very destructive consequences.

It is often advisable to wire each outlet on its own pair of conductors back to the header or other junction point. Then, when an outlet is abandoned, the associated pair of conductors can be withdrawn without disrupting other outlets on the run. Take care, however, to keep track of the total number of conductors at all portions of the duct, because the ampacity derating factors for mutual

conductor heating (see 372.23) will apply. Some jurisdictions provide limited waivers to these derating factors in underfloor applications, however, in order to encourage this practice and thereby discourage the reinsulation of conductors. When the conductors are withdrawn, leave a pull string in their place so the outlet can be easily reactivated in the future as necessary.

ARTICLE 374. CELLULAR METAL FLOOR RACEWAYS

374.2. Definitions. This is a type of floor construction designed for use in steel frame buildings in which the members supporting the floor between the beams consist of sheet steel rolled into shapes that are so combined as to form cells, or closed passageways, extending across the building. The cells are of various shapes and sizes, depending upon the structural strength required.

The cellular members of this type of floor construction form raceways. A cross-sectional view of one type of cellular metal floor is shown in Fig. 374-1.

Fig. 374-1. Cross section of one type of cellular-method floor construction. (Sec. 374.2.)

374.18. Cellular Metal Floor Raceways Installation. Connections to the ducts are made by means of *headers* extending across the cells. A header connects only to those cells that are to be used as raceways for conductors. Two or three separate headers, connecting to different sets of cells, may be used for different systems (e.g., for light and power, signaling systems, and public telephones).

Figure 374-2 shows the cells, or ducts, with header ducts in place. By means of a special elbow fitting the header is extended up to a cabinet or distribution center on a wall or column. A junction box or access fitting is provided at each point where the header crosses a cell to which it connects.

CELLULAR STEEL FLOOR contains unlimited number of channels for enclosing and isolating various electrical services. Wiring is routed from distribution panels to floor outlets through header ducts as shown.

Fig. 374-2. Components for electrical usage in cellular metal floor must be properly applied. (Sec. 374.3.)

(A) Connection to Cabinets and Extensions from Cells. This section establishes the acceptable methods for connection to equipment and enclosures supplied from a cellular metal floor raceway. Flex and liquidtight flex may be used, provided they are not installed in concrete. Where installed in concrete, RMC, IMC, EMT, or “approved fittings” are permitted. Where the equipment or enclosure has provisions for connecting and equipment grounding conductor, then nonmetallic conduit, ENT, and LFNMC are permitted. As stated by the last sentence, where listed for installation in concrete, LFMC and LFNMC are recognized to supply equipment and enclosures from cellular metal floor raceways.

(B) Junction Boxes. The fittings with round covers shown in [Fig. 374-2](#) are termed *access fittings* by the manufacturer but actually serve as junction boxes. Where additional junction boxes are needed, a similar fitting of larger size is provided, which may be attached to a cell at any point.

(C) Inserts. The construction of an insert is shown in Fig. 374-3. A $1\frac{5}{8}$ -in. diameter hole is cut in the top of the cell with a special tool. The lower end of the insert is provided with coarse threads of such form that the insert can be screwed into the hole in the cell, thus forming a substantial mechanical and electrical connection.

Fig. 374-3. Typical insert for connecting from cell-to-floor outlet assembly. (Sec. 374.10.)

(D) Markers. The markers used with this system consist of special flat-head brass screws, screwed into the upper side of the cells with their heads flush with the floor finish.

374.23. Ampacity of Conductors. This section makes clear that the rules given in 310.15(B) (3) requiring derating of conductors where there are more than three current-carrying conductors within a raceway, cable, or trench apply to conductors installed within cellular metal floor raceways. See the extensive comments on the topic of discontinued outlets at 374.58.

374.58. Discontinued Outlets. When an outlet is discontinued, the conductors supplying the outlet shall be removed from the raceway. The general practice is to loop wire intermediate receptacles between the header and the end of the run. This requirement assures that reinsulated conductors will not be resting in the raceway below an abandoned outlet. This in turn prevents a fish wire inserted afterward from a downstream location from getting caught on a reinsulated conductor, with very destructive consequences.

It is often advisable to wire each outlet on its own pair of conductors back to the header or other junction point. Then, when an outlet is abandoned, the associated pair of conductors can be withdrawn without disrupting other outlets on the run. Take care, however, to keep track of the total number of conductors at all portions of the duct, because the ampacity derating factors for mutual conductor heating (see 374.23) will apply. Some jurisdictions provide limited waivers to these derating factors in underfloor applications, however, in order to encourage this practice and thereby discourage the reinsulation of conductors. When the conductors are withdrawn, leave a pull string in their place so the outlet can be easily reactivated in the future as necessary.

ARTICLE 376. METAL WIREWAYS

376.2. Definition. Metal wireways are sheet metal troughs in which conductors are laid in place after the wireway has been installed as a complete system. Wireway is available in standard lengths of 1, 2, 3, 4, 5, and 10 ft (0.30, 0.61, 0.91, 1.22, 1.52, and 3.05 m), so runs of any exact number of feet can be made up without cutting the duct. The cover may be a hinged or removable type. Unlike auxiliary gutters, wireways represent a type of wiring, because they are used to carry conductors between points located considerable distances apart.

The purpose of a wireway is to provide a flexible system of wiring in which the circuits can be changed to meet changing conditions, and one of its principal uses is for exposed work in industrial plants. Wireways are also used to carry control wires from the control board to remotely controlled stage switchboard equipment. The definition here explicitly uses the term “raceway” in contradistinction to 366.2 for auxiliary gutters which does not. An installation of wireway is shown in [Fig. 376-1](#).

Fig. 376-1. Wireway in industrial plant—installed exposed, as required by 376.10 provides highly flexible wiring system that provides easy changes in the number, sizes, and routing of circuit conductors for machines and controls. Hinged covers swing down for ready access. Sec. 376.56 permits splicing and tapping in wireway. And 376.70 covers use of conduit for taking circuits out of wireway. (Sec. 376.10.)

376.10. Uses Permitted. [Figure 376-1](#) shows a typical Code-approved application of 4- by 4-in. wireway in an exposed location.

376.20. Conductors Connected in Parallel. Where single conductor cables comprising each phase, neutral, or grounded conductor of an alternating-current circuit are connected in parallel, the conductors must be installed in groups consisting of not more than one conductor per phase, neutral, or grounded conductor. This is being required to prevent current imbalance in the paralleled conductors due to inductive reactance. The requirement here parallels equivalent text for cable trays in 392.20. A failure to apply this procedure resulted in documented uneven current distribution in a very large feeder run with parallel conductors in a wireway, which was then fully corrected by rearranging the conductors into phase groups. The same rule applies to auxiliary gutters and to nonmetallic wireway.

376.22. Number of Conductors and Ampacity. Wireways have two general conductor limitations covered in this section. The first addresses the physical realities of dealing with large conductor fills with a multitude of potential destinations. The second addresses mutual conductor heating in a context where there will be greater air circulation than in a tubular raceway, and where the conductors are enclosed in a steel enclosure that will function as a heat sink and which affords a ready heat transfer ability to the ambient air.

Part (A) limits the combined cross sectional area of all contained conductors at any given cross section to 20 percent of the cross-sectional area of the wireway. This rule covers both power and control conductors taken together as conductors occupying any given cross section of a wireway.

Part (B) has two sentences. The second correlates with 725.51(B)(2), assuming the control wiring carries its usual load profile of less than 10 percent of its ampacity being carried on any continuous basis. In such cases, based on the I^2R relationship, a 10 percent load will equal 0.1^2 or 1 percent of its potential heat contribution in comparison to its heat when loaded to its ampacity. Such a miniscule heat contribution can be disregarded, which is why the allowance exists in Art. 725 and this sentence makes it so for wireways. With these conductors disregarded, the first sentence tackles power circuits. If the number of current-carrying conductors does not exceed 30, including only those neutrals that must be counted as required by 310.15(B)(5), *mutual conductor heating as reflected in the adjustment factors that are normally applied in accordance with 310.15(B)(3)(a) is ignored and the adjustment factors are not applied.*

Note that spares are not counted here—refer to the discussion regarding Table 310.15(B)(3)(a) and the change in its left-hand column heading for more information on the significance of this consideration. If more than 30 conductors at any cross section are current-carrying, then the adjustment factors for mutual conductor heating will apply to every conductor passing through that cross section. Referring to Table 310.15(B)(3)(a), a 31st current-carrying conductor at a cross section dooms the entire fill at that cross section to have its allowable ampacities reduced by 60 percent, which in most cases will be unacceptable and sufficient to redesign the application. This permission, as far as it goes, is a crucial characteristic of metal wireways.

Figure 376-2 shows examples of wireway fill calculations. The example at the bottom shows a case where power and lighting wires (which *are* current-carrying wires) are mixed with signal wires. Because there are not over 30 power and light wires, no derating of conductor ampacities is needed. If, say, 31 power and light wires were in the wireway, then the power and light conductors would be subject to derating. If all 49 conductors were signal and/or control wires, no derating would be required. But, in all cases, wireway fill must not be over 20 percent.

Basic rule

1. Any number of current-carrying conductors up to a maximum of 30, without derating.

2. The sum of the cross-section areas of all the conductors (from table 5 in Chap. 9 of the *NEC*) must not be more than $20\% \times W'' \times D''$

Note: Signal and motor control wires are not considered to be current-carrying wires. Any number of such wires are permitted to fill up 20% of wireway cross-section area.

THIS IS OK !

Fig. 376-2. Wireway fill and need for derating must be carefully evaluated. (Sec. 376.22.)

376.23. Insulated Conductors. Deflected conductors in wireways must observe the rules on adequate enclosure space given in 312.6. This section is based on the following substantiation for its submittal for the 1990 **NEC** (the internal Code references have been updated to agree with current numbering within [Chap. 3](#)):

Although wireways don't contain terminals or supplement spaces with terminals, pull boxes and conduit bodies don't either. This rule borrows language from both 366.58(A) and 314.28(A)(2), Exception, in an attempt to produce a consistent approach in the Code. Although in some cases the deflected conductors travel long distances in the wireway and are therefore easily inserted, in other cases the conductors are deflected again within inches of the first entry. The result is even more stress on the insulation than if they were entering a conduit body.

The next logical step, as in part **(B)** of this section, is to squarely address short wireway sections that are used as pull boxes. This part now assures that the usual requirements in 314.28 will be applied.

376.30. Securing and Supporting. Wireway must be supported every 5 ft (1.5 m). Wireway lengths over 5 ft (1.5 m) must be supported at *each end or joint, unless* listed for other support. In no case should the distance between supports for wireway exceed 10 ft (3.0 m). Vertical runs can use a 4.5 m (15 ft) interval, provided there is no more than a single joint between supports.

376.56. Splices, Taps, and Power Distribution Blocks. The conductors should be reasonably accessible so that any circuit can be replaced with conductors of a different size if necessary and so that taps can readily be made to supply motors or other equipment. Accessibility is ensured by limiting the number of conductors and the space they occupy as provided in 376.22 and 376.23. For power distribution blocks, the bending space requirements of 312.6(B) (the bigger distance table) apply even if a particular entry may happen to be arranged at a right angle. In addition, the block design must include an insulating cover so the uninsulated live parts are not exposed after the block installation is complete, even with the wireway cover open. [Figure 376-3](#) shows an example of the devices in use. The 2014 **NEC** has added another qualification, lifted from 314.28(E) (5), that the wiring end up arranged so the terminals on the blocks remain unobstructed after the completion of work.

Fig. 376-3. Power distribution blocks in a wireway; although difficult to see in this photo, the blocks are covered with clear polycarbonate. (Sec. 376.56.)

The 2014 **NEC** has placed a listing restriction from the UL Guide Card information (category QPQS) on these blocks, one that most installers have been completely unaware of, by adding it to 376.56(B)(1) as black letter code. They are not permitted on the line side of service equipment. This cancels, for the time being, one of the more elegant applications of this equipment, namely, the subdivision of large service conductors within a wireway section into 2 to 6 m and switches permitted at one location. It remains to be seen whether the industry will take the necessary steps to accommodate this practice, and at best it is likely to be a lengthy process.

376.70. Extensions from Metal Wireways. Knockouts are provided (or they can be field-punched) in wireways so that circuits can be run to motors or other apparatus at any point. Conduits connect to such knockouts, as shown in [Fig. 376-1](#).

Sections of wireways are joined to one another by means of flanges which are bolted together, thus providing rigid mechanical connection and electrical continuity. Fittings with bolted flanges are provided for elbows, tees, and crosses and for connections to cabinets. See 250.118.

ARTICLE 378. NONMETALLIC WIREWAYS

This article covers nonmetallic wireways. As given in 378.22, the maximum conductor fill is

determined in the same manner as for metal wireways, but support requirements are slightly different. 378.30 requires support at 3-ft (0.9-m) intervals, instead of 5-ft (1.5-m) spacing. The most significant difference is found in 378.22 with respect to mutual conductor heating derating factors. Because nonmetallic wireways are not efficient heat sinks and transfer heat comparatively poorly, the 30-conductor allowance prior to the imposition of derating factors that pertains to metal wireways does not apply to nonmetallic wireways. The derating factors begin to apply with the fourth current-carrying conductor, just like ordinary tubular raceways.

ARTICLE 380. MULTIOUTLET ASSEMBLY

380.1. Scope. UL data (Guide Card PVGT) are as follows:

This category covers multioutlet assemblies, accessories for use with multioutlet assemblies, and factory-assembled wiring kits intended for installation into multioutlet assemblies.

Multioutlet assemblies consist of an enclosure or raceway and outlet wiring devices that provide power for connection of utilization equipment. Multioutlet assemblies are intended for use in dry locations, other than hazardous (classified) locations, in accordance with ANSI/NFPA 70, “National Electrical Code” (**NEC**). Multioutlet assemblies are intended to be connected to permanently installed branch circuits operating at frequencies between 50 and 400 Hz and dc (direct current) circuits.

A multioutlet assembly may be provided with channels for additional power circuits, control circuits, power-limited circuits and communication-circuit wiring for audio, video and data.

Accessories are parts that may be added to a multioutlet assembly either by the manufacturer or by the installer to add functionality, e.g., hangers, retainers, luminaires, remote-control modules, signs.

Wiring kits are assemblies of conductors and devices, such as receptacle outlets and switches, which are supplied as a wiring system for use in specific multioutlet assemblies.

A part used to connect, change direction, or terminate a multioutlet assembly (e.g., a transition coupler, an end cap, a corner, a tee, an adapter, a box) or a specific wiring device that completes the system is covered under Multioutlet Assembly Fittings (PVUR).

380.2. Uses Permitted. These assemblies are intended for surface mounting, except that the metal type may be surrounded by the building finish or recessed so long as the front is not covered. The nonmetallic type may be recessed in baseboards. Section 380.76 allows them, if metal, to extend through a dry partition provided no outlet is left within the partition and provided the removable cover can be removed on each side from all exposed portions. In calculating the load for branch circuits supplying multioutlet assembly, see 220.14(H).

380.23. Insulated Conductors. This new section incorporates the wireway conductor bending space provisions applicable to 4 AWG and larger conductors in multioutlet assemblies. Although this may seem a stretch, the proposal substantiation demonstrated the existence of multioutlet assemblies as large as 10 in. wide and 5 in. deep, containing very large devices. The rule only applies to field-assembled equipment.

ARTICLE 382. NONMETALLIC EXTENSIONS

A nonmetallic extension is an assembly of two insulated conductors within a nonmetallic jacket or an

extruded thermoplastic covering. The assembly is mounted directly on the surface of walls or ceilings. Nonmetallic extensions are permitted only if (1) the extension is from an existing outlet on a 15- or 20-A branch circuit and (2) the extension is run exposed and in a dry location. Nonmetallic extensions are limited to residential or office buildings that do not exceed three stories above grade. This category also, as a new 2008 **NEC** category in this article, includes *concealable nonmetallic extensions*, which comprise two, three, or four insulated circuit conductors that mount on wall and ceiling surfaces in a flat configuration that is capable of concealment behind paint, joint compound, wallpaper, etc. In this form, if identified for the purpose, concealable extensions are permitted in buildings of more than three stories. As of this writing, no products have been listed by UL in this category, but there are manufacturers who are strongly interested in the concept.

ARTICLE 384. STRUT-TYPE CHANNEL RACEWAY

384.1. Scope. This article covers the installation and use of channel raceways. It provides requirements for the channel manufacturer as well as for the designer and installer. As given in 384.2, such raceways must be resistant to moisture or protected against corrosion. The next sentence specifically recognizes galvanized steel, stainless steel, and enameled or PVC-coated aluminum and steel as satisfying this requirement for moisture and corrosion resistance.

384.10. Uses Permitted. Channel raceways are permitted for a variety of applications. Analysis of the locations and conditions of permitted use spelled out here indicates that channel raceway may be used within buildings where exposed in dry locations—and for limited cases in “damp or corrosive” locations—for power poles to feed receptacles, electrified partitions, undercarpet or under-floor applications, and the like. Such raceways may be used only for systems rated up to 600 V, and in hazardous locations as described in 501.4(B).

384.12. Uses Not Permitted. Here the Code prohibits the use of channel raceway systems where concealed and permits their use only indoors when constructed with ferrous metal (e.g., steel or iron) and protected only by enamel coating.

384.22. Number of Conductors. To determine the number of conductors in a strut channel layout, first note whether you are using couplings that mount inside the channel or outside it. Then read out the area available for conductor fill from Table 384.22. For example, a standard $1\frac{5}{8} \times 1\frac{5}{8}$ strut with an inside coupling (“joiner”) has 327 mm^2 (0.507 in.^2) available for wire fill. If all the wires you want to insert are the same size, divide this number by the csa of the wire from [Chap. 9 Table 5](#). Otherwise, add the proposed fill and compare it with what you just determined was available.

example If 3 8 AWG THHN wires will be used in the above strut, how many 10 AWG THHN could be added?

Step 1: As determined above, the maximum possible fill area is 0.507 in.^2 .

Step 2: Subtract the known fill, 3 8 AWG = $3 \times 0.0366 \text{ in.}^2 = 0.1098 \text{ in.}^2$. Therefore, remaining fill area is $0.507 - 0.110$ (three significant figures) = 0.397 in.^2 .

Step 3: Divide the remaining fill area by the csa of a 10 AWG wire based on Table 5; 10 AWG THHN csa is: 0.0211 in.^2 . $0.397 \div 0.0211 = 18.8$ conductors; therefore, the answer is 18 10 AWG

THHNs can be installed with the 3/8 AWG THHNs.

Note that there is a similar calculation to be done as part of a three-part procedure to determine if the installation qualifies for a waiver from the ampacity derating rules. This allowance depends on three factors being true, and then allows a similar waiver as applies to metal wireways. The second and third conditions are not difficult to meet. The first condition, however, apparently based on 386.22 for surface metal raceways, is impossible to meet. None of the raceways recognized by this article meet the 2500 mm² (4 in.²) threshold in total cross-sectional area. The largest one, the 1½ × 3 size just misses at 2487 mm² (3.854 in.²), and the others are all smaller. Therefore, this allowance cannot be used, all the wires are subject to the penalties in 310.15(B)(3)(a), and the exemption procedure should be ignored.

ARTICLE 386. SURFACE METAL RACEWAYS

386.1. Use. At one time, this article was titled “Surface Metal Raceways and Surface Nonmetallic Raceways.” The article now covers only metallic surface raceways (Fig. 386.1).

Fig. 386-1. Surface raceway has become popular for new works as well as for modernization. (Sec. 386.10.)

386.21. Size of Conductors. Manufacturers of metal surface raceways provide illustrations and details on wire sizes and conductor fill for their various types of raceway. It is important to refer to their specification and application data.

386.22. Number of Conductors in Raceways. The rules of conductor fill may now be applied to surface metal raceway in very much the same way as standard wireway (Fig. 386.2). This rule applies wireway conductor fill and ampacity determination to any surface metal raceway that is over 4 sq in. in cross section. As with wireway, if there are not more than 30 conductors in the raceway and they do not fill the cross-sectional area to more than 20 percent of its value, the conductors may be used without any conductor ampacity derating in accordance with 310.15(B)(3). This allowance only applies to raceways with over 2500 mm² (4 in.²) in cross-sectional area. Only as an example, in the Wiremold product line, that parameter applies to only two raceways, the 4000

(undivided only, 7.2 in.²) and the 6000 (16 in.²).

Fig. 386-2. NEC rule permits conductor fill of metal surface raceway *without* ampacity derating of wires. (Sec. 386.22.)

386.60. Grounding. In every type of wiring having a metal enclosure around the conductors, it is important that the metal be mechanically continuous in order to provide protection for the conductors and that the metal form a continuous electrical conductor of low impedance from the last outlet on the run to the cabinet or cutout box. A path to ground is thus provided through the box or cabinet, in case any conductor comes in contact with the metal enclosure, an outlet box, or any other fitting. See 250.118. This rule also requires transition boxes and fittings that are used to interface with other wiring methods, such as surface device-box extensions, to have an equipment grounding provision for attaching a grounding conductor from the other wiring method.

386.70. Combination Raceways. Metal surface raceways may contain separated systems as shown in Fig. 386-3. The separate compartments must be consistently distinguishable through the use of stamping, imprinting, or color coding of the interior finish. This is why the divider strips that are used to split these raceways in the field are usually painted with two different colors. It is very important to apply that color code consistently. The NEC used to insist that the relative orientation

of the divided segments be maintained throughout. That requirement has been deleted, and now only the color code identifies which divided segment is to be which.

Fig. 386-3. For separating high and low potentials, combination raceway or tiered separate raceways may be used with barriered box assembly. (Sec. 386.70.)

ARTICLE 388. SURFACE NONMETALLIC RACEWAYS

388.1. Scope. Although covered under the same article as surface metal raceway systems—which includes the associated fittings—this wiring method is now covered separately in its own article.

388.2. Definition. The Code describes the various characteristics that surface nonmetallic raceways must possess. Obviously, for any nonmetallic raceway to have the necessary moisture and corrosion resistance, mechanical strength, flame retardance, and low-smoke-producing characteristics, etc., such characteristics must be designed into the raceway system, which means that the manufacturer is responsible for ensuring compliance with this rule. Designers and installers are required to select a manufacturer whose product meets the requirements given here; that is, a *listed* product must be used. Remember to look for the “LS” (low-smoke producing) marking on the selected nonmetallic raceway system.

ARTICLE 390. UNDERFLOOR RACEWAYS

390.3. Use. Underfloor raceway (now defined in 390.2) was developed to provide a practical means of bringing conductors for lighting, power, and signaling systems to office desks and tables (Fig. 390.1). It is also used in large retail stores, making it possible to secure connections for display-case lighting at any desired location.

Fig. 390-1. Underfloor raceway system, with spaced grouping of three ducts (one for power, one for telephone, one for signals), is covered with concrete after installation on first slab pour. (Sec. 390.3.)

This wiring method makes it possible to place a desk or table in any location and it will always be over, or very near to, a duct line. The wiring method for lighting and power between cabinets and the raceway junction boxes may be conduit, underfloor raceway, wall elbows, and cabinet connectors.

390.4. Covering. The intent in paragraphs (A) and (B) is to provide a sufficient amount of concrete over the ducts to prevent cracks in a cement, tile, or similar floor finish. [Figure 390-2](#) shows a violation. Two 1½- by 4½-in. underfloor raceways with 1 in. high inserts are spaced ¾ in. apart by adjustable-height supports resting directly on a base floor slab, as shown. After raceways are aligned, leveled, and secured, concrete fill is poured level with insert tops. But spacing between raceways must be at least 1 in.; otherwise the concrete cover must be 1½ in. deep.

Fig. 390-2. The 1-in. cover is inadequate for raceways less than an inch apart. (Sec. 390.4.)

390.7. Splices and Taps. This section has a second paragraph that recognizes “loop wiring” where “unbroken” wires extend from underfloor raceways to terminals of attached receptacles, and then back into the raceway to other outlets. For purposes of this Code rule *only*, the loop connection

method is not considered a splice or tap (Fig. 390.3).

Fig. 390-3. “Loop” method permitted at outlets supplied from underfloor raceways. (Sec. 390.7.)

Note: As noted in the exception, splices and taps may be made in trench-type flush raceway with an accessible removable cover. The removable cover of the trench duct must be accessible after installation, and the splices and taps must not fill the raceway to more than 75 percent of its cross-sectional area.

390.8. Discontinued Outlets. When an outlet is discontinued, the conductors supplying the outlet shall be removed from the raceway. The general practice is to loop wire intermediate receptacles between the header and the end of the run. This requirement assures that reinsulated conductors will not be resting in the raceway below an abandoned outlet. This in turn prevents a fish wire inserted afterward from a downstream location from getting caught on a reinsulated conductor, with very destructive consequences.

It is often advisable to wire each outlet on its own pair of conductors back to the header or other junction point. Then, when an outlet is abandoned, the associated pair of conductors can be withdrawn without disrupting other outlets on the run. Take care, however, to keep track of the total number of conductors at all portions of the duct, because the ampacity derating factors for mutual conductor heating (see 390.17) will apply. Some jurisdictions provide limited waivers to these derating factors in underfloor applications, however, in order to encourage this practice and thereby discourage the reinsulation of conductors. When the conductors are withdrawn, leave a pull string in their place so the outlet can be easily reactivated in the future as necessary.

390.17. Ampacity of Conductors. This section makes clear that the rules given in 310.15(B) (3) requiring derating of conductors where there are more than three current-carrying conductors within a raceway, cable, or trench apply to conductors installed within underfloor raceways. See the above comment.

ARTICLE 392. CABLE TRAYS

392.2. Definition. Cable trays are open, raceway-like support assemblies made of metal or suitable nonmetallic material and are widely used for supporting and routing circuits in many types of buildings. Troughs of metal mesh construction provide a sturdy, flexible system for supporting feeder cables, particularly where routing of the runs is devious or where provision for change or

modification in circuiting is important. Ladder-type cable trays are used for supporting interlocked-armor cable feeders in many installations (Fig. 392.1). This article also covers cable tray with solid bottoms in numerous places, and wire mesh tray has been added to the fill tables [Tables 392.22(A) and 392.22(B)(1)] as of the 2011 Code edition. Where past Code editions treated a cable tray simply as a support system for cables, in the same category as a clamp or hanger, the Code today recognizes a cable tray as a conductor support method, somewhat like a raceway, under prescribed and extremely limited conditions, and an integral part of a Code-approved wiring method. However, the definition carefully avoids any mention of the term *raceway* within its provisions. Refer to the extensive commentary in this book at the definition of the term “raceway” in Art. 100. Any “raceway” must be an “enclosed” channel for conductors. A cable tray is a *support system*, not a raceway.

Fig. 392-1. Two basic types of cable tray. (Sec. 392.2.)

Cable trays are not generally available as a listed product. UL does classify it, but only for its suitability for use as an equipment grounding conductor. The relevant text in the Guide Card information reads as follows:

This category covers cable trays intended for assembly in the field and for use in accordance with Art. 392 of ANSI/NFPA 70, “National Electrical Code” (NEC). They have been Classified as to their suitability for use as equipment grounding conductors

in accordance with Secs. 392.60(A) and 392.60(B) of the **NEC**. The cable trays are marked on the outer surface of the sidewall of the tray indicating the cross-sectional area of the grounding metal.

Many have misunderstood the ramifications of the limited classification, supposing that if extensive modifications are made in the field, a listing would be compromised. There is no listing to compromise. However, if after all bonding connections have been made, any field changes affect the effective cross-sectional area of metal in a potential ground-fault return path, then the classification is necessarily void at that point for any disturbed sections of tray. Of course, if the tray will not be used as a fault current return path, (the usual case) then the absence of a classification means nothing in this context. See the discussion at 392.60 for more information.

392.10. Uses Permitted. The **NEC** recognizes a cable tray as a support for wiring methods that may be used without a tray (metal-clad cable, conductors in EMT, IMC, or rigid conduit, etc.), and a cable tray may be used in either commercial, industrial, or institutional buildings or premises (Fig. 392.2). Where cables are available in both single-conductor and multiconductor types—such as SE (service entrance) and UF cable—only the multiconductor type may be used in a tray. However, Sec. 392.10(B)(1) permits use of single-conductor building wires in a tray. Single-conductor cables for use in a tray must be 1/0 AWG or larger, listed for use in a tray, and “marked on the surface” as suitable for tray applications. In earlier **NEC** editions, single-conductor cable in a tray had to be 250 kcmil or larger. Sizes 1/0 through 4/0 AWG single-conductor cables may now be used but if used in a ladder-type tray the rung spacing must not be over 225 mm (9 in.) apart. Sizes 250 kcmil and larger may be used in any kind of tray. This rule states that such use of building wire is permitted in industrial establishments only, where conditions of maintenance and supervision ensure that only competent individuals will service the installed cable tray system. This applies to ladder-type trays, ventilated troughs, solid bottom, or ventilated channel-type cable trays.

Fig. 392-2. Cable-tray use is subject to many specific rules in Art. 392. (Sec. 392.10.)

Single-conductor cables used in a cable tray must be a type specifically “listed for use in cable trays.” This is a qualification on the rule that was in previous codes permitting use of single-conductor building wire (RHH, USE, THW, MV) in a cable tray. The wording permits any choice of conductor types that may be used, simply requiring that any type must be listed. It adds thin-wall-insulated cables, like THHN or XHHW, to the other types mentioned. Present UL standards make reference to cables designated “for CT (cable tray) use” or “for use in cable trays”—which is marked on the outside of the cable jacket. Such cables are subjected to a “vertical tray flame test,” as used for Type TC tray cable and other cables. Only cables so tested and marked “VW-1” would be recognized for use in a cable tray.

A cable tray is not a wireway without a cover. This is one of the most abused provisions in the entire **NEC**. Single-conductor cable tray has been found in exhibition halls and hospitals, and just about every other nonindustrial occupancy, except dwellings. None of those occupancies qualifies for single-conductor tray. Single-conductor tray has also been seen over industrial motor control centers, a qualified occupancy to be sure, but filled with motor branch circuit and control conductors running from 12 AWG up to 3/0 AWG. Again, a cable tray is not a wireway without a cover. Single conductors in cable trays are only permitted in the very restricted circumstances itemized here. Specifically, single conductors are only permitted in industrial occupancies with qualified maintenance and supervision, in sizes 1/0 AWG and larger. Medium-voltage conductors run as Type MV cable are permitted to run as single conductors, provided they follow the same rules.

Section 392.10(C) specifically uses the word “only” when referring to cable types that are permitted to be used in cable trays in hazardous locations. In previous Code editions, wording was more open-ended and permitted specific cables without limiting use to only such cables.

As covered in part (D), nonmetallic cable tray may be used in corrosive locations. This permits use of nonmetallic tray—such as fiberglass tray—in industrial or other areas where severe corrosive atmospheres would attack a metal tray. Such a tray is also permitted where “voltage isolation” is required.

392.12. Uses Not Permitted. Cable tray systems are excluded from hoistways and areas subject to severe physical damage. The language that used to be in this location limiting cable trays in other spaces for environment air, such as plenum cavity ceilings, was removed because 300.22(C) does permit metal cable trays in such spaces provided they only support wiring methods, such as metal-clad cables without nonmetallic coverings, that are allowed in such spaces generally. In addition, metal cable trays with solid bottoms and sides, and a solid cover, are permitted in such spaces to contain other wiring methods. See 300.22(C)(2).

392.18. Cable Tray Installation. Part (A) makes clear that cable trays *must* be used as a complete system—that is, straight sections, angle sections, offsets, saddles, and so forth—to form a cable support system that is continuous and grounded as required by 392.60(A). Cable trays must not be installed with separate, unconnected sections used at randomly spaced positions to support the cable, but must provide electrical continuity and the support required for the cabled wiring methods they contain. Manufactured fittings or field-bent sections of tray may be used for changes in direction or elevation. However, the degree to which this requires absolute end-to-end continuity has significantly evolved.

In the 1971 **NEC**, part (c) of Sec. 318-4 on Installation [now 392.18(A)] read as follows:

(c) Continuous rigid cable supports shall be mechanically connected to any enclosure or raceway into which the cables contained in the continuous rigid cable support extend or terminate.

That wording clearly made a violation of the kind of hookup shown in [Fig. 392-3](#), where the tray does not connect to the transformer enclosures—and is not bonded by jumpers to those enclosures. However, an informational note added in the 1993 Code—which was incorporated in the basic rule in 392.6(A) of the 1996 Code [now 392.18(A)]—indicates that use of “discontinuous segments” is intended to be acceptable—*but*, ground-continuity between the enclosure and the cable tray must be ensured. Refer to 392.30(B)(3) for allowable spacing on discontinuous tray segments containing single conductors, and 392.60(C) for bonding requirements between such sections for more information.

Fig. 392-3. This was clearly a violation of 318-4(c) in the 1971 **NEC** because the tray does not connect to the transformer enclosures. The tray continuity required by 392.18(A) of the present **NEC** is not absolute, provided the installed cables have the support the **NEC** requires. For single conductors as shown here, 392.30(B)(3) permits this discontinuity provided the distance does not exceed 1.8 m (6 ft) and this installation clearly complies in terms of distance, although bonding in accordance with 392.60(C) is not clearly evident. [Sec. 392.18.]

Figure 392-4 shows the rule of part (F). The first paragraph of part (G) covers the termination rules for cables and raceways arriving at the tray. In general, although raceways must always be secured to a tray they service, the tray is not to be used as a qualified point of support, and therefore the next support is the final one before the termination, and therefore must be, typically, within 900 mm (3 ft) of the tray. However, with qualified maintenance and supervision in industrial facilities, and with the knowledge that the tray system has been designed and installed to support the load, then the cable tray qualifies as being “permitted to support raceways and cables and boxes and conduit bodies.” In this case, the tray clamp or adapter for the raceway, which must be listed for this duty, becomes the support at a termination [within 900 mm (3 ft)] of the actual raceway bushing) and therefore the next point of support could be 3.0 m (10 ft) away, or at whatever the support interval is in the article for the arriving wiring method. This is a much more flexible and realistic procedure for most industrial occupancies. The other material addresses how to route wiring methods and boxes on the underside of a tray. Part (H) is new as of the 2011 **NEC** and requires cable trays supporting

medium-voltage wiring to have a readily visible warning label advising of this fact and posted at not over 3 m (10 ft) intervals.

Fig. 392-4. Tray spacing must simply be adequate for cable installation and maintenance. (Sec. 392.18.)

The 2014 edition granted limited relief to qualified industrial occupancies. For the portions of the tray that are not accessible as Art. 100 applies the term to equipment (admitting close approach, not guarded by ... elevation or other effective means), the warning labels can be omitted except as necessary to ensure safety.

392.20. Cable and Conductor Installation. Part (A) notes that any multiconductor cables rated 600 V or less may be used in the same cable tray, and Part (B) points out that high-voltage cables and low-voltage cables may be used in the same tray if a solid, fixed barrier is installed in the tray to separate high-voltage cables from low-voltage cables. And where the high-voltage (over 600 V) cables are Type MC, it is not necessary to have a barrier in the cable tray, and MC cables operating above 600 V may be used in the same tray with MC or other cables operating less than 600 V. But for high-voltage cables other than Type MC, a barrier must be used in the tray to separate high-voltage from low-voltage cables ([Fig. 392.5](#)), or another tray must be used.

Multiconductor cables rated up to 600 volts may be used in the same tray, even when voltage ratings differ.

A solid, noncombustible, fixed barrier must be used in tray to separate high-voltage and low-voltage cables with nonmetallic jackets — but barrier is not needed in tray if the high-voltage cables are Type MC.

Fig. 392-5. Cables of different voltage ratings may be used in the same tray. (Sec. 392.20.) The 2014 **NEC** has clarified that this rule turns on the actual cable operating voltage and not its rated voltage.

[Figure 392-6](#) shows how single-conductor cables must be grouped to satisfy part (C) of this section for a 1200-A circuit made up of three 500-kcmil copper XHHW conductors per phase and three for the neutral. By distributing the phases and neutral among three groups of four and alternating positions, more effective cancellation of magnetic fluxes results from the more symmetrical placement —thereby tending to balance current by balancing inductive reactance of the overall 1200-A circuit.

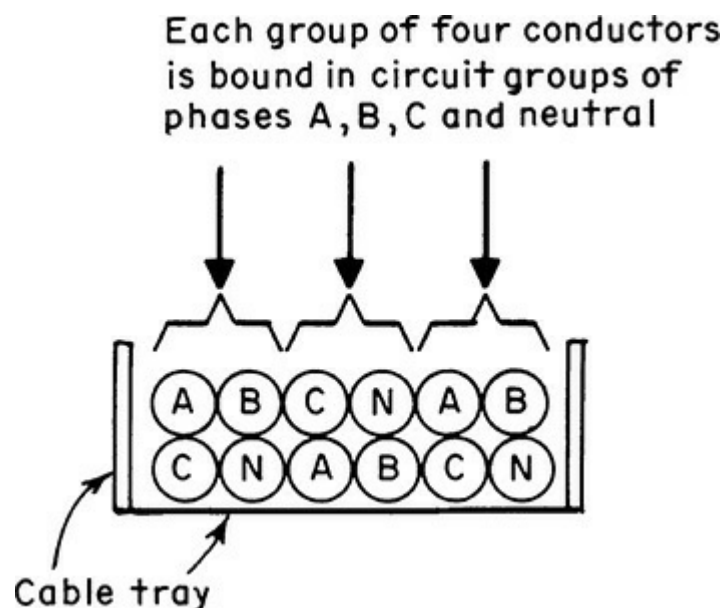

Fig. 392-6. A parallel 1200-A circuit must have conductors grouped for reduced reactance and effective current balance. (Sec. 392.20.)

Part **(D)** prohibits stacking of single conductors 1/0 to 4/0 AWG in ladder or ventilated trough cable trays, unless bound together as a circuit group.

392.22(A). Number of Multiconductor Cables, Rated 2000 V or Less, in Cable Trays. These rules apply to multiconductor cables rated 2000 V or less. For cables rated 2001 V or higher, the number permitted in a cable tray is now covered in 392.22(C). Note that if a tray is used with a divider, each resulting section is calculated separately in terms of allowable fill.

Section 392.22(A) is broken down into parts **(1)**, **(2)**, **(3)**, **(4)**, **(5)**, and **(6)**, each part covering a different condition of use. Section 392.22(A)(1) applies to ladder or ventilated trough cable trays containing multiconductor power or lighting cables or any mixture of multiconductor power, lighting, control, and signal cables.

Section 392.22(A)(1) has three subdivisions:

- (a) Where all the multiconductor cables are made up of conductors 4/0 AWG or larger, the sum of the outside diameters of all the multiconductor cables in the tray must not be greater than the cable tray width, and the cables *must* be placed side by side in the tray in a single layer, as shown in Fig. 392-7. If this applies, and 392.80(A)(1)(c) is used to determine free-air ampacities for the multiconductor cables using the Neher-McGrath engineering calculation, then the cable tray must be wide enough to show that the cables can be spread out as required.

1. Cable-tray width (W) = at least $d_1 + d_2 + d_3 + d_4 + d_5 + d_6 + d_7$ in.
2. All cables *must* lie flat, side by side, in one layer.

Fig. 392-7. No. 4/0 and larger multiconductor cables *must* be in a *single* layer. [Sec.392.22(A).]

- (b) Where all the multiconductor cables in the tray are made up of conductors smaller than 4/0 AWG, the sum of the cross-sectional areas of all cables *must not* exceed the maximum allowable cable fill area in column 1 of Table 392.22(A) for the particular width of cable tray being used. The table shows, for instance, that if a 450 mm (18 in.) wide ladder or ventilated trough cable tray is used with multiconductor cables smaller than 4/0 AWG, column 1 sets 13,500 sq mm (21 sq in.) as the maximum value for the sum of the overall cross-sectional areas of all the cables permitted in that tray, as in Fig. 392-8.

Note: Cross-section area (in sq in.) of each cable can be obtained from cable manufacturers' catalogs or spec sheets. If, in the case shown here, the sum of the cross-section areas of the 10 cables in the tray came to, say, 26 sq in., the smallest permissible width of cable tray would be 24 in., as shown in column 1 of Table 392.22(A). An 18-in.-wide cable tray would be good only for a sum of cable areas up to 21 sq in.

Fig. 392-8. Smaller than No. 4/0 cables may be stacked in tray. [Sec. 392.22(A).]

- (c) Where a tray contains one or more multiconductor cables 4/0 AWG or larger along with one or more multiconductor cables smaller than 4/0 AWG, there are two steps in determining the maximum fill of the tray.

First, the sum of the outside cross-sectional areas of all the cables smaller than 4/0 AWG must not be greater than the maximum permitted fill area resulting from the computation in

column 2 of Table 392.22(A) for the particular cable tray width. Then, the multiconductor cables that are 4/0 AWG or larger must be installed in a single layer, and no other cables may be placed on top of them (Fig. 392.9). Note that the available cross-sectional area of a tray that can properly accommodate cables smaller than 4/0 AWG installed in a tray along with 4/0 AWG or larger cables is, in effect, equal to the allowable fill area from column 1 for each width of tray minus 1.2 times the sum of the outside diameters of the 4/0 AWG or larger cables.

Inside width (W) of tray must not be less than that required by Table 392.22 (A), based on the calculation indicated in column 2 of the table.

Fig. 392-9. Large and small cables have a more complex tray-fill formula. [Sec. 392.22(A).]

Another way to look at this is to consider that, for any cable tray, the sum of the cross-sectional areas of cables smaller than 4/0 AWG, when added to 1.2 times the sum of the diameters of cables 4/0 AWG or larger, must not exceed the value given in column 1 of Table 392.22(A) for a particular cable tray width.

For the installation shown in Fig. 392-9, assume that the sum of the cross-sectional areas of the seven cables smaller than 4/0 AWG is 16 sq in. and assume that the diameters of the four 4/0 AWG or larger cables are 3 in., 3.5 in., 4 in., and 4 in. The abbreviation “Sd” in column 2 of Table 392.22(A) represents “sum of the diameters” of 4/0 AWG and larger cables installed in the same tray with cables smaller than 4/0 AWG. In the example here, then, Sd is equal to $3 + 3.5 + 4 + 4 = 14.5$, and $1.2 \times 14.5 = 17.4$. Then we add the 16-sq-in. total of the cables smaller than 4/0 AWG to the 17.4 and get $17.4 + 16 = 33.4$. Note that this sum is over the limit of 28 sq in., which is the maximum permitted fill given in column 1 for a 24-in. wide cable tray. And column 1 shows that a 30-in. wide

tray (with 35-sq-in. fill capacity) would be required for the 33.4 sq in. determined from the calculation of column 2, Table 392.22(A).

Section 392.22(A)(2) covers use of multiconductor control and/or signal cables (not power and/or lighting cables) in ladder or ventilated trough with a usable inside depth of 6 in. or less. For such cables in ladder or ventilated trough cable tray, the sum of the cross-sectional areas of all cables at any cross section of the tray *must not* exceed 50 percent of the interior cross-sectional area of the cable tray. And it is important to note that a depth of 150 mm (6 in.) must be used in computing the allowable interior cross-sectional area of any tray that has a usable inside depth of more than 150 mm (6 in.) (Fig. 392.10).

Permissible fill:

If the usable depth (D) in the above drawing is 6 in. or less, the sum of the cross-section areas of all contained cables must be not more than $\frac{1}{2} \times D \times W$. If the tray has a depth of more than 6 in., the value of (D) must be taken as 6 in. for computing tray fill.

Fig. 392-10. Tray fill for multiconductor control and/or signal cables is readily determined. [Sec. 392.22(A).]

Section 392.22(A)(3) applies to solid-bottom cable trays with multiconductor power or lighting cables or mixtures of power, lighting, control, and signal cables. The maximum number of cables is covered in three paragraphs that depend on whether or not 4/0 AWG and larger cables comprise the fill, are included in the fill, or are absent from the fill. Section 392.22(A)(4) also covers fill for solid-bottom tray, but for control or signaling cables only.

Section 392.22(A)(5) covers the fill allowances for ventilated channel tray, with the requirements reflected in a side table that is based on whether or not the tray supports a single cable or multiple cables. Section 392.22(A)(6) covers the same topic in the same way for solid channel tray.

392.22(B). Number of Single Conductor Cables, Rated 2000 V or Less, in Cable Trays. This section covers the maximum permitted number of single-conductor cables in a cable tray and stipulates that the conductors must be evenly distributed on the cable tray. This section

differentiates between (1) ladder or ventilated trough tray and (2) ventilated channel-type cable trays.

In Ladder or Ventilated Trough Tray

- (a) Where all cables are 1000 kcmil or larger, the sum of the diameters of all single-conductor cables must not be greater than the cable tray width, as shown in Fig. 392-11. That means the cable tray width must be at least equal to the sum of the diameters of the individual cables.

Tray must be wide enough to hold all cables side-by-side, as shown.

Fig. 392-11. For large cables, tray width must at least equal sum of cable diameters. [Sec. 392.22(B).]

- (b) Where all cables are from 250 up to and including 900 kcmil, the sum of the cross-sectional areas of all cables must not be greater than the maximum allowable cable fill areas in square inches, as shown in column 1 of Table 392.22(B)(1) for the particular cable tray width.

example 1 Assume a number of cables, all smaller than 1000 kcmil, have a total csa of 11 sq in. (7095 mm²). Column 1 of Table 392.22(B)(1) shows that a fill of 11 sq in. (7095 mm²) is greater than that allowed for 6 in. wide tray (6.5 sq in.) but less than the maximum fill of 13 sq in. permitted for 12 in. wide tray. Thus, 12 in. wide tray would be acceptable.

example 2 Assume four 4-wire sets of single-conductor, 600-kcmil RHH cables are used as power feeder conductors in a cable tray. Table 5 in Chap. 9 of the **NEC** shows that the overall csa of each 600-kcmil RHH conductor (without outer covering) is 0.9729 sq in. The total area of 16 such conductors would be 16×0.9729 , or 15.6 sq in. From Table 392.22(B)(1), column 1, 15.6 sq in. is over the maximum permissible fill for 12 in. wide tray, but it is well below the maximum fill of 17.5 sq in. permitted for 16 in. wide tray. Thus, 16 in. wide tray is acceptable.

- (c) Where 1000-kcmil or larger single-conductor cables are installed in the same tray with single-conductor cables smaller than 1000 kcmil, the fill must not exceed the maximum fill determined by the calculation indicated in column 2 of Table 392.22(B)(1)—in a manner similar to the calculations indicated above for multiconductor cables. Note that (d) following requires that if 1/0 through 4/0 AWG single-conductor cables are included in the fill, then the sum of all single-conductor diameters must not exceed the tray width.

example If nine 800-kcmil THW conductors are in a tray with six 1000-kcmil THW conductors, the required minimum width (W) of the tray would be determined as follows:

1. The sum of the csa of the nine 800-kcmil conductors (those smaller than 1000 kcmil) is equal to 9×1.2272 sq in. (from column 5, Table 5, Chap. 9, **NEC**), or 11.04 sq in.

- Each 1000-kcmil THW conductor has an outside diameter of 1.372 in. The sum of the diameters of the 1000-kcmil conductors is, then, 6×1.372 , or 8.232 in.
- Column 2 of Table 392.22(B)(1) says, in effect, that to determine the minimum required width of cable tray it is necessary to add 11.04 sq in. (from 1 above) to 1.1×8.232 (from 2 above) and use the total to check against column 1 of Table 392.22(B)(1) to get the tray width:

$$11.04 + (1.1 \times 8.232) = 11.04 + 9.05 = 20.1 \text{ sq in.}$$

From column 1, Table 392.22(B)(1), the fill of 20.1 sq in. is greater than the 19.5 sq in. permitted for 18 in. wide tray. But, this fill is within the permitted fill of 21.5 sq in. for 20 in. wide tray. The 20 in. wide tray is, therefore, the minimum size tray that is acceptable.

Where *any* cables in the tray are sizes 1/0 through 4/0, then all cables *must* be installed in a single layer. And the sum of the single-conductor cable diameters must not exceed the cable tray width as required for “Multiconductor Cables Rated 2000 V, Nominal, or Less” as covered in 392.22(A)(1) (a).

Section 392.22(B)(2) governs cable fill in ventilated channel cable trays. Where single-conductor cables are installed in 50 mm (2 in.), 75 mm (3 in.), 100 mm (4 in.), or 150 mm (6 in.) wide, ventilated channel-type trays, the sum of the diameters of all single conductors must not exceed the inside width of the channel.

392.22(C). Number of Type MV and Type MC Cables (2001 V or Over) in

Cable Trays. This section applies only to high-voltage circuits in a tray. Type MV cable is a high-voltage cable now covered by Art. 328. Type MC cable is the metal-clad cable operating above 2000 V—a cable assembly long known as interlocked armor cable. [Type MC or other armored cable [e.g., ALS or CS] operating at voltages up to 2000 V must conform to 392.22(A) and 392.80(A) on number and ampacities of cables when used in tray.] Type MV and Type MC medium-voltage cables must conform to the tray fill shown in [Fig. 392-12](#).

- Cable-tray width (W) = at least $d_1 + d_2 + d_3 + d_4 + d_5 + d_6 + d_7$ in.
- All cables *must* lie flat, side by side, in one layer.

Fig. 392-12. Tray must be wide enough for all medium-voltage cables in a single layer. [Sec. 392.22(C).]

392.30. Securing and Supporting. The **NEC** does not have prescriptive language regarding cable tray support intervals, instead leaving it to the various manufacturers to make specifications based on their product designs. If tray is used in a sloping or vertical orientation, the contained cabling must be fastened to the transverse portions of the tray system at points of crossing. Support is also required within the tray to relieve stress on cables as they enter raceways from the tray.

For discontinuous portions of a cable tray system, as anticipated in 392.18(A), the discontinuity cannot exceed the support distance limitations for the wiring methods supported. For single conductors the maximum spacing is 1.8 m (6 ft), which correlates with the support interval for Type MC cable. The conductors must be secured to the tray (or to the terminating location) at both ends. Refer also to 392.60(C) for required bonding at these transitions.

392.46. Bushed Conduit and Tubing. Cables or conductors can drop out of a tray in conduits or tubing provided they have protective bushings and are clamped to the tray side rail by cable tray conduit clamps to provide the bonded connections required by 392.60(B)(4). The clamps must also comply with 392.18(G), which requires listing for this equipment.

392.56. Cable Splices. Although splices are generally limited to use in conductor enclosures with covers and are prohibited in the various conduits, this section permits splicing of conductors in cable trays. Splices are now permitted to project above the side rails, if not subject to damage.

392.60. Grounding and Bonding. Part (A) specifically recognizes the optional use of the metal length of a cable tray as an equipment grounding conductor for the circuit(s) in the tray—in both commercial, industrial, and institutional premises where qualified maintenance personnel are available to ensure the integrity of the grounding path. Tray is not required to be, and frequently is not, used as an equipment grounding conductor. If it is, then it must meet the bonding requirements in 250.96 (which, in the terms of that section, only applies to enclosures used for equipment grounding).

However, any cable tray used to support electrical conductors must also meet the bonding requirements in Part IV or Art. 250, of which 250.86 applies in these cases generally, and requires a connection to the relevant equipment grounding conductor. Parallel rules apply to service conductor applications, as covered in 250.80.

These connections are easily made at the originating and terminating enclosures at each end of the tray. The **NEC** is unclear as to whether intermediate connections must be made, and under what circumstances. If the tray supports making frequent connections to building steel that has been properly bonded, and to which the enclosed grounding conductors are ultimately bonded as required in other **NEC** articles, then additional bonding serves no purpose. Where such connections are not made, one simple approach is to extend the largest relevant grounding conductor from end-to-end, picking up any sections that are discontinuous.

This procedure is sufficient where the tray supports cable assemblies with their enclosed equipment grounding conductors, because such tray applications are not considered to be likely to become energized. This is because a combination of at least two failures (cable jacket and conductor insulation) must both occur in order to energize the tray. However, if the tray supports individual conductors, as only permitted in accordance with 392.10(B), the tray should be considered likely to become energized, and the periodic bonding must comply with the note to Table 250.122 because

energized tray that does not promptly open an overcurrent device under the conditions cited could lead to catastrophic results. This would mean making an engineering judgment relative to the impedance of the steel members of the tray, which is frequently higher than that of the applicable equipment grounding conductor.

A new provision at this point is a requirement for a bonding jumper (size unspecified) for all discontinuous metal cable tray segments for cable tray applications that support only “nonpower conductors.” An informational note explains that such conductors include, but presumably are not limited to, nonconductive optical fiber cables (which are not conductors at all) and Class 2 and Class 3 power limited circuits. This rather odd rule says nothing about what these trays are supposed to be bonded to; only that their segments are to be bonded together. The substantiation pointed to a NECA/NEMA installation standard, #105, paragraph 4.7.3.2, which states that “Cable tray systems containing conductors outside the scope of Art. 250 (such as communications, data, signal cables, etc.) still require bonding and grounding for system operation and performance.” This does not describe a safety justification for the rule. When challenged, the panel cited 250.122 (or 250.66) “tied to the grounding system” but didn’t include this in the rule, and 250.112(I) waives equipment grounding for these circuits in most cases.

Part **(B)** of 392.60 permits (does not require and for very large circuits prohibits) steel or aluminum cable tray to serve as an equipment grounding conductor for the circuits in the tray. Even though metallic cable trays are permitted to act as an equipment grounding conductor in the same way that a metallic conduit, tubing, or cable sheath might be, it should be noted that a cable tray is not a “raceway” as defined in Art. 100. Therefore, other Code rules that apply to “raceways” (e.g., 200.7 on grounded conductor identification) do not apply to cable trays.

Note that paragraph **(4)** under part **(B)** requires all tray system components, as well as “connected raceways,” to be bonded together—either by the bolting means provided with the tray sections or fittings or by bonding jumpers, as shown in [Fig. 392-13](#).

Fig. 392-13. Bare equipment bonding jumpers tie together all tray runs, with jumpers carried up to the equipment grounding bus in the switchboard above. (Sec. 392.60.)

Part (C) is the bonding rule for discontinuous cable tray segments, and requires the isolated segments to be bonded with jumpers sized in accordance with 250.102 and installed in accordance with 250.96. The jumpers in [Fig. 392-13](#) clearly comply with this requirement. As previously noted, 250.96 does not actually apply to the majority of applications that do not employ the tray as an equipment grounding return path. The reference in (A) to Part IV of Art. 250 is the correct one in these cases, and it will apply throughout the tray system, including any discontinuous segments.

392.80(A). Ampacity of Cables, Rated 2000 Volts or Less, in Cable Trays

(1) Multiconductor Cables

When cable assemblies of more than one conductor are installed as required by 392.22(A), each conductor in any of the cables will have an ampacity as given in Table 310.15(B)(16) or 310.15(B)(18). Those are the standard tables of ampacities for cables with not more than three current-carrying conductors within the cable (excluding neutral conductors that carry current only during load unbalance on the phases). The ampacity of any conductor in a cable is based on the size of the conductor and the type of insulation on the conductor, as shown in those tables. For cables not installed in a cable tray, if a cable contains more than three current-carrying conductors, derating of the conductor ampacities must be made in accordance with 310.15(B)(3)(a). But the last sentence of 392.80(A)(1)(a) flatly exempts cables in a tray from these penalties unless the cable itself includes more than three current-carrying conductors, and even then the penalties only apply based on the cable content itself and not on the basis of the total cable population in the tray.

Section 392.11(A)(1)(b) reduces the above determination of conductor ampacities in the case of any cable tray with more than 6 ft (1.83 m) of continuous, solid, unventilated covers. In such cases, the conductors in the cable have an ampacity of not more than 95 percent of the ampacities given in Tables 310.15(B)(16) and 310.15(B)(18).

Section 392.80(A)(1)(c) applies to a single layer of multiconductor cables with maintained spacing (one cable width) between cables, installed in uncovered tray. In such a case the ampacity can be calculated based on the Neher-McGrath method in 310.15(C). An informational note points to a table in Annex B [Table B.310.15(B)(2)(3)] that has ampacities (for use under engineering supervision) calculated under what is effectively a free-air condition.

(2) Single-Conductor Cables

The ampacity of any single-conductor cable or single conductors twisted together is determined as follows:

(a) 600 kcmil and larger—Where installed in accordance with 392.22(B), the ampacity of any 600-kcmil or larger single-conductor cable in an uncovered tray is *not more* than 75 percent of the ampacity given for the size and insulation of conductors in Tables 310.15(B)(17) and 310.15(B)(19). Note that this means 75 percent of the free-air ampacity of the conductor. And if more than 6 ft (1.8 m) of the tray is continuously covered with a solid, unventilated cover, the ampacities for 600-kcmil and larger conductors must not exceed 70 percent of the ampacity value in the same tables.

(b) No. 1/0 through 500 kcmil—For any single-conductor cable in this range, installed in accordance with 392.10 in uncovered tray, its ampacity is not more than 65 percent of the ampacity value shown in Tables 310.15(B)(17) and 310.15(B)(19). And if any such cables in this range are used in a tray that is continuously covered for more than 6 ft (1.8 m) with a solid, unventilated cover, the ampacities must not exceed 60 percent of the ampacity values in the same tables.

(c) Where No. 1/0 and larger single-conductor cables are installed in a single layer in an uncovered cable tray with a maintained spacing of not less than one cable diameter between individual conductors, the ampacities of such conductors are equal to the free-air ampacities given in Tables 310.15(B)(17) and 310.15(B)(19), as shown in [Fig. 392-14](#). However, if the tray has a solid bottom, this procedure is not allowed because the cables will overheat, and the calculation must be

done using the Neher-McGrath method of 310.15(C).

Fig. 392-14. With spacing, cables in tray may operate at free-air ampacity. [Sec. 392.80(A).]

(d) If the single conductors are arranged in a triangle or diamond configuration, with a maintained free space not less than 2.15 times a conductor diameter between bundles, the ampacities of 1/0 AWG and larger conductors can be calculated on the basis of two- or three-conductors in a bundle of conductors run on a messenger, using 310.15(B). This in effect allows the use of (and an informational note points to) the messenger cable ampacity table, Table 310.15(B)(20) for these purposes.

(3) Combinations of Multiconductor and Single-Conductor Cables—When both types are mixed, the ampacities for the single cables and the ampacities for the multiconductor cables are calculated independently using the applicable procedures above. However, this only applies if (1) the multiconductor fill per 392.22(A) and then expressed as a percentage of the total allowable fill in the cable tray, (2) the single conductor fill per 392.22(B) and then expressed as a percentage of the total allowable fill in the cable tray, and (3) total together not over 100 percent. In addition, the multiconductor cables must be installed in accordance with 392.22(A) and the single-conductor cables must be installed in accordance with 392.22(B) and 392.20(C) and (D) with respect to binding parallel makeups and balanced, crossed phase groupings of conductors $(A + B + C + N) + (A + B + C + N)$, etc.

392.80(B). Ampacity of Type MV and Type MC Cables (2001 V or Over) in Cable Trays. This section covers the ampacities of MV and MC cables operating above 2000 V in cable trays—both single-conductor and multiconductor. 392.80(B)(1)(b) recognizes the improved heat dissipation afforded by spacing of the cables and allows use of the free-air ampacity tables in loading multiconductor cables. The spacing of “one cable diameter” is also recognized for single conductors in 392.80(B)(2)(b), with a separate provision in (c) for triangular and square configurations.

ARTICLE 393. LOW-VOLTAGE SUSPENDED CEILING POWER DISTRIBUTION SYSTEMS

393.1 Scope. The heart of this system is a specially constructed suspended ceiling grid work system. The grid is engineered to simultaneously carry ceiling panels and support luminaires, while distributing a low-voltage power system to power luminaires and other utilization equipment capable of operating within Class 2 parameters. Current designs include T-bars that look much like conventional hung ceiling supports but with the power bus available on the very top of the inverted T (Fig. 393.1) to support LED drop-in luminaires that can operate on Class 2 limits, and split T-bars that allow for pendant power takeoffs to suspended luminaires (Fig. 393.2).

Fig. 393-1. The top of this T-bar has a conductor running on both sides of it carrying a Class 2 circuit accessible through the fitting being installed in the photo to supply the luminaire. [Sec. 393.40(A)(1).] (Courtesy of EMerge Alliance®.)

Fig. 393-2. This luminaire is fed from a pendant fitting that attaches to the inside of a specially constructed grid. [Sec. 393.40(A)(2)]. (Courtesy of EMerge Alliance®.)

The basic electrical approach to this system is very similar to the approach taken in Art. 411, in this case with the voltage set not over 30 V ac or 60 V dc and with the Class 2 circuits mandated as ungrounded in 393.60(B). [Figure 393-3](#) shows a power supply for one of these systems arranged to perch above a ceiling tile. Sec. 393.45 implements the general rule in 725.121(B) prohibiting interconnections between Class 2 sources unless listed for that possibility, because if not managed properly, such an interconnection could result in a circuit operating at a higher power level than permitted for a Class 2 system, compromising safety.

Fig. 393-3. This power supply will supply 16 separate grid lines, which the manufacturer estimates will cover between 800 and 1000 sq. ft of ceiling. The listing mark is just visible at the opposite corner. [Sec. 393.6(B)(2).] (Courtesy of EMerge Alliance®.)

As in the case of Art. 411, there is an option to install the entire system completely as a listed entity [393-6(A)], or to assemble the system from components, all listed by function as covered in 393.6(B). As noted, the rails themselves are listed elements of the whole, and 393.30 includes support requirements for the grid structure. The hardware needs to come with the system or be specified in detail in the installation instructions.

These systems are extremely interesting and the article is well drawn and belongs in the Code. However it seems a poor fit in [Chap. 3](#) because it describes an equipment assembly and not a wiring method. This article probably belongs in either [Chap. 4](#) or 6, either near Art. 604 or 605 (Manufactured Wiring Systems or Office Furnishings) or 411 given the obvious close technical connections to that article on lighting operating on similar voltages. These systems will undoubtedly raise administrative issues out of the scope of the Code with respect to the identity of the personnel permitted to install the system. The manufacturer has taken a stab at this by suggesting the grid go up as specified by an interior designer or architect and installed by a ceiling installer along with lay-in panels, and the remainder of the work be specified by a lighting designer or an electrical engineer and installed by an electrical contractor.

ARTICLE 394. CONCEALED KNOB-AND-TUBE WIRING

394.10. Uses Permitted. Note that this wiring method is restricted to use only for extensions of existing installations and is not Code-acceptable as a general-purpose wiring method for new

electrical work. Under the conditions specified in (1) and (2), concealed knob-and-tube wiring may be used to extend an existing installation, and in all other cases only if special permission is granted by the local inspection authority having jurisdiction as noted in the second sentence of 90.4.

394.12. Uses Not Permitted. Of particular interest here is item (5), which forbids this wiring method to be used in joist or stud cavities that are insulated in a manner that envelops the conductors. This, for all practical purposes prohibits the use of this wiring method in exterior walls. Fiberglass, cellulose, blown foam will all envelop the conductors, in violation of this rule. Probably the only way to insulate a wall with this wiring method in it is to use rigid foam board, and that would require opening the wall. With the wall open, no one would be likely to try to save a wiring method that has no equipment grounding conductor, and therefore this wiring method is almost incapable of extension without tripping over a number of other serious code issues.

394.23. In Accessible Attics. Where the wiring is installed at any time after the building is completed, in a roof space having less than 3-ft (900-mm) headroom at any point, the wires may be run on knobs across the faces of the joists, studs, or rafters or through or on the sides of the joists, studs, or rafters. Such a space would not be used for storage purposes, and the wiring installed may be considered as concealed knob-and-tube work.

An attic or roof space is considered accessible if it can be reached by means of a stairway or a permanent ladder. In any such attic or roof space wires run through the floor joists where there is no floor must be protected by a running board and wires run through the studs or rafters must be protected by a running board if within 7 ft (2.1 m) from the floor or floor joists.

394.104. Conductors. Conductors for concealed knob-and-tube work may be any of the general-use types listed in Table 310.104(A) for “dry” locations and “dry and wet” locations such as TW, THW, XHHW, and RHH.

ARTICLE 396. MESSENGER-SUPPORTED WIRING

396.2. Definition. This article covers a wiring system that has long been manufactured and widely used in industrial installations. The basic construction of the wiring method has been used for many years as service-drop cable for utility supply to all kinds of commercial and residential properties.

From long-time application, messenger-supported wiring is actually an old standard method, even though it has not been covered by the **NEC** up until recent years. In 225.6(A)(1), the rule refers to “supported by messenger wire,” and that phrase has been in the Code for over 60 years. [Figure 396-1](#) shows an example of triplex service-drop cable used for supplying floodlights at an outdoor athletic field. So coverage of this type of wiring is important—especially for the vast amounts of outdoor use where messenger-cable wiring offers so many advantages over open wiring. But messenger-supported wiring is recognized for both indoor and outdoor branch circuits and/or feeders. Refer to the discussion under 225.6 for outdoor use of messenger supported wiring.

Fig. 396-1. Messenger-supported cable, used here to supply pole-mounted floodlights, may be constructed in a number of different assemblies, such as this service-drop cable with an ACSR messenger cabled with insulated conductors.

396.10. Uses Permitted. Messenger support is permitted for a wide range of cables and conductors—for use in commercial and industrial applications. Part (B) covers ordinary building wires supported on a messenger and recognizes use of messenger supported wiring in “industrial establishments *only*” with “any of the conductor types given in Table 310.104(A) or Table 310.104(B).” These tables include single-conductor Types MV, RHH, RHW, and THW and also accept all the other single-conductor types, such as THHN, XHHW, TW. All such application is recognized either indoors or outdoors—provided that any conductors exposed to the weather are “listed for use in wet locations” and are “sunlight-resistant” if exposed to direct rays of the sun. The ampacity of the wiring method is easy to determine now that Table 310.15(B)(20) has come out of Annex B and is now available for general use. Any of the cabled wiring methods in Table 396.10(A) can now, by right, be supported by a messenger, including tray cable, multiconductor service entrance cable, UF cable, etc., along with Type MV where consistent with other rules governing medium-voltage wiring.

396.30. Messenger. Part (B) of this section, through a somewhat circular reference to 225.4, now recognizes the use of this wiring method under the first exception to 250.32(B) where the neutral is also the equipment grounding conductor and therefore both a current-carrying conductor and a grounding conductor. Its normal function is as a grounding conductor that does not routinely carry current.

ARTICLE 398. OPEN WIRING ON INSULATORS

398.2. Definition. Conductors for open wiring may be any of the general-use types listed in Table 310.104(A) for “dry” locations and “dry and wet” locations such as THW, XHHW, THHN, and so on.

The conductors are secured to and supported by insulators of porcelain, glass, or other composition materials. In modern wiring practice open wiring is used for high-tension work in transformer vaults and substations. It is very commonly used for temporary work and is used for runs of heavy conductors for feeders and power circuits, as in manholes and trenches under or adjacent to switchboards, to facilitate the routing of large numbers of circuits fed into conduits.

398.10. Uses Permitted. This section limits open wiring on insulators to industrial or agricultural establishments, up to 600 V.

398.19. Clearances. The additional insulation on the wire referred to in this rule, is to prevent the wire from coming in contact with the adjacent pipe or other metals.

398.23 spells out such installations in unfinished attics and roof spaces.

398.30. Securing and Supporting. Methods of dead-ending open cable runs are shown in [Fig. 398-1](#).

Method of dead-ending heavy conductors used in open wiring.

Method of dead-ending heavy conductors used in open wiring.

Fig. 398-1. Proven methods must be used for dead-ending open wiring. (Sec. 398.30.)

Where heavy ac feeders are run as open wiring, the reactance of the circuit is reduced and hence the voltage drop is reduced by using a small spacing between the conductors. Up to a distance of 15 ft between supports the 2½-in. spacing may be used if spacers are clamped to the conductors at intervals not exceeding 4½ ft. A spacer consists of the three porcelain pieces of the same form as used in the support, with a metal clamping ring.

In the rule of part **(B)**, reference to “mill construction” is generally understood to mean the type of building in which the floors are supported on wooden beams spaced about 14 to 16 ft apart. Wires not smaller than No. 8 may safely span such a distance where the ceilings are high and the space is free from obstructions.

[Figure 398-2](#) illustrates the rules of subpart **(D)** on mounting of knobs and cleats for the support of No. 14, No. 12, and No. 10 conductors. For conductors of larger size, solid knobs with tie wires or single-wire cleats should be used.

Split knobs for supporting small wires used in open wiring or concealed knob-and-tube work.

Single-wire cleat for supporting large conductors used in open wiring.

Fig. 398-2. Proper wiring support devices must be correctly mounted. (Sec. 398.30.)

ARTICLE 399. OUTDOOR OVERHEAD CONDUCTORS OVER 600 VOLTS

399.2. Definition. These conductors are single conductors, whether insulated, covered, or bare, that are run outdoors on supporting structures.

This article, new as of the 2011 **NEC**, is quite odd. At slightly less than 12-column inches it is shorter than all but a handful of articles in the Code, and it contains no prescriptive information.

The components are essentially all to be as evaluated and specified by a professional engineer. It describes neither a wiring method nor material, but instead covers wiring design. As such, it probably belongs in [Chap. 2](#) and not [Chap. 3](#) of the Code, and not as a standalone article. It would be a natural fit in Part III of Art. 225, which already addresses the topic and which is under the jurisdiction of a Code-making panel with direct experience in this subject matter.

These wiring designs are frequently employed by major industrial occupancies to supply campus style layouts when they are accepting service at medium voltage or even high voltage (over 69,000 V by IEEE definition). The real significance of the article is that when such distributions are premises wiring, the authority having jurisdiction now has a basis to review the engineering documentation on the distribution layout, and enforce changes if required. An informational note points to the National Electrical Safety Code, which does have comprehensive requirements for these systems because electrical utilities have been performing this work for over a century. The topic certainly deserves to be covered in the Code.

On balance it is probably correct to leave the prescriptive design information in the NESC. There is precedent for this approach. When manholes came into the **NEC** through a proposal by this author, there was also a great deal of prescriptive information in the NESC that could have entered the **NEC**, but for very little benefit. The significance of the informational note now at 110.71, under a section that simply requires a design under engineering supervision, is that there are cases where too much information doesn't really help. Manholes have been in the **NEC** now for many Code cycles, and no proposal has ever been offered to expand this section. That said, there is definitely room to question the article status and chapter location.

Chapter Four

ARTICLE 400. FLEXIBLE CORDS AND FLEXIBLE CABLES

400.1. Scope. Flexible cords are equipment, not wiring methods, which is why the rules covering them reside in [Chap. 4](#). In addition the rules in the article apply to flexible cords even after they have been manufactured into power supply cords and extension cords (cord sets). A new informational note as of the 2017 **NEC** notes the relationship and points to the rules on permissible use in 400.10 and 400.12. The text in those sections has been carefully adjusted to resolve a major topic of recent discussion relative to whether those rules still applied after the cord had been manufactured into a cord set. The terminology throughout the article, including its title, was adjusted at the same time to include the word “flexible” ahead of “cables” to additionally clarify that the cables covered here are not [Chap. 3](#) wiring methods.

400.3. Suitability. This rule requires that any application of flexible cord or cable may require use of “hard usage” cord (such as SJ cord) or “extra hard usage” cord (such as S or SO cord) if the cord is used where it is exposed to abrasion or dragging or repetitive flexing and/or pulling, depending on severity of use. As noted in Table 400.4, cords for portable heaters must be one of those types when used in damp places. Determination of the need for a particular cable on the basis of use severity is subjective. Table 400.4 also indicates the types of portable cable—that is, for data processing and elevator circuits—and conditions under which each type is suitable, as for hazardous or nonhazardous locations. Flexible cord is not a wiring method, which is why it appears in [Chap. 4](#) as equipment, and not in [Chap. 3](#).

Table 400.4 and its accompanying endnotes contain a great deal of important information that is necessary to proper field application of flexible cord. For example, many are aware that the letter “W” in a cord type suffix indicates wet location suitability, as in, for example SOOW (hard service, 600-V rating, oil-resistant conductor insulation and oil-resistant outer jacket, wet location suitability). However, the “W” carries an additional meaning clarified in the 2011 **NEC**. It also denotes sunlight resistance, as covered in Footnote 9 to the table. This has obvious implications for usage where it could be left unattended for long periods, such as for an outdoor swimming pool filter motor field connected with a cord.

400.5. Ampacities for Flexible Cords and Flexible Cables. Unlike other current-carrying conductors and cables recognized by the **NEC**, the permissible value of current permitted for those assemblies listed as “flexible cords and flexible cables” is determined in accordance with this section, instead of the rules given in 310.15. Generally speaking, compliance with these requirements can easily be accomplished by selecting listed cords and cables and using them within their rating.

A three-conductor cord set is permitted by 250.140 to be used with one conductor serving as *both*

the neutral conductor *and* the equipment grounding conductor, with the frame of the range or dryer grounded by connection to the neutral, *but* only for an existing branch circuit. It should be noted that the common neutral-grounding conductor does not count as a current-carrying conductor, thereby making the 3-wire cord suitable for use at the higher ampacity shown under column B in Table 400.5A—which is for cord with not more than two wires.

This section now addresses the effects of elevated temperature by specifically incorporating the ampacity correction factors for ambient temperatures other than 30°C that are included in Table 310.15(B)(2)(a). In addition, cords that are rated at 105°C now have their ampacities referred for elevated ambient temperatures to the 90°C column of the table for the simple reason that no 105°C column exists for that table. Note, however, that the parent language in 310.15(B)(2) permits the use of an adjustment formula in lieu of table values should this be problematic.

example The design load from an Art. 220 load calculation for a floating commercial enterprise moored in a tidal basin on the southeastern coast of Texas is 105 A from a 208Y/120V system, of which 60 A is continuous and comprised of primarily nonlinear loads. The feeder conductors will be connected directly to the terminals of a 125-A molded-case circuit breaker. The building will be subjected to constant tidal motion of the base water level, in addition to periodic wave effects. The design temperature based on the ASHRAE 2 percent temperature database is 95°F.

Flexible cord solution Section 553.7(B) allows portable power cable rated for extra hard usage, sunlight resistance, and wet locations to be used as a feeder to a floating building.

Conductor calculation The load current is 105 A, but there will be mutual conductor heating because over half the load is nonlinear and will result in harmonic currents flowing on the neutral, per 400.5(A). This will result in an 80 percent factor from Table 400.5(A)(3), together with a 0.96 percent correction factor based on a 90°C conductor rating. Therefore, the minimum size of the cord to address the conditions of use is: $105\text{ A} \div 0.8 \div 0.96 = 137\text{ A}$. For this, the ampacity can be taken from Table 400.5(A)(2) using the 90°C column. A 2 AWG Type W power cable could be used based on this calculation, ampacity 152 A.

Termination calculation The size of the conductor on the terminals of the circuit breaker must accommodate the continuous portion of the load taken at 125 percent plus the noncontinuous load, or $1.25(60\text{ A}) + 45\text{ A} = 120\text{ A}$. The wire size, per 110.14(C)(1)(b), must be referenced to the 75°C column of Table 310.15(B)(16) and not Table 400.5(A)(1) or (A)(2) per 110.14(C)(1). The smallest size copper wire that will allow the overcurrent device to function as intended on this load profile is 1 AWG copper. Because the design constraint is that the cord conductors terminate directly at the circuit breaker, this calculation produces the worst-case, highest conductor size, and therefore this is the correct answer. Because this is flexible cord, undoubtedly more finely stranded than Class C concentric, the terminal on the circuit breaker will most likely not accommodate the stranding. Listed ferrules rated for the class of stranding will need to be crimped on to the cord conductors, and then landed on the breaker. Refer to the discussion at 110.14 for more information.

400.10. Uses Permitted. Figure 400-1 shows accepted uses for flexible cord. Flexible cord may be used for luminaires under **(A)(2)**. Refer to 410.24(A) for limitations on use with electric-discharge luminaires and 410.62(B) and (C) for luminaires that require aiming or adjusting after installation and conditional use with other electric discharge lighting. The 2014 **NEC** added an eleventh expressly permitted use, and the context will likely be extremely controversial. The original proposal responded to kits being offered at home stores that allow for homeowners to wire flush receptacle outlets for large-screen, wall-mounted televisions without needing to cope with line-

voltage wiring. In fact, the installation instructions expressly forbid any direct connection between the contents of the kit and the wiring system in the building. These kits are being marketed as compliant with the **NEC**; however, the actual contents and installation instructions for these kits appear to raise major **NEC** compliance issues.

Fig. 400-1. Permitted uses for flexible cable and cord include pendant pushbutton station for crane and hoist controls (left), and connection of portable lamps. (Sec. 400.10.)

The kits generally come with two integral device boxes within an overall self-trimming enclosure flange so that once the assembly is secured to the wall the device opening and mounting is complete. The self-trimming enclosures are also available with an additional slot next to the enclosure through which power limited cables related to the audio/video system can enter and exit the wall, resulting in no cables being visible around the screen. The two devices are in one case a recessed flanged inlet, installed at normal receptacle height, and in the other case either a single or a duplex receptacle, also recessed, installed behind the flat-screen appliance. A short run of NM cable that comes with the kit and is fished in the wall connects the two device openings. The homeowner then takes what amounts to an extension cord, which comes with the kit, and plugs the inlet into an adjacent perimeter receptacle.

The new permitted use comes in the context of likely concern that the semi-permanent extension cord from the receptacle to inlet amounts to the substitution of flexible cord for permanent wiring in the building. The new permitted use would make that issue disappear. However, the actual requirement states “the inlet, receptacle outlet, and [Chap. 3](#) wiring method and fittings shall be a *listed assembly specific for this application*” [emphasis supplied]. This lines up with the substantiation that came with the wording, which expressed concern over users providing a smaller AWG size in the cord with resulting overheating. This accompanying substantiation, says in relevant part “The use of *non-standard configuration inlets* or the use of overcurrent protection at the inlet are two possible methods that could be provided in the listing of the assembly to address the hazard” [emphasis supplied].

The cord set and devices supplied with the kit, particularly including the inlet and the female cord body supplied with the extension cord, have conventional NEMA 5-15 configurations that cannot,

particularly in this context, be considered as “specific for this installation.” Actually, the cord set appears to be a conventional 6-ft extension cord. Therefore, compliance with the 2014 **NEC** is unlikely at best. In addition, the installation instructions and optional equipment raise many other issues. One installation option is to connect an NM cable lead to both enclosures and then connect them using a splicing device that is buried in the wall. The picture of the splicing device shows something that looks very much like the devices covered in 334.40(B). These devices, revisited in the 2014 **NEC**, can only be used for “repair wiring” in this context, and clearly a new flat-screen television is not an example of repair wiring. Another instruction calls for 4 in. of cable in the outlet box (on this point the instructions are inconsistent and some models call for 6 in.) with 3 in. of sheath removed. This plainly fails to comply with 300.14, which requires 6 in. of free conductor “measured from the point in the box where it emerges from its raceway or cable sheath.” Although the default assembly anticipates not over 5 ft separating the two boxes, the instructions include an option to purchase enough cable to allow for a 75-ft separation between the two boxes. This raises a host of issues relative to how such a length of cable installed in most applications would be secured and supported, especially by untrained installers.

All of this together raises the question as to how such a kit might have been certified as a “listed assembly.” The literature that accompanies this kit plainly implies that it has been so listed. It provides the logo of a particular testing laboratory (not UL) followed by the word “LISTED” and then the word “conforms to UL Std. 514C.” UL 514C is the standard that covers nonmetallic outlet boxes, flush device boxes, and covers. Although it is very possible, in fact probable, that the device boxes built into the kit components comply with that standard, compliance therewith clearly cannot justify compliance with the many other standards that come into play, including those covering the flexible cord, the devices, the in-wall cable assembly, etc.

Part **(B)** states that *if* flexible cord is used to connect portable lamps or appliances, stationary equipment to facilitate frequent interchange, or fixed or stationary appliances to facilitate removal or disconnection for maintenance or repair, the cord “shall be equipped with an *attachment plug* and shall be energized from a *receptacle outlet or cord connector body* (*Fig. 400-2*).”

Fig. 400-2. This use of flexible cord to supply an outdoor lampholder assembly can readily be described as a “substitute for fixed wiring”—which is a prohibited use of cord. Here, the lampholders could have been attached to one or more threaded openings on an outlet box. (Sec. 400.12.)

It should be noted that the cords referred to under this section are the cords attached to the appliance and not extension cords supplementing or extending the regular supply cords. The use of an extension cord would represent a conflict with the requirements of the Code in that it would serve as a substitute for a receptacle to be located near the appliance, thereby violating 210.50(B).

Extension cords are intended for temporary use with portable appliances, tools, and similar equipment which are not normally used at one specific location.

Be careful not to confuse flexible cord, regulated within the scope of Art. 400, with bus-drop cable that is not classified as flexible cord and that is not therefore covered in Art. 400. Refer to the coverage in this book of 368.56(B) for more information. This cable may be used to feed down to machines in factories.

400.12. Uses Not Permitted. Although 400.10 says that flexible cord may be used for “wiring of luminaires,” that must be applied in the context of 400.12(1) that prohibits the use of cord as a substitute for fixed wiring. That rule could be strictly enforced to require all luminaires to be supplied by fixed wiring methods—approved, Code-recognized cables like NM or BX or by a standard raceway method (EMT, rigid, flex, etc.). This sort of narrow reading raises the question, “Is there ever a case where a luminaire could *not* be fed by a fixed wiring method?” Certainly, any luminaire that might be supplied by a cord connection from a junction box to the luminaire could just

as easily be fed by conductors in flexible metal conduit or in liquidtight flexible metal conduit—both of which conduit-and-wire connections are considered “fixed wiring” methods. If there are no cases where a luminaire could not be fed by such a fixed wiring connection, then every use of flexible cord to supply a luminaire is “a substitute for fixed wiring.” The relationship between 400.10(A)(2), 400.12(1), 410.24(A), 410.62(B), and 410.62(C) must be carefully evaluated to assure ready compliance with Code rules—particularly because cord connection of luminaires has been used so long and so successfully for both indoor and outdoor applications.

The best way to approach wording issues like this in the **NEC** is to apply an old principle of statutory interpretation that goes back many centuries in the courts: Read both rules that could be viewed as being in conflict, and apply an interpretation that gives the maximum effect to both of the rules. In this case, 400.10 and many other rules in the **NEC** that provide specific instances where cord connections can be used should be honored; however, any expansion of cord usage beyond that point should be closely questioned under the substitution for fixed wiring methods prohibition. In other words, in those cases where the **NEC** specifically permits the use of cord, it is presumed not to be a substitute for fixed wiring methods.

Figure 400-2 shows one of a number of twin floodlight units that were installed outdoors for lighting of the facade of a building. The use of cord from a junction box to a stab-in-the-ground twin lampholder assembly does not comply with “(2) wiring of luminaires” in 400.10 because it does not satisfy 410.62, which regulates use of cord for luminaires, as previously noted under 400.10. And the application does not comply with the other permitted uses in 400.10. Because floodlights could have been installed in lampholders that thread into hubs on a weatherproof box, use of the cord is an evasion of a fixed or permanent connection technique that would totally avoid the potential shock hazard of cord pull-out or breakage. Mounting the floodlights on the box would still allow adjustment. This use of cord is a substitute for fixed wiring and is a violation.

Flexible cord is not permitted to be attached to a building surface **(4)**, unless it is part of a busway branch as covered in 368.56(B). This rule clearly limits the once common practice of running wireway overhead in industrial occupancies, in a manner very similar to busway, and feeding cord drops to machine tools and other equipment. Although permitted by 376.70, the wireway must be carefully located because the cord must drop very nearly straight down to the equipment. [Figure 400-3](#) gives another example of this permission, because the strain relief at the box cover is not a connection to a building surface. A swag out to a strain relief over the equipment is a connection to a building surface, and as such is disallowed for all cord connections, except the busway applications.

Fig. 400-3. Strain-relief for flexible cord must protect cable jacketing from damage at box connectors and protect wire terminations from pull-out. Spring-loaded come-along support supports cable against weight on bottom end of pendant and also provides up-and-down movement of cable end. (Sec. 400.14.)

The prohibition in **(5)** against concealed usage behind structural surfaces, together with the ban on usage above suspended ceilings has received extensive attention recently, particularly regarding suspended ceilings. Many types of small-scale equipment are routinely furnished with flexible cords and plugs, such as condensate pumps for just one example. Generally, this equipment is also available with an option for hard wiring. Take it. The 2017 **NEC** now includes an exception here that, although phrased correctly in general terms, illustrates extremely well just how tightly this rule is being policed. A manufacturer of AV equipment created an open metal housing for its equipment, designed for ceiling grid applications, that was open only in the downward direction, and that had been evaluated for use in an air-handling ceiling. The equipment required flexible cord connections because some of it was capable of reposition for obvious reasons. Because this equipment resided above the plane of the suspended ceiling, the manufacturer had encountered extensive resistance from inspectors. The exception that resulted was narrowly crafted to apply to that sort of application only.

Flexible cords and cables may not be installed in raceways, except where the **NEC** specifically recognizes such uses. Part **(6)** clarifies such use of flexible cords and cables, limiting their use in raceways to applications described or inferred in 400.10 and other Code rules—such as 550.10(G) for sleeving of a mobile home power-supply cord, 551.46(A)(2) on the same technique for recreational vehicles, 645.5(B)(3) for computer-room connecting cables, and 680.23(B) on the flexible cord run in conduit for a wet-niche luminaire—and similar limited applications. One very

important allowance occurs in 400.14. The reason for this limitation is that flexible cord ampacities, as expressed in Table 400.5(A) and (B), are evaluated on the ability of the cord to freely radiate its heat.

400.14. Pull at Joints and Terminals. Figure 400-4 shows methods of strain relief for cords. The “Underwriters’ knot” has been used for many years and is a good method for taking the strain from the socket terminals where lamp cord is used for the pendant, through the hole in the lampholder or switch device. For reinforced cords and junior hard-service cords, sockets with cord grips such as shown in Fig. 400-3 provide an effective means of relieving the terminals of all strain. Figure 400-3 shows a support technique that comes under “other approved means.”

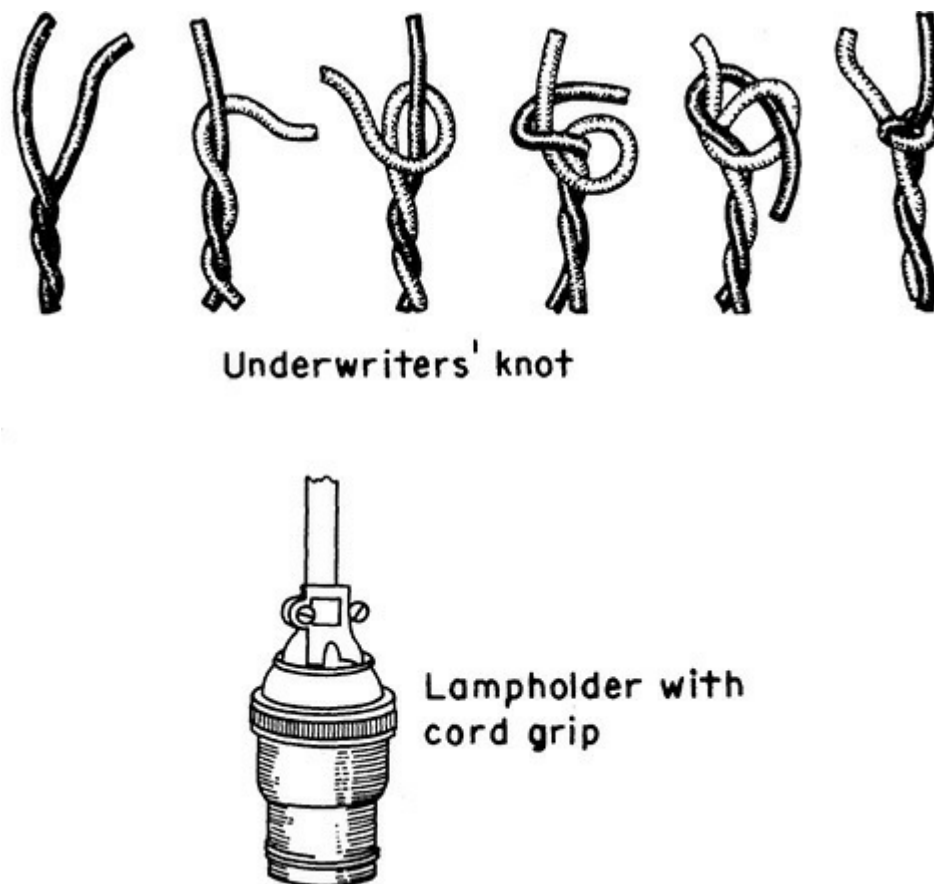

Fig. 400-4. Strain-relief must be provided at cord connections to devices. (Sec. 400.14.)

400.15. In Show Windows and Showcases. Because of the flammable material nearly always present in show windows, great care should be taken to ensure that only approved types of cords are used and that they are maintained in good condition.

400.17. Protection from Damage. Flexible cord must be protected from damage where it passes over sharp edges through the use of bushings, etc. The second paragraph recognizes a very common practice on machine tools in industrial occupancies, where cord is used to wire sensors or solenoids on flexible parts or other instances where the flexibility of cord is crucial to orderly equipment function. Cord is permitted for these uses generally, but as soon as the need for flexibility stops, then a wiring method transition must be arranged. This in turn usually means a box with splices inside, the very location where problems crop up most often in electrical systems. The language in the second paragraph allows a raceway to extend from the industrial control panel (Art. 409) (or other point of origin) out to the desired location, with a raceway-to-cord transition fitting at the outer end.

This entirely avoids a box needing support plus a set of splices out on the equipment. If mutual conductor heating is an issue, the derating factors apply to all conductors in the raceway, and not cord by cord. The raceway cannot exceed 15 m (50 ft) in length, which correlates with rules in **NFPA 79**, *Electrical Standard for Industrial Machinery*.

400.22. Grounded-Conductor Identification. These are the rules for identifying the grounded circuit conductor in cord sets, which itemize many methods in addition to white and gray insulation. One of the more important is item (F), which includes a ridge on the outer surface of the cord. This is commonly used for floor and table lamps wired with SPT 2 (“zip cord”) wire, and also for pendant applications where the cord weaves through chain links holding a chandelier. It is absolutely essential to know how to recognize and verify proper connections to this wiring, because otherwise Edison-base screw-shells of lampholders will be energized any time the luminaire is lit. This is a hazard during relamping because the screw-shell of the lamp will be hot as soon as it comes in contact with the lampholder, even while someone’s finger is touching it.

ARTICLE 402. FIXTURE WIRES

402.5. Allowable Ampacities for Fixture Wires. Note that Table 402.5 gives the ampacity for each size of fixture wire *regardless of the type of insulation used on the wire*. For instance, an 18 AWG fixture wire is rated for 6 A whether it is Type TFN or PF or any other type.

402.7. Number of Conductors in Conduit or Tubing. The maximum number of any size and type of fixture wire permitted in a given size and type of conduit is selected from the same tables as the ones used for determining conduit fill for building wire (THW, THHN, etc.). This must be carefully observed, especially when using fixture wires for Class 1 remote-control, signaling, or power-limited circuits, as permitted and regulated by 725.49 and 725.51.

402.8. Grounded Conductor Identification. This is where the rules in 400.22 become incorporated as rules for identifying fixture wire as well. For example, 400.22(B) allows two fixture wires with yellow braids to be used for a luminaire, with the one finished with a contrasting tracer color, such as red, being the grounded circuit conductor. Many people are fooled by this, and think the red tracer is the hot conductor because its color does not suggest white or gray.

402.10. Uses Permitted. Fixture wires may be used for internal wiring of luminaires and other utilization devices. They may also be used for connecting luminaires to the junction box of the branch circuit—such as by a flex whip to satisfy 410.117(C) ([Fig. 402-1](#)).

Fig. 402-1. Fixture wires may connect luminaires to branch-circuit wires. (Sec. 402.10.)

402.12. Uses Not Permitted. With the exception of their use for remote-control, signaling, or power-limited circuits, fixture wires are not to be used as general-purpose branch-circuit wires. An example of the use permitted by 725.49 would be, say, 18 AWG fixture wires run as remote-control wires in a raceway from a motor starter to a remote pushbutton station, where the 6-A rating of the wire is adequate for the operating current of the coil in the starter. Another issue that often comes up is lighting installed for commercial cooking hoods using the special luminaires required by 410.10(C). These luminaires usually have 110°C minimum supply temperature conductor ratings. Because fixture wires of the required temperature rating are quite common, and because branch conductors rated above 90°C are difficult to find on a supply house shelf, and because each luminaire is an outlet on a branch circuit, this section makes it mandatory to order the branch-circuit conductors with the required temperature ratings.

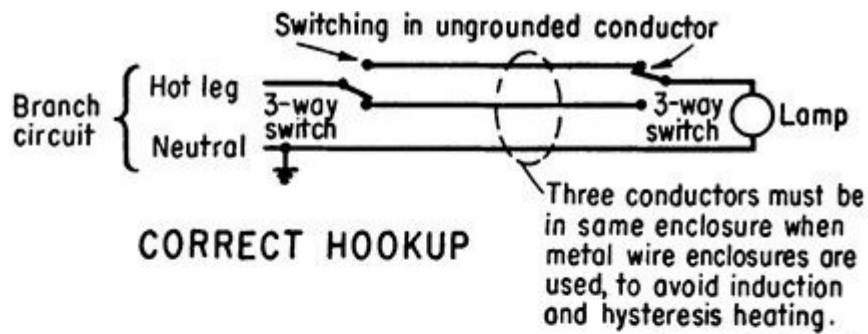

402.14. Overcurrent Protection. This rule refers to 240.5, which covers overcurrent (OC) protection requirements for fixture wire as a separate matter from other building wire and cable, and permits No. 18 and No. 16 fixture wire of any type to be protected by a 15- or 20-A fuse or CB, provided the distance limitations in 240.5(B)(2) are met. That covers use of 18 AWG or 16 AWG in luminaire “whips” on 15- or 20-A branch circuits. Coverage for remote-control, signaling, or power-limited circuits is addressed in 725.43 and as frequently modified for taps in 725.45(C).

ARTICLE 404. SWITCHES

404.1. Scope. Note that all the provisions of this article that cover switches *also* apply to circuit breakers, which are operated exactly as a switch whenever they are manually moved to the ON or OFF position. The scope also now makes clear that the article only covers equipment operating at 600 V and below. Medium-voltage switches are covered in Art. 490.

404.2. Switch Connections. The rule of part (A) is shown in Fig. 404-1. Keeping both the supply and return conductors in the same raceway or cable minimizes inductive heating, as described under 300.20(A). The routing of both the supply and return conductors within the same raceway provides for mutual cancellation of both conductors’ magnetic fields and thereby reduces inductive

heating, as required under 300.20(A). This is also an issue with multiple 2-conductor (as opposed to a single 3- or 4-conductor) Type NM cable run to steel boxes and entering through separate knockouts for multiple loads on a single circuit (such as a bathroom fan-light unit) or a three-way switch loop run with the travelers in one cable. In either case there will be inductive heating unless both cables enter a single knockout. Fortunately there are numerous cable connectors now listed for two cables that will solve this problem.

... AND THE RULE APPLIES FOR ANY LAYOUT OF SWITCH AND OUTLET BOXES

NOTE: Wiring between switches — in the armor of BX or in metal raceway — must have all three conductors within the single cable or raceway.

Fig. 404-1. All three-way and four-way switches must be placed in the hot conductor to the load. (Sec. 404.2.)

The rule of part (B) is illustrated in [Fig. 404-2](#). The three-pole switch satisfies the exception.

Opening only the grounded wire of a 2-wire circuit would leave all devices that are connected to the circuit alive and at a voltage to ground equal to the voltage between wires on the mains. In case of an accidental ground on the grounded wire, the circuit would not be controlled by the single-pole switch.

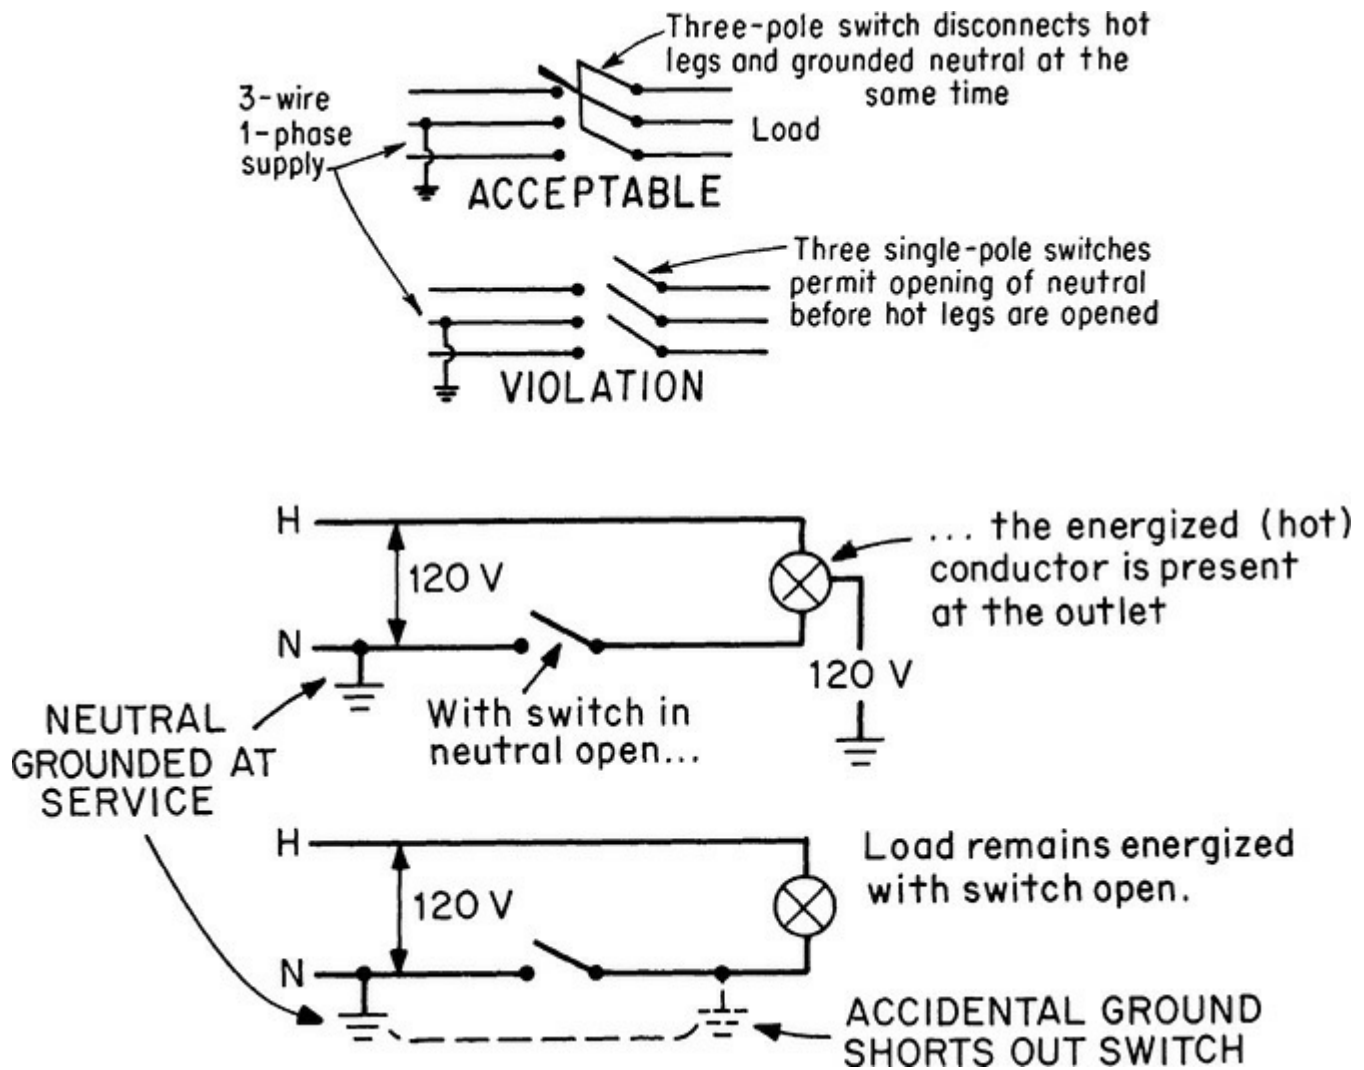

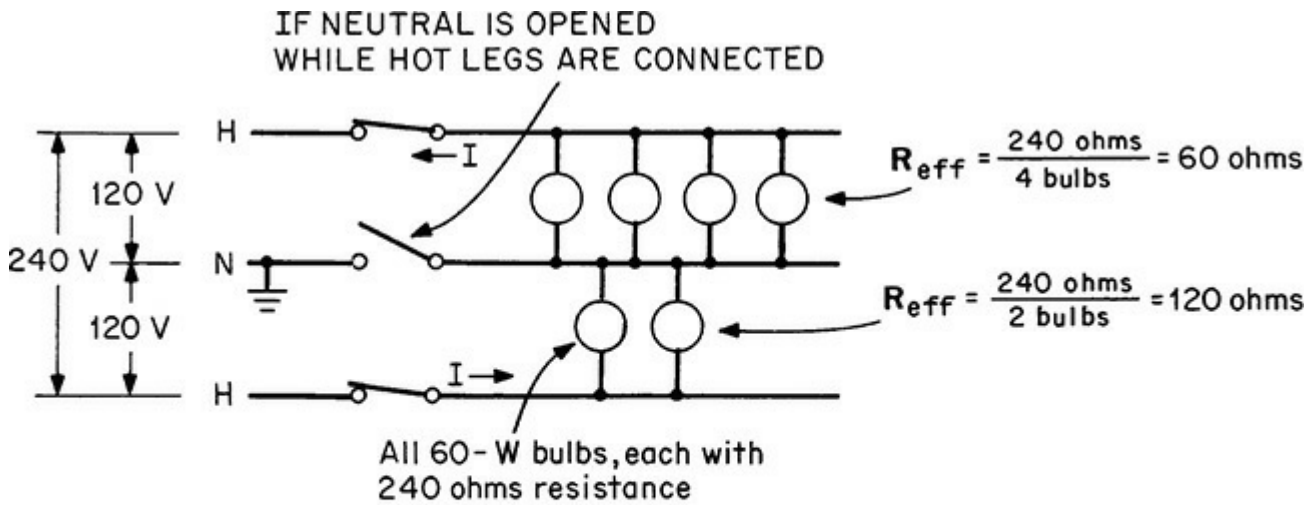

Fig. 404-2. A single-pole switch must not be used in a grounded circuit conductor. (Sec. 404.2.)

In Fig. 404-3, the load consists of lamps connected between the neutral and the two outer wires and is not balanced. Opening the neutral while the other wires are connected would cause the voltages to become unbalanced and might burn out all lamps on the more lightly loaded side.

$$\text{Current} = \frac{240 \text{ V}}{60 + 120} = 1.33 \text{ A}$$

$$\text{Voltage on top bulbs} = 1.33 \times 60 \text{ ohms} = 80 \text{ V}$$

$$\text{Voltage on bottom bulbs} = 1.33 \times 120 \text{ ohms} = 160 \text{ V}$$

Fig. 404-3. A single-pole switch in neutral can cause damaging load unbalance if opened. (Sec. 404.2.)

Except for 514.11(A), which requires a switch in a grounded neutral for a circuit to a pump at a gas station, the neutral does not need to be switched. But where a grounded neutral or grounded phase leg is switched, it must never be by a single-pole switch or single-pole CB, even if the CBs are provided with handle ties.

A switch may be arranged to open the grounded conductor if the switch simultaneously opens all the other conductors of the circuit.

Part (C), new for the 2011 **NEC**, generally requires accommodating switch locations to receive electronic switching devices, such as occupancy sensors, for lighting loads. The rule applies in all occupancies with limitations that apply to wiring configurations that allow the white wire to be installed subsequently with relative ease. With increasing national concerns around energy conservation, building codes are increasingly mandating the installation of occupancy-sensing switching, so lights will not be inadvertently left on. An example of such a switch is shown in [Fig. 404-4](#). This switch is capable of replacing either a conventional single-pole or three-way switch; it has three leads for the switch, and if used as a single-pole switch, one of the three leads is simply capped off. If used as a three-way switch, however, it must be wired to replace the three-way switch that is electrically closest to the load. It is capable of a 180° field of vision over a floor area of approximately 20 ft wide by 20 ft deep. In accordance with 210.70(A)(1) Exception No. 2, the switch is equipped with a manual bypass, so it can be turned on or off at its location regardless of the actual state of occupancy.

Fig. 404-4. An occupancy-sensor type of switch, designed to replace conventional switches, the four leads are color-coded, and allow for the switch to function as either a single-pole or three-way switch. The fourth lead is green and grounds the switch yoke as well as allowing the electronic controls in the switch to function with the lights off. [Sec. 404.2(C).]

The particular switch illustrated here shows some of the limitations involved with this technology at the current time. The switch, purchased new at the end of 2010, is rated for 500 VA incandescent lighting, or 400 VA rapid-start fluorescent lighting, but the fluorescent lighting ballasts must be the old-fashioned magnetic ballasts and not the modern electronic ballasts. Some sensor switches are more robust than the one in Fig. 404-4, even with small horsepower ratings, but none can control a receptacle. This is due to the unknown loading that can result. However, the **NEC** clearly allows such uses generally including the express permission for residential lighting, and such switches are exempted accordingly from the need to run standby neutrals. The **NEC** waives the requirement in other instances where the application is such that an occupancy switch would not or could not be installed. The neutral is not required where the switch does not serve a habitable room other than a bathroom; a frequently cited example of this is a door-jamb switch controlling a closet light. A neutral does not need to be brought to a switch with an integral enclosure [covered in 300.15(E) and 334.30(C)] because it couldn't be landed once it arrived anyway. If there are multiple switch locations that “see” the entire lit space, then the neutral need be brought to only one of those locations. The term “habitable” in some building codes is limited to residential uses; the 2017 **NEC** adds “or occupancy” to address this issue. It was always intended that these rules would be applied generally and not just in dwellings. Some locations use snap switches in series with occupancy sensors so the lights are sure to go off when the room is unoccupied, and also forced off by a switch in order to guarantee darkness, such as for a projected presentation. Such switch locations clearly do not require a neutral. Note that a neutral is required, however, for a switch location outside but that still controls the lit area. Although an occupancy sensor would never replace such a switch, some high-end dimmers require a neutral and therefore the Code-making panel elected to leave the

requirement in place for these locations.

The switch in Fig. 404-4 does not require a neutral connection to operate. In order for the switch to function with the lights off, it must be connected to a complete circuit so its electronic sensor will function. Current product standards allow such switches to “leak” up to 0.5 milliamperes to the equipment grounding system for this purpose. This is a very small amount of current, but if many such switches are installed, there can be appreciable current imposed on equipment grounding conductors, which are only supposed to carry current in the event of a ground fault. The Code change must be understood in this context. Over time the **NEC** Committee always intended that the product standard for switches such as these would require them to have terminals for the connection to a grounded circuit conductor, and that the intentional leakage of routine current into the equipment grounding system would be discontinued.

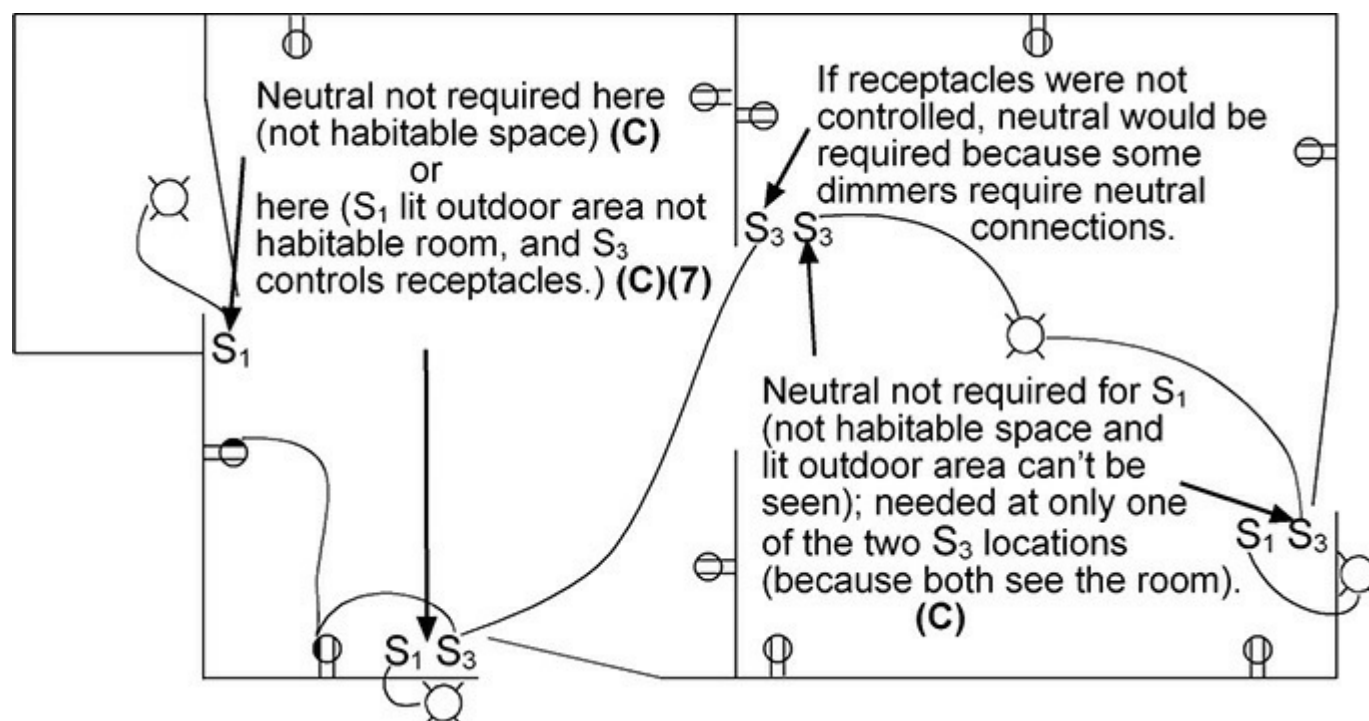

Fig. 404-5. The 2014 **NEC** has added important exemptions to the neutral at every switch rule to accommodate applications where a neutral would not be useful. [Sec. 404.2(C)].

That time is now firmly in view. The 2017 **NEC** added a second paragraph to the rule, requiring the neutral to be extended to the switch location if it weren't already there (such as through the allowance to run it later if the raceway wiring method had sufficient room to add it), and then to actually land it on any switch requiring line-to-neutral voltage to operate. The paragraph also includes a reference to 404.22 in Part II of the article (Construction Specifications). This part of an article chiefly addresses the product standards for the equipment governed by the article. Sec. 404.22, also new for 2017, largely puts the old electronic switch designs on the road to extinction. As of Jan. 1, 2020, the old-style designs will no longer be recognized, with one important exception, and this is correlated with the exception that follows the new paragraph in 404.2(C).

The two exceptions cover an old-style design that will remain acceptable for an indefinite time period, but limited to replacement/retrofit applications only. By the parent wording in 404.22, all electronic switches must be listed (effective immediately); those for old-style applications must be specifically listed and marked by their manufacturer for use in replacement or retrofit applications

only. As would be expected, with respect to field wiring as covered in 404.2(C) Exception, the same effective date applies with respect to the requirement to land a neutral on an electronic switch. Obviously installers can't be expected to wire switches that aren't available. However, the exception has several additional features that require careful attention.

First, the exception applies only to switch locations wired prior to local adoption of 404.2(C). In general, that would be prior to local adoption of the 2011 (or later) **NEC**. In addition, the switch location in question must be difficult to rewire. Specifically, creating a neutral connection must involve the removal of surface materials. For example, if the switch is wired with a raceway method to which the neutral can be added, then it must be added. Another example would involve a switch in an office with open-walled partitions extending to open suspended ceilings. With very little effort a new cable that included the neutral could be sent down a 4-ft open cavity to the switch box. The inspector will make the final decision, but the clear intent is to minimize the necessity to apply the exception.

Second, the degree of leakage current is restricted through numerical limits (5 for a branch circuit and 25 for a feeder) on the number of electronic devices connected. At 0.5 mA each, the leakage current on any branch circuit will be limited to 2.5 mA and a feeder to 12.5 mA. The numbers are conservative but high enough to provide a necessary degree of flexibility for existing occupancies. For example, the branch-circuit number is half the customary trip setting for a GFCI.

Finally, the exception makes it very clear that a neutral bus in service equipment equipped with a functioning main bonding jumper carries no limits. That is the location where neutral and equipment ground join, and any leakage currents arriving become ordinary neutral currents and need not be limited. The reference to 200.2(B) is potentially important in this regard. Review [Fig. 200-1](#) in this book. If the violation shown in that drawing exists, then the leakage currents returning over the neutral will only exacerbate the problem that led to 200.2(B) in the first place. That violation is comparatively simple to correct, and must be completed if one of these retrofits is to go forward.

404.3. Enclosure. [Figure 404-6](#) shows the basic rule of this section and 404.4. This rule also requires adequate wire bending space at terminals and inside gutters of switch enclosures. In this section and in other sections applying to wiring space around other types of equipment, it is a mandatory Code requirement that wire bending space and side gutter wiring space conform to the requirements of Table 312.6(A) for side gutters and to Table 312.6(B) for wire bending space at the line and load terminals, as described under 404.18. Those tables establish the minimum distance from wire terminals to enclosure surface or from the sides of equipment to enclosure side based on the size of conductors being used, as shown in [Fig. 404-7](#).

Fig. 404-6. Switch and CB enclosures must be suitable. (Sec. 404.3.)

EXAMPLES:

Fig. 404-7. Terminating and gutter space in switch enclosures must be measured. (Sec. 404.3.)

This whole concern for adequate wiring space in all kinds of equipment enclosures reflects a repeated theme in many Code sections as well as in Art. 110 on general installation methods. One of the most commonly heard complaints from constructors and installers in the field concerns the inadequacy of wiring space at equipment terminals. 404.3 is designed to ensure sufficient space for the necessary conductors run into and through switch enclosures.

404.4. Damp or Wet Locations. Refer to [Fig. 404.6](#) and discussion under 312.2. In addition, this rule prohibits switches from being installed in the wet location of a tub or shower space. Although the yoke would be grounded by other rules, the concern is how long the gasket will hold up before water, particularly from a shower, gets behind it and starts rotting out the connections, including the grounding connections. An exception exempts a switch in a “listed tub or shower assembly” under the understanding that some hydromassage tubs or spas may have air or low-voltage switching to control the water or airflow; such controls are carefully controlled by the listing process

in terms of potential hazards.

404.5. Time Switches, Flashers, and Similar Devices. Any automatic switching device should be enclosed in a metal box unless it is a part of a switchboard or control panel which is located as required for live-front switchboards. Such devices must not present exposed energized parts, except under very limited conditions where they are accessible only to qualified persons.

404.6. Position and Connection of Knife Switches. The NEC requires that knife switches be so mounted that gravity will tend to open them rather than close them (Fig. 404-8). But the Code recognizes use of an upside-down or reverse-mounted knife switch where provision is made on the switch to prevent gravity from actually closing the switch contacts. This permission is given in recognition of the much broader use of underground distribution, with the intent of providing a switch with its line terminals fed from the bottom and its load terminals connected at the top (Fig. 404-9). With such a configuration, an upside-down knife switch provides the necessary locations of such terminals, that is, “line” at bottom and “load” at top. However, use of any knife switch in the reverse or upside-down position is contingent upon the switch being approved for such use, which virtually means UL-listed for that application, and also upon the switch being equipped with a locking device that will prevent gravity from closing the switch. The same type of operation is permitted for double-throw knife switches.

Fig. 404-8. Movable knife blade of a knife switch must be pivoted at its bottom. (Sec. 404.6.)

To be used in this position where gravity tends to close an open switch, the switch must:

1. Be approved for such use, and
2. Be equipped with a locking device to hold switch open.

Fig. 404-9. This type of knife-switch operation is permitted. (Sec. 404.6.)

As required by part (C), knife-switch blades must be “dead” in the open position, except where a warning sign is used (Fig. 404-10). In a number of electrical system hookups—UPS systems, transformer secondary ties, and emergency generator layouts—electrical backfeed can be set up in such a way as to make the load terminals, blades, and fuses of a switch energized when the switch is in the OFF or open position. Where that might happen, the exception to this section says a permanent sign must be prominently placed at or near the switch to warn of the danger. The sign must read, “Warning—switch may be energized by backfeed.”

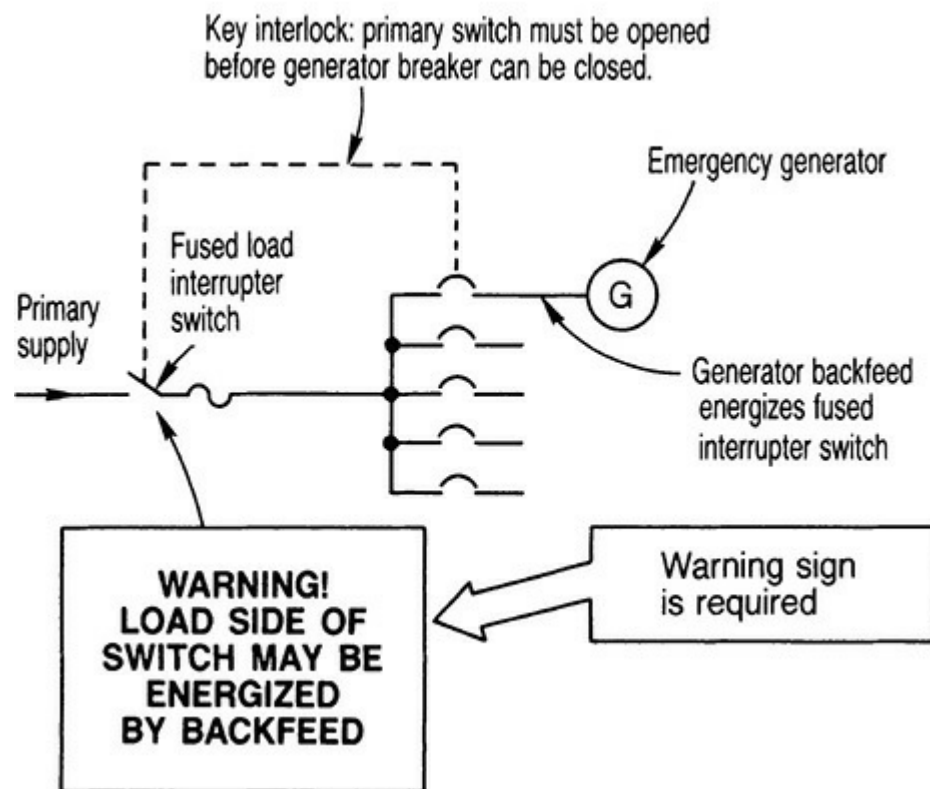

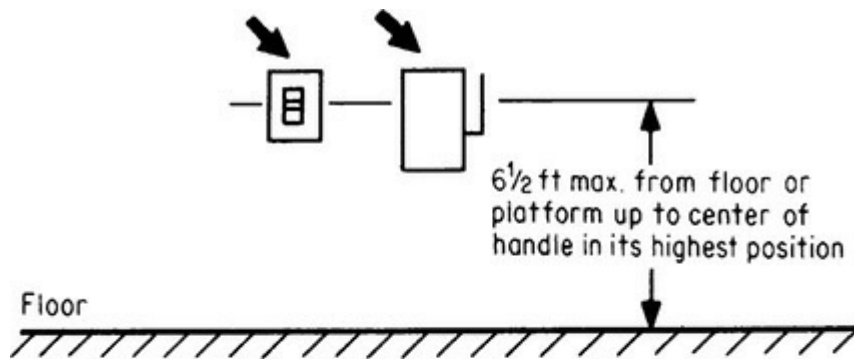

Fig. 404-10. Supply conductors must connect to “LINE” terminals of switch, but backfeed is permitted if carefully marked. (Sec. 404.6.)

This potential hazard has long been recognized for high-voltage systems (over 600 V), and 490.21(E) covers the matter. This rule that the load side of the switch be de-energized when the switch is open applies the same concept to systems operating up to 600 V.

404.7. Indicating. Switches and circuit breakers in individual enclosures must be marked to clearly show ON and OFF positions, and vertically operated switches and CBs must be ON when in the up position. This is basically a repetition of the rule that has been in 240.81 for circuit breakers

used in switchboards and panelboards. Exception No. 2 covers busway switches that have a center-pivoting switch, so with one side pulled down the switch is ON and with the other side down the switch is OFF. This makes the switch easy to work from the floor with a hook stick. The positions must be clearly marked so the status of the switch will be visible from the usual operating location.

404.8. Accessibility and Grouping. The rule of part (A) of this section presents certain requirements regarding the *accessibility* (as defined in Art. 100 for equipment) generally required for disconnects and OC devices. This rule, along with the exceptions, is shown in [Fig. 404-11](#). Exception No. 1 cross-references with 368.17(C). Exception No. 2 correlates with 240.24(A)(4), and Exception No. 3 makes the hook stick principle apply generally to other isolating switches.

EXCEPTIONS

1. Fused switch or CB may be up on busway . . .

2. Switch adjacent to motor, appliance, or other equipment it supplies, at high mounting, but accessible by portable ladder or similar means

3. Hookstick-operable isolating switches are permitted at heights over 6 1/2 ft

Fig. 404-11. All switches and circuit breakers used as switches must be capable of being operated by a person from a readily accessible place. (Sec. 404.8.) Note that the maximum height dimension

has been slightly changed to 2.0 m (6 ft 7 in.) from 6½ ft.

Part **(B)** of this section applies where 277-V switches, mounted in a common box (such as two- or three-ganged), control 277-V loads, with the voltage between *adjacent* switches in the common box being 480 V. Anyone changing one of the switches without disconnecting the circuit at the panel could contact 480 V, as shown in Fig. 404-12. The rule of this section requires permanent barriers between adjacent switches located in the same box where the voltage between such switches exceeds 300 V. This rule applies anytime adjacent devices operate over 300 V between them, whether or not the terminals are exposed or use pigtail connections. Of course, the hookup shown would be acceptable if a separate single-gang box and plate are used for each switch, or a common wire from only one phase (A, B, or C) supplies all the three switches in the three-gang box.

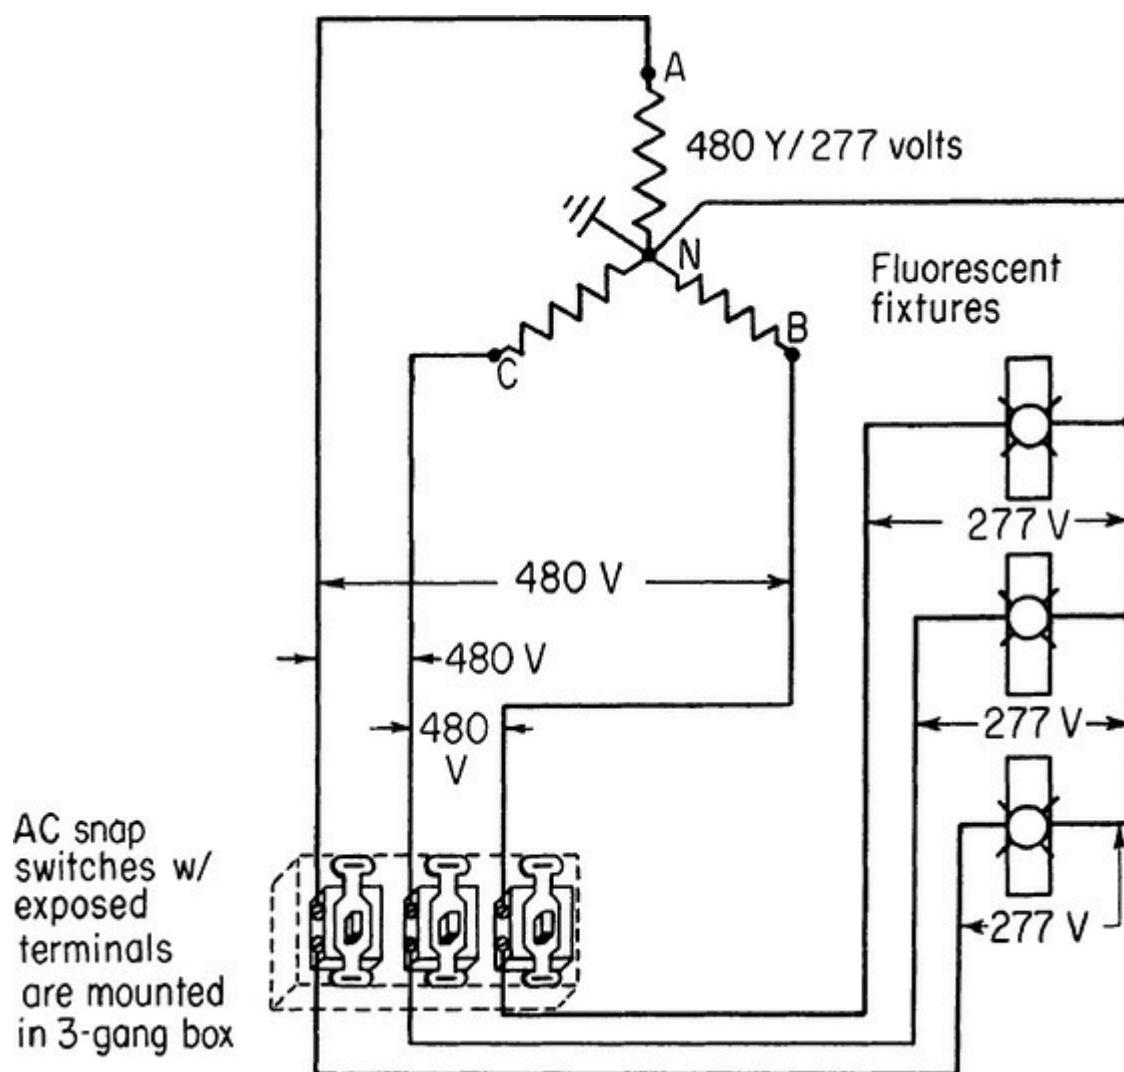

Fig. 404-12. This is a violation if barriers are not used between switches in the box. (Sec. 404.8.)

This rule has been broadened to include snap switches mounted with other devices, such as receptacles. Although the actual voltage between a 277-V snap switch and a 125-V receptacle is not necessarily over 300 V (depending on which phases of the two systems are involved and the amount of phase shift between them), the intent is to classify this as impermissible without the grounded barrier between the devices. This rule has been reinforced by similar language appearing in 406.5(G), and means that the old practice of putting a snap switch for a 277-V lighting system together with a 125-V general-purpose receptacle as the only opening in small rooms with

specialized equipment is no longer possible the way it used to be done. However, square outlet boxes with 2-gang plaster rings are generally manufactured with notches and drillings that easily accommodate these barriers, and nonmetallic box manufacturers now have similar products available.

Part (C) covers multipole snap switches. It effectively ratifies the following statement in the UL Guide Card requirements: “Multi-pole, general-use snap switches have not been investigated for more than single-circuit operation unless marked ‘2-circuit’ or ‘3-circuit.’” Since no such switches have been in production with that marking except by special order, almost any practical use would be a violation of this limitation, which is citable under 110.3(B). A 2008 NEC change attempted to trump this limitation by allowing it by right, provided the line-to-line voltage didn’t exceed the snap switch rating.

Facing concerted industry opposition, the Code-making panel backed away from the challenge. Enforcement of this particular listing limitation has been sporadic at best, but may increase in view of the recent activity.

404.9. Provisions for General-Use Snap Switches. The first sentence of this section [Part (A)] requires that faceplates be installed to cover the wall opening completely to ensure that the box behind the faceplate is properly covered and to prevent any openings that could afford penetration to energized parts.

Part (B) requires that metal faceplates be grounded, even if they are installed in the future. This is done by writing the rule to require that snap switches, including dimmer and similar control switches, be connected to an equipment grounding conductor, and that in the process the snap switch provide a means to connect the faceplate to the grounding conductor, “whether or not a metal faceplate is installed.” Although “what if” code writing is generally a poor practice, in this case it is necessary because unqualified persons change faceplates all the time without benefit of permits and inspections. This way, whenever a metal faceplate is installed, it will be safely grounded in the process.

There are two methods of accomplishing this objective. The first is to use an actual bonding jumper between an equipment grounding terminal on the device yoke and the equipment grounding system for the box. The second is to rely on a conductive connection between the device yoke and a metal box or metal cover that is connected to an equipment grounding conductor for the supply circuit, or to a nonmetallic box with an integral equipment grounding conductor. Put simply, this could be two 6-32 screws from yoke to metal device box, or from the yoke to a raised cover.

At this point, many ask how this compares with 250.146, where receptacles are only permitted to rely on the 6-32 screws when the box is surface mounted, or in a raised cover with crushed corners and locking means for the cover screws, or where a special yoke modification holds the 6-32 screw securely. The answer is simple: this wording is more lenient, and very intentionally so. A receptacle is a portal to a quasi-branch-circuit extension whenever it supplies a cord-and-plug-connected load. This is not the case for a snap switch, which has to protect only itself. The panel is not aware of any credible loss experience that would support revisiting the quality of this connection.

Figure 404-13 shows the basic operation of the exception to this part of the section. Note that the recessed metal box is not grounded and that is not acceptable by 314.4; however, the NEC is not retroactive and at one time this was acceptable because the box is not exposed to contact, and this exception is for replacement duty only. Note also that, as an alternative, and in correlation with 410.42(B) Exception No. 2 for ungrounded luminaires with exposed conductive parts, if the switch circuit has GFCI protection arranged ahead of the switch, it can have a metal faceplate.

Fig. 404-13. Nonmetallic faceplate eliminates shock hazard. (Sec. 404.9.) The faceplate screws must also be nonmetallic.

Two additional exceptions apply to special circumstances. The first correlates with 406.5(D) Exception and addresses a product line of devices that come with proprietary nonmetallic faceplates that cannot be mounted on any other device line, and that cannot accept a metal faceplate. A grounding connection in such an instance is impossible, as is the case with the second exception that correlates with 300.15(E) and 334.30(C). These devices, designed for nonmetallic-sheathed cable connected without a box, have an integral nonconductive faceplate and cannot be retrofitted with a metal faceplate.

404.10. Mounting of Snap Switches. The purpose of paragraph (B) is to prevent “loose switches” where openings around *recessed* boxes provide no means of seating the switch mounting yoke against the box “ears” properly. It also permits the maximum projection of switch handles through the installed switch plate. The cooperation of other crafts, such as drywall installers, will be required to satisfy this rule. The 2014 **NEC** added language effectively outlawing drywall or other unrecognized screws from being used to support snap switch yokes.

404.11. Circuit Breakers as Switches. Molded-case CBs are intended to be mounted on a vertical surface in an upright position or on their side. Use in any other position requires evaluation for such use. ON and OFF legends on CBs and switches are not intended to be mounted upside down. This general permission does not specifically state that any CB used as a switch must be listed for such use and be marked “SWD,” which indicates only that the CB has been evaluated for a particular

type of switching duty during product testing for listing, namely, fluorescent lighting banks. [See 240.83(D).]

404.12. Grounding of Enclosures. This section calls for the metallic enclosures and metal switch boxes used to house switches and circuit breakers to be connected to an equipment grounding conductor. 250.110 requires *all* exposed metal parts (including enclosures) of fixed equipment to be grounded under any of the conditions described. And any switch or CB enclosure must be grounded, either by an equipment grounding conductor run with the circuit conductors, or by a metallic conduit or a metal-sheathed cable with listed fittings. In addition, provisions must be made when nonmetallic enclosures are used with metallic raceways and cables to ensure grounding continuity between all interconnected raceways, cables, and any equipment within the enclosure.

404.13. Knife Switches. UL data on ratings and application correspond to the Code data (Fig. 404-14).

Fig. 404-14. UL data must be correlated to the Code rules. (Sec. 404.13.)

404.14. Rating and Use of Switches. The usual snap switch is covered in (A), which is the snap switch rated for ac only. These switches will control inductive and resistive loads up to the switch rating; motor loads up to 80 percent of the switch rating, and tungsten filament lamp loads up to the switch rating on a 120-V circuit.

The ac and dc snap switch will control dc loads, although that is seldom a concern on today's branch circuits and these switches are comparatively unusual. Because they have a dc rating, which is a more difficult switch function because there is no current zero, they are built differently and have a much louder "click" when actuated. Some people actually specified them for their children's bedrooms because they wanted to hear if their kids turned the lights back on after bedtime. They will handle the full rating of the switch for resistive loads, the full rating for tungsten filament lamp loads

(but only if “T” rated) and inductive loads up to 50 percent of the switch rating.

Part (C) covers the special devices with an enhanced design on their terminal screws rated for direct aluminum terminations, known by the mandatory labeling “CO/ALR.” For snap switches rated 20 A or less, these are the only permissible switches unless the aluminum wires are pigtailed to copper for the final device terminations.

Part (D) covers the 347-V snap switches primarily used in the Canadian market. Instead of using 480Y/277V systems, they more commonly use 600Y/347V systems, and these switches are engineered accordingly. They will handle most applicable inductive and resistive loads up to the switch rating; however, any limitations imposed as part of a listing process must be observed. They must not be rated less than 15 A, and they must be physically configured so that flush applications in device boxes will not be readily interchangeable with switches identified for 120/240, or 208Y/120, or 480Y/277V systems.

Part (E) prohibits the use of dimmer switches to control receptacles; they are only permitted to control fixed incandescent lighting, unless specifically listed otherwise.

Part (F), new as of the 2011 **NEC**, and extended to “control devices” in the 2017 edition to capture electronic control equipment, addresses a previously unforeseen consequence of the long-standing permission in 210.21(B)(3) for 20-A branch circuits with multiple receptacles to allow for either 15 or 20 A-configured plugs. The usual 20-A NEMA 5-20R tee-slot receptacle will accept either a 5-20P 20-A plug (uncommon in practice but they are used) or a 5-15P 15-A parallel blade plug (common). If the 20-A receptacle is controlled by a snap switch and receives the 5-20P plug of an appliance drawing more than 15 A, a 15-A snap switch will be overloaded. The new rule requires that such a snap switch be rated at not less than the maximum branch-circuit rating that correlates with 210.21(B) and the receptacle configuration. In this case, a 20-A snap switch must be used ahead of the 20-A receptacle. The exception covers the unusual condition where only a single 15-A receptacle is installed on a multireceptacle 20-A branch circuit. This is permitted by 210.21(B)(3) for 20-A branch circuits. In this case the snap switch rating can follow that of the receptacle.

404.20. Marking. Part (B) of this section requires any switch with a marked “OFF” position to completely disconnect all ungrounded conductors to the load. This is comparable to the rule for electric heating thermostats with “OFF” positions, as covered in 424.24(A). The reason for this was incidents where electronic switches, such as occupancy sensors, were installed on circuits with no grounded conductor present, and the switch leaked a small amount of current through the load in order for its electronics to work. Workers in the room replacing ballasts assumed that since the lights were out, there was no voltage at the luminaires. The amount of current is regulated by the product standards and is not a shock hazard, but it was enough to startle the workers to the point of falling off the ladder. Now these switches must use some other indication, such as “standby.” Be aware that a switch with some marking other than “OFF” very likely will pass voltage to the luminaires even when they appear to be off. A good example is the lit-handle snap switches that have the toggle handle illuminated with the load off (pilot-handle switches, lit with the load on, use a grounded circuit conductor connection and are OK). These devices also pass current through the load in the OFF position, and for that reason the normally OFF position of the toggle no longer reads “OFF.”

404.22. Electronic Lighting Control Switches. This is the product standard counterpart to the wiring requirement in 404.2(C). Refer to that location, particularly the new second paragraph, for the complete discussion.

404.28. Wire Bending Space. At terminals of individually enclosed switches and circuit breakers, the spacing from lugs to the opposite wall *must* be at least equal to that of Table 312.6(B) for the given size and number of conductors per lug. The larger spacing of that table, rather than the smaller spacing of Table 312.6(A), must be used regardless of how conductors enter or leave the enclosure—on the sides or opposite terminals.

Figure 404-15 shows the rule on wire bending space in switch or CB enclosures.

Fig. 404-15. Top wire-bending space contains offset (S) bends and must have dimensions from Table 312.6(B). Bottom wiring space has single (L) bends—but must conform to Table 312.6(B), not Table 312.6(A). That varies from 312.6(B)(4), which permits terminal space from Table 312.6(A) when wires go out the side of the enclosure.

ARTICLE 406. RECEPTACLES, CORD CONNECTORS, AND ATTACHMENT PLUGS (CAPS)

406.1. Scope. Previously part of Art. 410 in the 1999 *NEC*, this article gives a number of requirements for the proper use of receptacles, cord connectors, and attachment plugs.

406.3 Receptacle Rating and Type. In part (A), the Code makes a general statement regarding any receptacle that is used. *All* receptacles must be listed by a third-party testing agency, such as Underwriters Laboratories, for the specific application. This wording effectively prohibits the use of any receptacle that is not listed, as well as the use of listed receptacles that are not specifically listed for that use. The only way to ensure compliance with this requirement is to read and understand the product literature supplied with the receptacle. Then one can evaluate the acceptability of any receptacle for any application, based on the listing of the receptacle in question.

Part (B) requires that receptacles be rated no less than 15 A at either 125 or 250 V. This establishes the minimum acceptable ampere rating for receptacles recognized by the Code for general

wiring, in any occupancy.

Part (C) requires that receptacles rated 20 A or less for direct aluminum connections be listed as and marked CO/ALR type.

Part (D) covers the so-called isolated-ground (IG) receptacles that are intended for use in accordance with 250.146(D). Such receptacles may *only* be used as indicated by 250.146(D). That is, if used, the ground *must* be isolated. This prevents anyone coming along later from being fooled into believing the receptacle is an isolated-ground receptacle when it's not. All IG receptacles *must* be isolated; however, there is no **NEC** requirement as to how far upstream the isolation must be maintained because that is a design issue. The isolation might stop at the local branch-circuit panelboard, or it might continue as far as the main disconnect for the building, system, or service except as limited in 250.146(D). If the receptacle is installed in a conventional nonmetallic box with no integral mechanism to bond the device yoke, then only nonmetallic faceplates are permitted.

It should be noted that isolated-ground receptacles must be identified by an orange triangle on the face. Although receptacles that are orange overall are the most common form of these receptacles, even with the overall color if you look carefully, there will be an orange triangle, and technically the only orange on that receptacle face that indicates the isolating function is the orange within the triangle. It is entirely legal to make an orange receptacle with no triangle, and sell it as a conventional receptacle for Halloween celebrations, or for whatever reason orange is desired. Conversely, the receptacle face can be any other color, but with an orange triangle, and it will be one that employs an isolated equipment grounding construction.

Part (E) is new as of the 2014 **NEC** and requires all customary straight-blade 15- and 20-A, 125-V receptacles that are automatically controlled by any form of building automation including energy management to be marked with the symbol as shown in [Fig. 406-1](#). The final language in the 2017 edition requires explanation on some key points. The first paragraph is very close to the 2014 text, and refers to two different control modalities. The first, “controlled by an automatic control device” refers to some upstream relay control, not incorporated into the receptacle, that switches the power that flows over the wires connected to the receptacle. The second, “incorporate control features that remove power from the receptacle” refers to a receptacle that includes (“incorporates”) within it some sort of relay function responsive to an external signal that can disable the receptacle.

Fig. 406-1. A compliant marking of a controlled receptacle. The common connection tab(s) has (have) been broken open as required so only the lower half of this duplex receptacle is controlled automatically. The upper half is always available. [406.3(E)].

The first paragraph then, at its end, requires the device to be “permanently” marked (new for 2017) with the specified symbol, so a faceplate marking does not suffice. That symbol is like the one for 2014, but includes the word “Controlled” underneath it. The paramount concern was that without the word being added, far too many people would be completely unaware of the true significance of the symbol alone. The only way to realistically mark the device itself is to have it done by the manufacturer. Indeed receptacles are now available from several manufacturers that have both the symbol and the word. In general, the market is showing a very strong preference for a split receptacle, so one side will always be available. To that end, most factory-marked receptacles will need to be installed as split receptacles; receptacles that show both ends as controlled will likely only be available on special order.

The new second paragraph further clarifies that if option one above (the automatic control device)

is used, the receptacle must be marked on its face (again, the face of the receptacle, not the faceplate) and in a way that is visible after installation. And, again, even without a dedicated paragraph, an option two receptacle still also needs a permanent marking and the word “controlled” on the managed receptacle(s). The final paragraph, quite properly working from the established principle that a duplex receptacle is not a single device but consists of two receptacles, clarifies that the function of each of the two receptacles of a duplex is to be apparent upon looking at them as installed, and visible regardless of whatever faceplate is being used.

Although it is difficult to imagine how a manually operated snap switch in a dwelling unit and similar locations (such as those addressed in exceptions within 210.70) could be a constituent of such a control system, a harmless exception nevertheless exempts such receptacles from the new marking requirement.

Part (F), new as of the 2017 **NEC**, covers receptacles that incorporate USB charging slots for cell phone and comparable charging equipment. Such equipment must be made so the USB circuitry is integral with the receptacle. In this way the USB power circuit wiring, which operated under Class 2 parameters, is precluded from being in contact with the branch-circuit wiring. There have been separate, add-on modules available without the system separation required by 725.136(A). However, the integral design permitted here complies with 725.136(B), and in addition, the entire assembly must be listed in its entirety.

406.4. General Installation Requirements. Parts (A) through (F) of this section provide the general requirements for installing receptacles in any occupancy. Part (A) of this rule calls for the use of 15- and 20-A receptacles that are factory-equipped with a grounding terminal. The next sentence prohibits the use of receptacles at currents and voltages for which they are not rated, except as indicated in Tables 210.21(B)(2) and (B)(3), which give the maximum current rating of the circuits to which the standard-rated receptacles may be safely connected. And the first sentence of this rule recognizes the use of nongrounding-type receptacles for replacement as described in 406.4(D).

Collectively these requirements provide a general framework that is an essential element of electrical safety, namely, receptacle configurations “advertise” circuit characteristics, and electrical equipment users are generally entitled to believe what they see. If they have a 20-A 125-cord cap (with the grounded conductor blade at right angles to the ungrounded conductor blade), they are entitled to believe that there is a 20-A overcurrent device and 20-A capable wiring ahead of the receptacle. A receptacle with a grounding terminal can be counted on as providing a connection to an equipment grounding conductor unless marked otherwise, as covered in (D)(2)(b or c).

Part (B) calls for the receptacle’s “grounding contacts,” usually the U-shaped connector, to be grounded, and part (C), which generally requires receptacles to be grounded by connection to the circuit equipment grounding conductor, indicates how this must be accomplished. The exceptions to part (B) exempt receptacles on vehicle-mounted generators and replacement receptacles from the need for connection to an equipment grounding conductor, as permitted by 250.34 and 406.4(D).

The basic requirement of 406.4(D) mandates that when receptacles are replaced for any reason, the replacements must be in accordance with the requirements indicated in parts (D)(1), (2), (3), and (4). New language in the 2014 **NEC** mandated that both GFCI and AFCI receptacles be installed in readily accessible locations. This will facilitate the monthly testing they are supposed to undergo. Note that accessibility requirements for receptacles will be of very questionable enforceability due to the inherent lack of inspection following furniture rearrangements. Although the location of this rule only applies to replacement devices, the requirement applies generally because it backs up the

general circuit requirements to the same effect in 210.8 and 210.12.

As covered in 406.4(D)(1), the Code generally requires any two-slot, nongrounding receptacle that becomes defective to be replaced with a grounding-type receptacle if there is a “grounding means” in the outlet box. The grounding means may be the equipment grounding conductor generally required to be run with the circuit conductors by the rule of 406.4(C) to provide for grounding of receptacles. Or, it may be an equipment ground installed in accordance with 250.130(C). In either case, a grounding-type receptacle must be used as a replacement for the defective nongrounding type. And the green ground screw on the receptacle must be connected to the available grounding means. It should be noted that it is not necessary to install a ground in accordance with 250.130(C), but if one chooses to do so, the use of a grounding-type receptacle becomes mandatory. And in either case, the grounding conductor installed in accordance with 250.130(C) must be connected to the green equipment ground screw on the receptacle.

Part **(2)** of 406.4(D) covers those instances where a replacement must be made at a receptacle enclosure that does not contain a grounding means. In that situation the Code offers three options for replacement. It should be noted that there is no evidence in any available documentation to suggest that this section is presenting these options in an order of preference. Any of the three indicated replacement alternatives is equally acceptable.

The first option, in part **(a)**, is to replace the existing two-slot (nongrounding) receptacle with another nongrounding-type receptacle. Although acceptable, such replacement may not be the most desirable where the receptacle has to supply grounded equipment. This has the virtue of strict accordance with the principle of truth in advertising discussed in **(A)**, that is quite simply, no ground equals no ground holes. At this point extensive debates begin. “They’ll cut off the ground pins” or “They’ll avoid the ungrounded connection” or “If they cut off the ground pin they know they are doing something bad” or “They’ll plug into the grounding-type (but not functionally grounded) receptacle with no understanding of a possible problem” or “GFCI is no substitute for grounding” or “Surge protective devices will appear to be installed properly and fail,” etc. All of these arguments have merit, but the issue has been settled in the **NEC**. [Figure 406-2](#) summarizes the options.

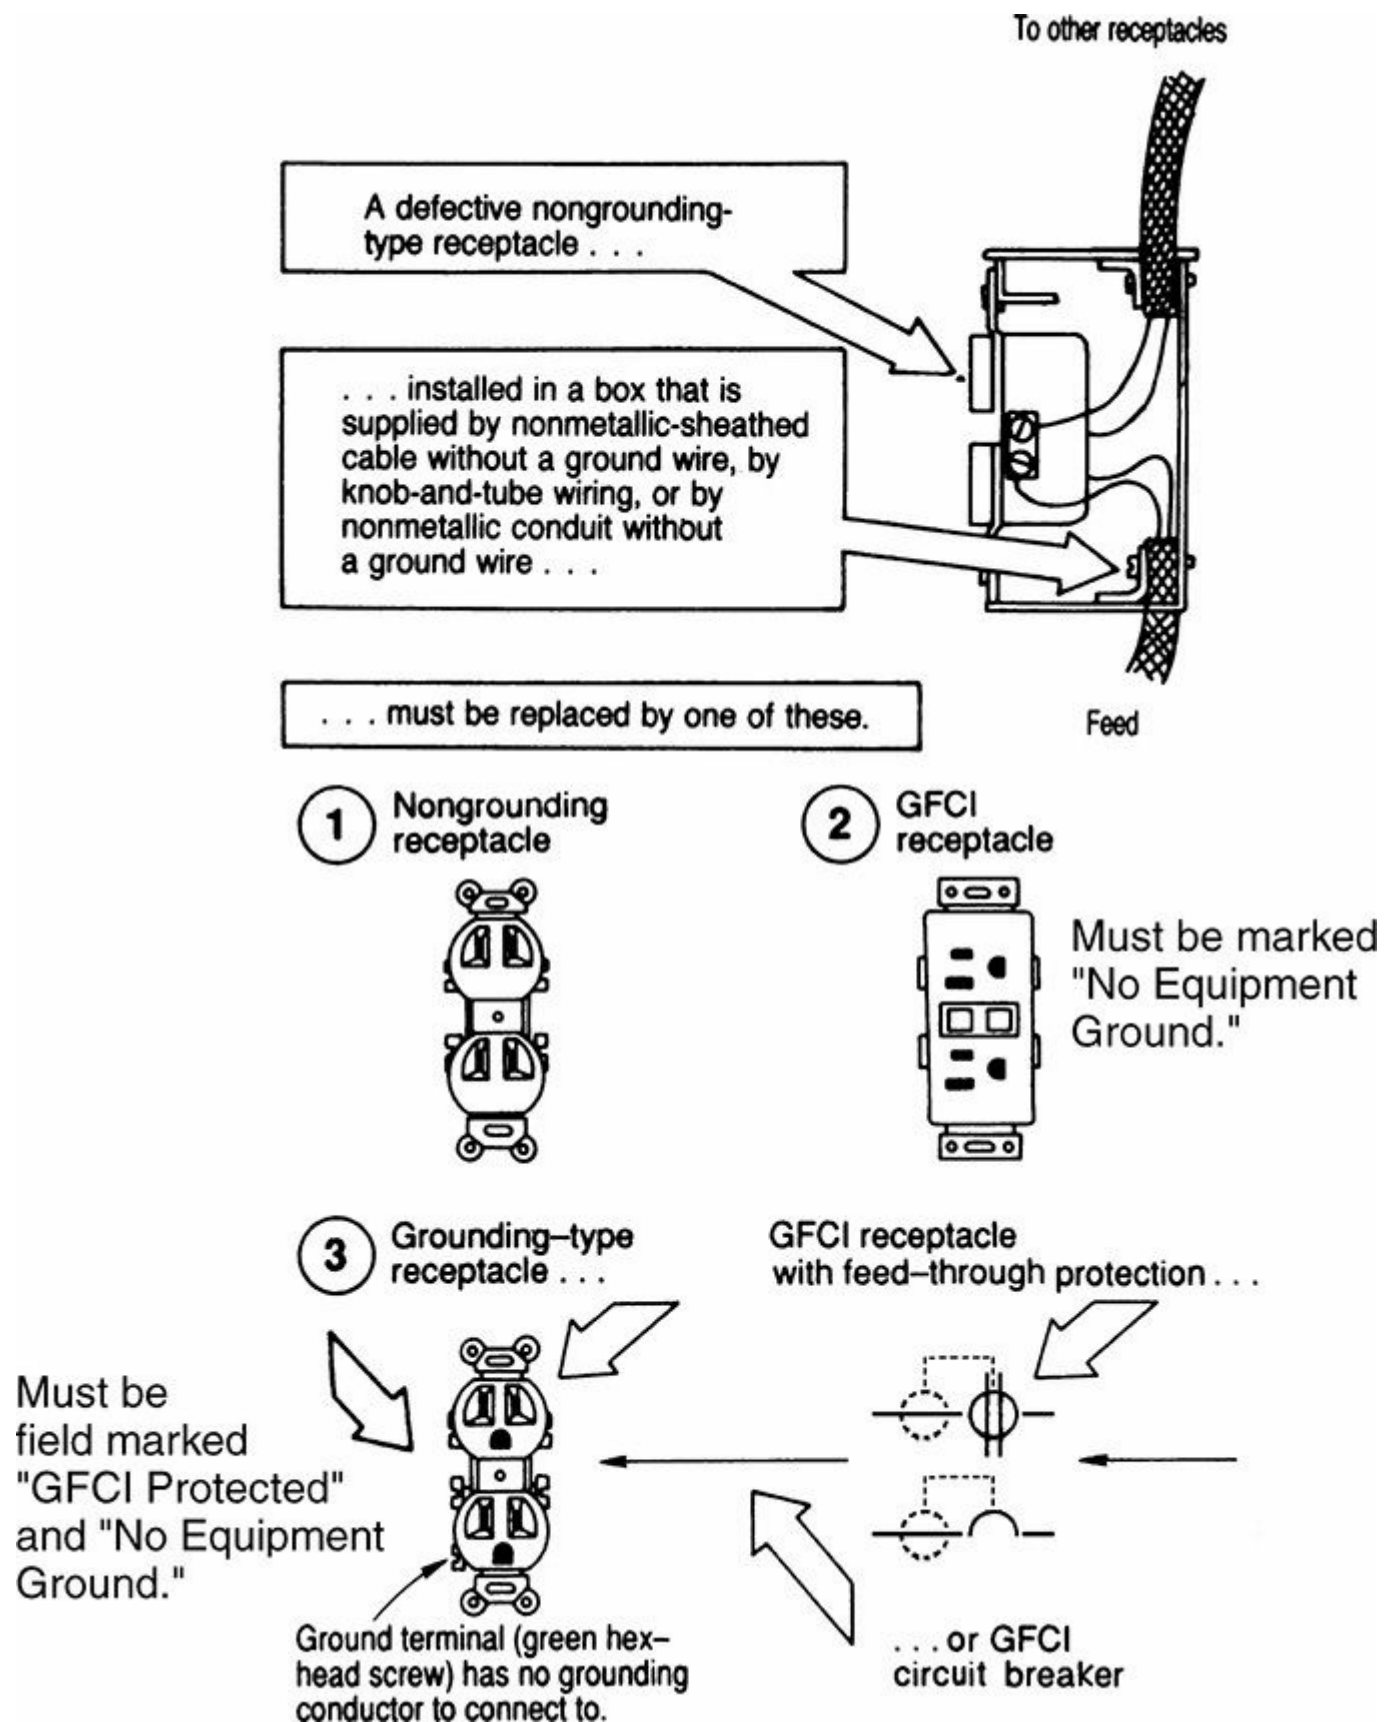

Fig. 406-2. A nongrounding-type receptacle, a GFCI-type receptacle, or GFCI protection, must always be used when replacing a nongrounding receptacle in any case where the box does not contain an equipment grounding conductor. [Sec. 406.4(D).]

The rule of part **(D)(2)(b)** recognizes a GFCI receptacle as replacement of a nongrounding-type receptacle where there is no ground in the box. Such a receptacle will provide automatic opening of the supply under fault conditions without connection to an equipment grounding conductor. This is

accomplished through the internal electronic circuitry of the GFCI device. Given the much lower threshold (5 ± 1 mA) at which the GFCI receptacle operates compared to the instantaneous trip for a 15-A CB, the GFCI offers a much better level of shock protection.

The next sentence requires that a GFCI receptacle installed as a replacement for a nongrounding receptacle, in a box where a ground is not available, be marked “No Equipment Ground.” This requirement is intended to alert anyone using that outlet that, even though the GFCI receptacle has a U-shaped ground slot, there is no connection to the grounding system. This is important where supplying electronic equipment, such as computers, electronic cash registers, and the like, because an equipment grounding conductor is critical for proper operation of such equipment. The field marking “No Equipment Ground” will serve to prevent a user from being fooled into thinking that there is a ground connection. The required marking may be placed on the device or on the cover plate.

If there is no ground in the box, 406.4(D)(2)(c) permits replacement of a nongrounding-type receptacle with a GFCI-protected grounding-type receptacle. And, in addition to the marking “No Equipment Ground,” the receptacle must be marked “GFCI Protected.” The warning about the absence of an equipment ground is required for the same reason it is required where a GFCI receptacle is used as a replacement in accordance with part **(D)(2)(b)**. And the “GFCI Protected” marking can be on the device or (more likely) on its faceplate, and must be visible after installation wherever located. It is provided to help service electricians in the future. A lot of time could be wasted if the GFCI device protecting the grounding-type receptacle tripped, leaving the protected receptacle de-energized, and the service electrician was unaware of the upstream GFCI device. By providing such a field marking, any service electrician will be immediately advised of the possibility that the upstream GFCI device—receptacle or breaker—may have de-energized the circuit. Two informational notes address the fact that a GFCI is not a substitute for a ground-fault return path. Some appliances come with installation instructions that effectively require an equipment grounding connection, and 250.114 specifies equipment with the same requirement. The marking rules in this paragraph put users on notice that the three-wire grounding configuration to the contrary notwithstanding, the nongrounding connection offered in this context does not meet the requirements.

The only possible replacement combination not addressed here, because it is covered in other ways, is where a two-slot (nongrounding) receptacle is used as a replacement at a location that is now required to be GFCI-protected. There is no intent to prohibit the use of a nongrounding-type receptacle and a GFCI breaker would satisfy the need for replacement and GFCI protection. Such an application fully complies with all the requirements. The GFCI protection in the circuit breaker meets 406.4(D)(3) because the new receptacle is “GFCI protected” and the nongrounding receptacle meets 406.4(D)(2)(a).

Next, 406.4(D)(3) requires that where any receptacle is to be replaced, if the Code now requires a receptacle in that location to be GFCI protected, a GFCI-protected receptacle must be provided. That requirement has the effect of making all GFCI rules retroactive where a replacement is made. That is, normally there is no requirement to apply a new Code to an existing building and bring that building into compliance with the new Code. But, in an existing installation—say, in a bathroom of a commercial office building—if a receptacle should need replacement, 210.8(B)(1) in conjunction with 406.4(D)(3) would require that the replacement receptacle be GFCI protected.

The 2014 **NEC** added an exception that still remains and that allows upstream GFCI protection of a replacement receptacle in the event a GFCI receptacle in the subject location is impracticable, such as in cases where the existing outlet box is too small. This exception creates the erroneous impression

that 406.4(D)(3) requires the use of a GFCI receptacle. It does not. It requires the use of a “ground-fault circuit interrupter protected receptacle.” Any conventional receptacle on the load side of a GFCI protective device complies with this rule regardless of motivation. The **NEC** exception is completely unnecessary.

The exception is also technically incorrect because it requires the use of labeling indicating “GFCI protected” and “no equipment ground.” The latter label should not be used if an equipment ground is present and yet would be required. There are many applications of small outlet boxes containing old wiring that nevertheless do provide an equipment grounding return path. This exception, which is permissive and therefore does not vary the rule it follows, can technically be ignored. However, it is very likely to cause confusion.

Three numbered paragraphs extend the rules for receptacle replacements. Item (4) is the most intriguing and controversial. If a dwelling unit receptacle, or any other receptacle should later editions of the **NEC** require AFCI protection for it, fails at an outlet that, if newly wired would require AFCI protection, then AFCI protection must be arranged for the replacement receptacle. This requirement took effect on January 1, 2014, in jurisdictions enforcing the 2011 **NEC** whether or not the 2014 **NEC** was in effect on that date.

If the panelboard and circuit protection are fairly new, an AFCI circuit breaker could be wired ahead of the replacement receptacle, assuming AFCI breakers are available for the wiring configuration; for example, even after all this time certain major manufacturers of overcurrent protective devices still do not have two-pole models, and if the damaged receptacle is on a multiwire branch circuit that will not be an option. It also will not be an option on any of the untold numbers of obsolete panelboard designs still in service. However, AFCI receptacles (the outlet branch circuit style) will be able to be applied either ahead of or even at the damaged receptacle location.

By placing the 3-year delay in the 2011 **NEC**, the Code-making panel placed a bet that the AFCI receptacles would be available in the market. The panel won that bet because the devices are indeed available. Refer to the coverage at 210.12 for further information. Two exceptions follow as of the 2017 **NEC**, the first allowing the use of GFCI protection [406.4(D)(2)(b)] in lieu of AFCI protection. This exception is extremely limited, with three conditions that clearly indicate the context. The first limits its use to where there is no equipment grounding conductor in the box, *and* it is impracticable to install one using a separate grounding conductor as covered in 250.130(C). The second limits its use to applications where the branch circuit originates in archaic equipment for which no combination-style AFCI device is available. The third limits its use to the time period prior to commercial availability of a combination GFCI/AFCI receptacle. If any of the three limits are not true when the receptacle is replaced, then conventional GFCI substitution does not apply. In fact, well before the beginning of 2017, combination AFCI/GFCI receptacles have become commonplace in supply houses and even home stores, making the first exception largely moot.

The second exception addresses a misapplication of 210.12(D) Exception, which is intended to apply to panelboard replacements on the supply side of branch circuits where the conductors need minor extensions in order to complete the work. It was never intended that one could add a few inches of conductor within the outlet box, count that as an extension of less than 6 ft, and then escape from arc fault protection requirements. That foolishness now ends. Note that under the **NEC** Style Manual this exception should have been listed first because it is a mandatory exception next to a permissive exception.

Items (5) and (6) require that replacement receptacles in locations requiring tamper-resistant receptacles or weather-resistant receptacles, respectively, under the applicable **NEC** provisions for new wiring, be replaced with new receptacles that comply with those provisions. This is just as has been the case for many years for GFCI receptacles. Intriguingly, as of the 2017 **NEC**, a nongrounding receptacle in an outlet normally required to be tamper resistant, can be replaced by another of the same style, because these receptacles are not manufactured in tamper-resistant configurations. Note that the new (2017) language here is unnecessary because 406.12 Exception already waives the tamper-resistant requirement in such cases. On the other hand, 406.4(D)(6) offers no such relief and 406.9(B)(1) does not either.

406.5 Receptacle Mounting. As required by this part, receptacles must be securely mounted in outlet boxes or “assemblies” (e.g., power poles) that are “identified” (meaning, as per Art. 100, generally recognizable as being suitable). This wording should be interpreted to mean that the box or assembly must be listed for use in the particular location (e.g., wet, dry, damp, indoors, outdoors, hazardous location). The last part of this sentence [in (A)] requires a receptacle to be “held rigidly at the finished surface” in any instance where the box is set back, as allowed for some building surfaces in 314.20. And the screws need to be actual 6-32 machine screws or otherwise as the enclosure manufacturer intended, and not drywall screws or other random fastenings.

This is an important requirement, because receptacles must accept considerable force in while cord caps are plugged in and pulled out. Some wall finishes are installed with close enough spacing (see also 314.21) so the plaster ears on the device yokes have enough bearing surface to comply with this rule, but many do not. In such cases spacers (#6 washers, ¼ in. nuts, whatever is handy) need to be mounted between the box ears and the underside of the yoke so when the 6-32 yoke screws are turned down, the yoke is securely held at the plane of the finished surface, and the receptacle yoke has enough bearing surface to not rock or twist in use, even with no faceplate installed. Then, and only then, add the faceplate. For boxes not set back, covered in (B), secure the receptacle tightly to the box, and for boxes that project from the wall or that are surface mounted, remove at least one of the fiber retaining washers if the yoke connections are to be relied upon for grounding continuity, per 250.146(A).

406.5(C) requires receptacles mounted in a raised cover use more than a single screw for this purpose. This is not done for grounding continuity. There were numerous instances where a single screw in a duplex receptacle loosened to the point where the receptacle fell back far enough into the box to actually pivot on the remaining screw threads. If a cord cap was at all loose, and the pivot moved toward the ungrounded blade, the result was a shower of sparks and a destroyed cord cap. Raised cover designs now all address this requirement and include the required hardware. See the discussion at 250.146(A) for more information on the use of this hardware for grounding.

406.5(D) is intended to prevent short circuits when attachment plugs (caps) are inserted in receptacles mounted with metal faceplates—in which case, the metal of the plate could short (or bridge) the blades of the plug cap if the faceplate is not set back from the receptacle face. The rule requires that the “faces” of receptacles project at least 0.015 in. (0.4 mm) through the faceplate opening when the faceplate is metallic. And it is necessary to assure a solid backing for receptacles so that attachment plugs can be inserted without difficulty. The requirement for receptacle faces to project at least 0.015 in. (0.4 mm) from installed metal faceplates will also prevent faults caused by countless existing attachment plugs with exposed bare terminal screws. With receptacle faces and faceplates installed according to 406.5(D), attachment plugs can be fully inserted into receptacles and

will provide a better contact. The cooperation of other crafts, such as plasterers or drywall applicators, will be needed to satisfy the requirements. Note that compliance with this requirement is best assured by rigorous enforcement of the rule in (A), because the product standards require receptacle faces to project forward from their yokes by enough margin to comply with these rules. Of course, this only works if the yokes are at the building surface the way they are supposed to be.

406.5(E) and (F), new as of the 2017 **NEC**, address “countertops” and “work surfaces” in separate paragraphs. In so doing they respond to differences in the testing protocols between receptacles seemingly designed to be applied in comparable locations. It turns out that liquid spillage on a “work surface” is assumed comparable to a cup of liquid spilled, and similar spillage on a “countertop” (assumed to be in a kitchen or bathroom) assumes a much larger volume of water (actually ½ gallon of saline solution, such as a pot going over). For that reason, a countertop exposure requires a countertop listing, and a work surface exposure requires a work surface listing, but a countertop listing is also permitted because the requirements are either similar to or exceed those for work surfaces. Another key difference between the paragraphs is that the product standard connected to work surfaces is essentially about furniture capable of relocation. The standard connected to the countertop rules is focused on locations such as kitchen counters that are part of the building.

406.5(G) as of the 2014 cycle applies to countertops in all occupancies and not just for residential applications. It prohibits the placement of a receptacle in a face-up orientation. This rule does not prohibit pop-up receptacle assemblies that fully recess when not in use, whether supporting conventional or GFCI receptacles. These are also discussed in this book as part of the requirements for kitchen counters in 210.52(C)(5).

406.5(H) was entirely new as of the 2014 **NEC** and covers receptacle mounting in “seating areas and other similar surfaces.” The focus of this rule is on receptacles now increasingly popular in airport gate seating areas that support travelers with laptop computers. Many of these devices also directly support USB charging equipment for smaller electronic devices. The pop-up receptacles discussed in (E) above are the third of four options for these applications, with the traditional floor box as the fourth. The first two options address listed assemblies that are part of a “furniture power distribution unit” if cord-and-plug-connected, and part of listed household or commercial furnishings if permanently located.

406.6. Receptacle Faceplates (Cover Plates). The 2017 **NEC** added a fascinating new subsection (D) covering faceplate assemblies that are constructed with insulated probes that are designed to make contact with the terminals on each side of a duplex receptacle (see [Fig. 406-3](#)). A small amount of power is taken and used to provide either night-lighting or a USB charging point or both. As in the case of 406.3(F), to assure safety this equipment must now be listed and designed so any Class 2 circuitry is integral with the cover plate.

Fig. 406-3. This faceplate is also a device, in this case a USB charging point powered by the conductive pick-ups that engage the energized terminal screws on a duplex receptacle. [Sec. 406.6(D).]

406.7. Attachment Plugs, Cord Connectors, and Flanged Surface Devices.

These rules contain the requirement for dead-front construction of cord caps, so the simple loss of a fiber or paper cover over the terminal screws will not result in energized parts near metal faceplates. Part (B) prohibits wiring schemes that result in circuits being energized through a receptacle connection of some sort to an energized plug. This has been a problem for years when untrained individuals attempt to connect fixed loads to the output of a portable generator, etc. The proper method is to have an energized connector body connect to a flanged inlet, as covered in (D) and shown in [Fig. 406-4](#).

Fig. 406-4. This flanged inlet is energized by the mating connector body, and therefore no exposed and energized plug blades are possible. [Sec. 406.7(B)].

406.9. Receptacles in Damp or Wet Locations. The definition of *location* in Art. 100 describes places that would be considered wet or damp locations. Any receptacle used in a damp location—such as an open or screened-in porch with a roof or overhang above it—may not be equipped with a conventional receptacle cover plate. It must be provided with a cover that will make the receptacle(s) weatherproof when the cover or covers are in place—no plug inserted. The type of cover plate that has a thread-on, gasketed metal cap held captive by a short metal chain or a closeable cover would be acceptable for damp locations (Fig. 406-5). The type of receptacle cover that has horizontally opening hinged flaps (doors) to cover the receptacles may be used in damp but not wet locations as described in part (B), even if the flaps are self-closing (i.e., if the flaps cannot stay open; Fig. 406-6). Of course, any cover plate that is listed for weatherproof use may also be used in damp locations.

Fig. 406-5. Chain-held screw-cap cover is suitable for damp, but not wet, locations. (Sec. 406.9.)

Fig. 406-6. Cover assembly with stay-open doors may be used in damp but not in wet locations. (Sec. 406.9.)

A new requirement as of the 2008 **NEC**, and that covers both damp and wet locations equally, in all occupancies, is that 15- and 20-A, 125- and 250-V nonlocking receptacles be listed as “weather resistant.” This makes the receptacles themselves a second line of defense in case the wet-location cover required to be functional with a plug inserted (required in wet locations) is left open or falls off. These receptacles have additional corrosion-resistant features on their metal parts, as well as UV and cold-weather impact resistance on their nonmetallic parts. They are identified in the field with a “WR” marking.

In part (B)(1), in addition to the requirement for weather resistance, the **NEC** clearly requires that

all 15- and 20-A, 125- and 250-V receptacles installed in wet locations outdoors must be provided with covers that are weatherproof when the plug cap is inserted (a so-called “in-use” cover, shown in Fig. 406-7). This applies to all occupancies, and unlike the weather-resistance rule, to both straight-blade and locking-configured receptacles. There is no distinction within the wording used that bases compliance on occupancy. However, in-use covers are not NEMA 4 rated and will not stand up to a hose stream, as many wet locations, particularly wet locations indoors, are characterized by. For this reason, an exception allows covers that will be subject to “routine high-pressure spray washing” to have an enclosure that is weatherproof only when the plug is removed. Figure 406-5 is one classic style of a receptacle cover that is suitable for such exposures.

Fig. 406-7. A listed “outlet box hood” additionally identified as “extra duty.” This cover will protect the receptacle even when a cord-and plug-connected load is in use. (Sec. 406.9.)

A new concept accepted in the 2011 **NEC** involves an “extra-duty outlet box hood.” These hoods (Fig. 406-7) are now defined in 406.2, and are more robust versions of the “in-use” or “bubble” covers required before that time, and which tended to fail with disturbing regularity. As of the 2014 **NEC**, these are now required for all wet location exposures, whether or not residential, and however mounted, whether or not from grade.

As of the 2017 **NEC**, useful alternatives involving installations that use other listed assemblies or enclosures that do not employ outlet box hoods are relieved of the necessity of obtaining the “extra duty” marking. The **NEC** also added very useful information to Informational Note No. 1 that describes important limitations to the “extra duty” classification and expressly recognizes outdoor

enclosure types covered in Table 110.28 that do not use an outlet box hood. [Figure 406-8](#) shows an installation in an outdoor location that dates from when the only requirement was that the enclosure be weatherproof whether or not the attachment plug was inserted. Nevertheless, it anticipated the 2017 allowances very nicely. There is room through a removable plate in the bottom to admit as necessary up to 24 hard service extension cords along with a 6/4 hard service cord with a right-angle cord cap, and when the cover is closed and latched every plug and receptacle combination is immune to weather.

Fig. 406-8. A grouping of 12 duplex 125 V 20A duplex receptacles (each connected to a 20A GFCI circuit breaker) along with a 125/250-V 50A 3-pole 4-wire grounding receptacle, all within a fully gasketed enclosure with a hinged door.

There are other more common applications of this concept, such as the traditional mobile home or RV receptacle in a common enclosure with a duplex GFCI convenience receptacle, all within an overall enclosure door that assures that the elements do not bother the plugged-in connections while they are in use.

Wet-location receptacles other than those covered by part **(B)(1)** are covered in **(B)(2)**, such as receptacles for higher voltages and current ratings. As given here, all other wet-location receptacles must be used with either of two types of cover assemblies: If the receptacle will be used only while attended, such as for portable tools, a receptacle such as the one in [Fig. 406-5](#) can be used, that is, one that is only weatherproof with the plug removed and the cover in place. If the receptacle will be kept in use, then some arrangement must be used that will maintain its integrity with the plug inserted. Some wet-location covers have a flat area around the receptacle that will seal to a wet location boot applied over a plug. Another approach is to use a pendant receptacle body on a short length of flexible cord with an expanding or flanged rubber boot, which will mate to a similar boot applied to the plug.

Part **(C)** of 406.9 prohibits the installation of receptacle outlets “within or directly over a bathtub or shower stall.” The minimum exclusion area is that area, measured from the outside edge of the tub or shower enclosure, from the floor to the ceiling. Although luminaires are permitted when installed at least 8 ft (2.5 m) above the maximum water level, installation of a receptacle would be a violation of the wording given here. Note the differences between this wording and its counterpart in 404.4 for switches. Part **(D)** requires standpipes to floor-mounted receptacles to “allow floor cleaning” without damaging the floor-mounted device. Part **(E)** pertains to flush-mounted boxes in which receptacles are installed.

406.10. Grounding-Type Receptacles, Adapters, Cord Connectors, and

Attachment Plugs. Paragraph **(3)** of part **(B)** requires a “rigid” terminal for equipment grounding connection in grounding adapters for insertion into nongrounding receptacles ([Fig. 406-9](#)). Adapters with pigtail leads are not acceptable to the rule. This rule prevents the forked grounding terminal at the end of a pigtail from finding the energized slot of a receptacle ([Fig. 406-10](#)), and also eliminates the possibility of using two such adapters at a duplex receptacle, or one on a single receptacle either as a conventional device or as is common in pull-chain lampholders. Remember that these adapters must be polarized, and therefore only one of them can be used at a duplex receptacle where it will fit under the cover screw.

***NE Code* AND UL VIOLATION!** The *NE Code* prohibits use of the pigtail grounding adapters that have been available and widely used for many years. Such devices also do not satisfy UL construction standards.

THIS IS UL AND *NE Code* RECOGNIZED. Grounding adapter has rigid tab with spade end for connecting grounding terminal of the adapter to metal screw contacting the grounded metal yoke that mounts receptacle to the grounded metal box of the outlet (or to an equipment grounding conductor in NM cable used with a nonmetallic outlet box). Different-width blades on adapter polarize it for insertion in only one way into the polarized blade-openings on the receptacle.

Fig. 406-9. This is the **NEC** and UL position on grounding adapters. (Sec. 406.10.)

Fig. 406-10. Pigtail adapter can present shock hazard to personnel. (Sec. 406.10.)

Figure 406-11 shows a very important rule from part (E) of 406.10.

Fig. 406-11. A 3-wire cord must be used when connecting a grounding-type plug-cap. (Sec. 406.10.)

406.12. Tamper-Resistant Receptacles. Another major change as of the 2008 **NEC** concerns the requirement for tamper-resistant receptacles at virtually all receptacle outlets in dwelling units. The same requirements were also extended to guest rooms and guest suites of hotels and motels, and to child care facilities (defined in 406.2 as for more than four children 7 years of age and under). These devices have shutter mechanisms that will move out of the way when two blades of a plug, of equal length, hit both shutters at the same time, which then allow the plug to be inserted (see [Fig. 406-12](#)). A toddler experimenting with a bobby pin or other similar object will see only an immovable shutter. These receptacles have been required for a very long time in pediatric wards of hospitals. This requirement, extended to 250-volt receptacles in the 2017 **NEC**, applies to “all 15- and 20-ampere non-locking-type receptacles in areas specified in 210.52 and 550.13.”

Fig. 406-12. A residential grade tamper-resistant receptacle. Note the shutters over the slot contact points, and the “TR” mark on the lower left corner of the yoke. With the faceplate off, this marking must be fully visible with the receptacle otherwise completely installed. (Sec. 406.12.)

This last reference, also new in the 2017 **NEC**, addresses comparable exposures in mobile/manufactured homes, and as a [Chap. 4](#) amendment of [Chap. 5](#) rules sets an interesting precedent. Generally, Art. 550 is at least a cycle behind the rest of residential requirements and often more, because these units move in interstate commerce and there are issues at the federal regulatory levels. Art. 550, being in [Chap. 5](#), has generally been considered as effectively requiring at least some degree of regulatory consent before imposing the latest requirements from the rest of the **NEC**. The regulations governing mobile/manufactured home construction were authorized under a congressional enactment that specifically invoked the supremacy clause in the U.S. Constitution. The **NEC** is not a federal document. It is a set of rules adopted by the several states under the police powers implicitly reserved to the states under the 10th Amendment. Any attempt at electrical inspection and enforcement of the **NEC** without at least the acquiescence of federal authorities is

unlikely to succeed, and place local inspectors in a very difficult position if they attempt to enforce these provisions when one of these homes arrives on site.

The reference to 210.52 has been clarified through the placement of an exception that correctly correlates this requirement in a sensible way with 210.52(A) and with 210.50(B). For example, 210.52(A) does not count receptacles in luminaires and appliances, or over 1.7 m (5½ ft) above the floor; now 406.12 exempts those areas as well. The high receptacles are Out of toddler reach and the others would never be available in a tamper-resistant form. Receptacles located behind what used to be called stationary appliances to meet 210.50(B) are clearly no threat to a toddler either. The last exemption in the exception is for nongrounding replacement receptacles allowed by 406.4(D)(2)(a), which will never be available in a tamper-resistant form.

Note that this requirement also applies to GFCI receptacles, and they are available with the tamper-resistant features. The requirement also applies to outdoor receptacles installed to meet 210.52(E), so those receptacles will also need to meet the weather-resistance rules (TR + WR). The 2017 **NEC** drastically expanded the reach of this section, by effectively adding all locations where children are likely to congregate. List item (4) adds preschool and elementary schools. The literal text uses the word “facilities” so this would include areas devoted to schooling children of those age levels within other occupancies. Item (5) reaches business offices, waiting rooms and corridors of most medical occupancies. Item (6) reaches four of the assembly occupancies included in 518.2(A), and item (7) adds dormitories.

ARTICLE 408. SWITCHBOARDS AND PANELBOARDS

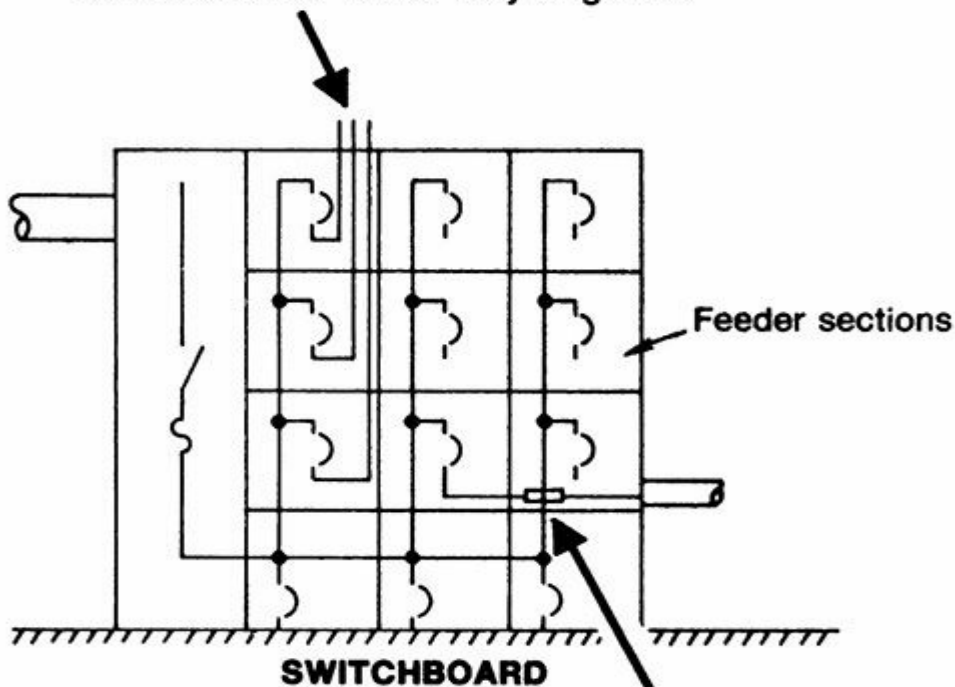

408.1. Scope. As in the case of Art. 404, the scope now clarifies that the provisions within Art. 408 do not apply to medium-voltage equipment, which is exclusively addressed in Art. 490. In addition, the Code-making panel removed, as of the 2011 cycle, the reference to “distribution boards.” This terminology had been a source of endless speculation as to what a distribution board might actually be, and the panel concluded that it was an anachronism that should be discarded. This terminology was literally a century old, originating in Rule 70 of the 1911 **NEC** as part of the phrasing (under a heading covering manufacturing requirements for “Cabinets”) “For panel and distributing boards, cutouts and switches.” From this and subsequent **NEC** language, it seems quite clear that the terminology simply reflected parallel usage long ago that described the same equipment, and there was no technical issue or problem raised in deleting the term.

The term “switchgear” was folded in throughout this article (in fact, throughout the 2014 **NEC**) with parallel coverage to switchboards. Modern versions of both are quite similar, being exclusively metal enclosed, and follow whatever product standard their manufacturers submitted them under when seeking a listing. Switchgear tends to encompass more sophisticated electronics for monitoring and control than current switchboard designs. The coverage of the term “switchgear” in this book in Art. 100 includes additional information relative to differences between the two types of equipment. Although the product standards differ, the Code rules for both are identical. The term “switchboard” still encompasses antique designs with open switches on slate backplanes, etc.

Because the differences primarily reflect design preferences on the part of the owner or specifying engineer, and do not have an impact on the minimum applicable **NEC** requirements, in this book the usual term will continue to be “switchboard” for the sake of brevity. Unless stated otherwise, the minimum requirements apply equally to switchgear.

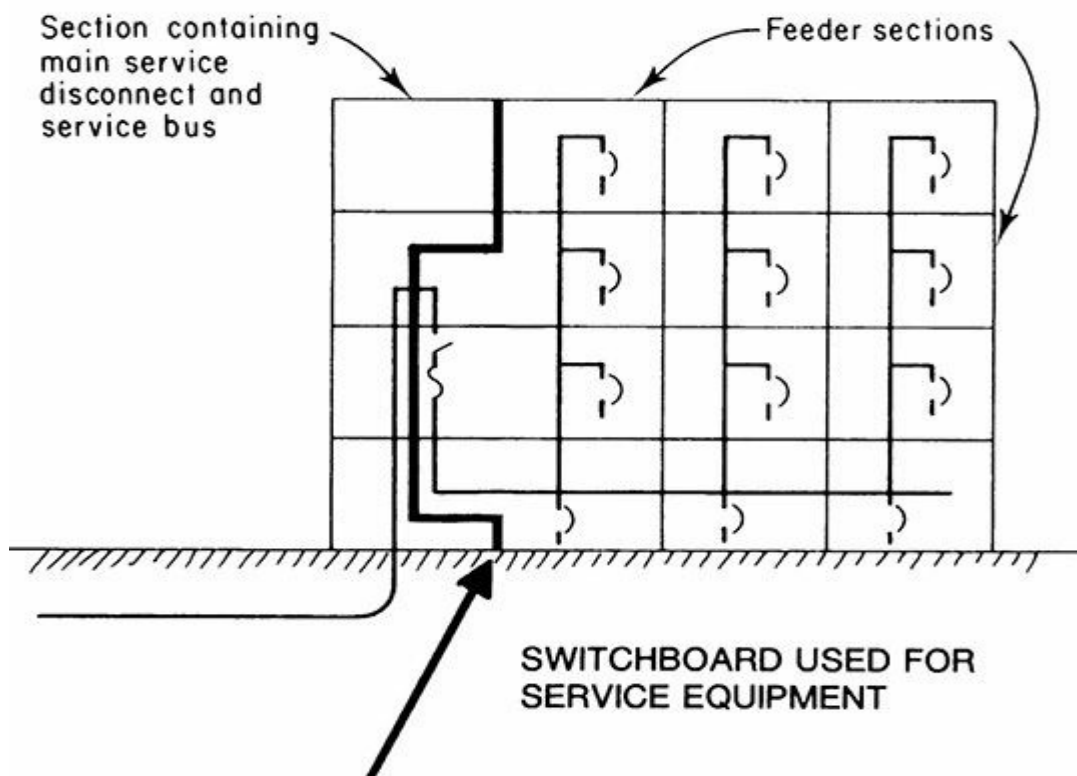

408.3. Support and Arrangement of Busbars and Conductors. Part (A)(2) requires that all service switchboards have a barrier installed within the switchboard to isolate the service busbars and the service terminals from the remainder of the switchboard as shown in [Fig. 408-1](#). Because it is usually impossible to kill the circuit feeding a service switchboard, it has become very common practice for mechanics to work on switchboards with the service bus energized. The hazard associated with this has caused concern and is the reason for this addition to the Code.

BASIC RULE: Load conductors must vertically exit from section in which they originate.

EXCEPTION: Horizontal run of load conductors may be used if isolated from busbars by a barrier

All conductor terminals within a switchboard must be used only for connection to conductors that leave the switchboard vertically from the same switchboard section in which the terminals are located—with the conductors run out the top or out of the bottom of the switchboard.

In every service switchboard, large or small, a barrier must isolate all feeder sections from the service busbars and terminals.

Fig. 408-1. These are basic rules on switchboard wiring. (Sec. 408.3.)

Switchboard manufacturers in many parts of the country have been supplying switchboards with these barriers in place; this Code rule aims to make such protection for personnel a standard requirement. With a barrier of this type installed in a service switchboard, mechanics working on feeder devices for other sections of the switchboard will not be exposed to accidental or surprise contact with the energized parts of the service equipment itself.

As of the 2017 **NEC**, comparable requirements are now in place for panelboards incorporating service disconnects. See [Fig. 408-2](#) for one example of how this rule is expected to be implemented. The change has been proposed for many cycles and is now in place. This is not directly comparable to the Canadian rules, and still allows branch circuit entries in the service protection end of the panel.

Fig. 408-2. An example of making ungrounded and uninsulated service terminals unexposed to inadvertent contact while energized. [408.3(A)(2).] (Courtesy, Square D/Schneider)

Part **(A)(3)** notes that only those conductors intended for termination in a vertical section of a switchboard may be run within that section, other than required inner connections and/or control wiring. This rule was intended to prevent repetition of the many cases on record of damage to switchboards having been caused by termination failures in one section being transmitted to other parts of the switchboard. In order to comply with this requirement, it will be necessary in some cases to provide auxiliary gutters. The basic concept behind the rule is that any load conductors originating at the load terminals of switches or breakers in a switchboard must be carried vertically, up or down, so that they leave the switchboard from that vertical section. Such conductors may not be carried horizontally to or through any other vertical section of the switchboard, except as indicated in the sketch at the top of [Fig. 408-1](#). Because of field conditions, in which the installer does not know the location of protective devices in a switchboard at the time of conduit installations, the exception modifies the requirement that conductors within a vertical section of a switchboard terminate in that

section. Conductors may pass horizontally from one vertical section to another, *provided* that the conductors are isolated from switchboard busbars by some kind of barrier.

Part (C) requires a bonding jumper in a switchboard or panelboard used for service equipment to connect the grounded neutral or grounded phase leg to the equipment grounding conductor (the metal frame or enclosure of the equipment). UL data apply to this rule:

1. Switchboard sections or interiors are optionally intended for use either as a feeder distribution switchboard or as a service switchboard. For service use, a switchboard must be marked "Suitable for use as service equipment."
2. Some switchboard sections or interiors include neutral busbars factory-bonded to the switchboard enclosure. Such switchboards are marked "Suitable *only* for use as service equipment" and may *not* be used as subdistribution switchboards (Fig. 408-3). A bonded neutral bus in a service switchboard may also serve as an equipment grounding busbar.

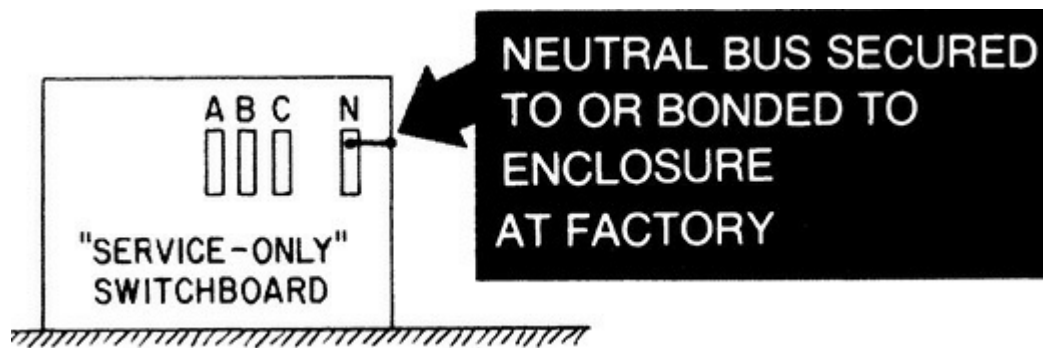

Fig. 408-3. Bonded neutral bus limits switchboard to service applications. (Sec. 408.3.)

3. UL-listed unit substations have the secondary neutral bonded to the enclosure and have provision on the neutral for connection of a grounding conductor, as shown in Fig. 408-4. A terminal is also provided on the enclosure near the line terminals for use with an equipment grounding conductor run from the enclosure of primary equipment feeding the unit sub to the enclosure of the unit sub. Connection of such an equipment grounding conductor provides proper bonding together of equipment enclosures where the primary feed to the unit sub is directly buried underground or is run in nonmetallic conduit without a metal conduit connection in the primary feed.

Fig. 408-4. Unit subs have bonded neutral in secondary switchboards. (Sec. 408.3.)

4. Unless marked otherwise (with both the size and temperature rating of wire to be used), the termination provisions on switchboards are for 60°C wire from No. 14 to No. 1 and 75°C for No. 1/0 and larger wires.

The rule of 110.15 is shown in [Fig. 408-5](#) and correlated to the rule of part (E). On a 3-phase, 4-wire delta-connected system (the so-called red-leg delta, with the midpoint of one phase grounded), the phase busbar or conductor having the higher voltage to ground must be marked, and the higher leg to ground must be phase B, as required by 110.15. Without identification of the higher voltage leg, an installer connecting 120-V loads (lamps, motor starter coils, appliances) to the panelboard shown in the diagram might accidentally connect the loads from the high leg to neutral, exposing the loads to burnout with 208 V across such loads.

Fig. 408-5. Safety requires "high leg" identification on 4-wire delta systems. (Sec. 408.3, informational note.)

408.3(E) requires a fixed arrangement (or phase sequence) of busbars in panels or switchboards. The installer must observe this sequence in hooking up such equipment and must therefore know the phase sequence (or rotation) of the feeder or service conductors. This new rule has the effect of requiring basic phase identification at the service entrance and consistent conformity to that identification and sequence throughout the whole system (Fig. 408-6).

Three-phase buses must be arranged as A, B, C . . .

. . . as viewed from the front of the switchboard or panelboard

Fig. 408-6. Phase sequence in panelboards and switchboards must be fixed. (Sec. 408.3.)

Difficulty has been encountered with the rule of part (E)(1) requiring the high leg to be the B phase, because utility company rules may call for the high leg to be the C phase and the right-hand terminal in a meter socket—rather than the middle terminal. As shown in Fig. 408-7, the utility phase rotation can be converted to a Code phase rotation by applying the concept that phase rotation is relative, not absolute. If the utility C phase is designated as the **NEC** B phase, then the other phase legs are identified for **NEC** purposes as shown. The phase rotation C-A-B is the same as A-B-C, with voltage alternations such that wave B follows wave A by 120° , wave C follows wave B by 120° , wave A follows wave C by 120° , and so on. With the phase legs identified as at the bottom of the drawing, each is carried to the appropriately designated phase lug (A-B-C, left to right) at the panelboard shown in Fig. 408-5.

Fig. 408-7. Utility C phase becomes **NEC** B phase for high-leg identification. [Sec. 408.3(E), Exception.] In the past, the “B” phase was required to be the “high leg.” Now such transposition is

not needed.

The exception to part **(E)(1)** will permit the high leg (the one with 208 V to ground) to be other than the B phase (such as the C phase) where the meter is within the same enclosure as the switchboard or panelboard and the phase configuration of the utility supply system requires other than the B phase for the high leg at the meter.

The concept behind this exception is to permit the same phase identification (such as C phase at 208 V) for the metering equipment and the busbars *within the switchboard or panelboard*. And it is the intent of the Code panel that the different service phase identification (such as C phase as the high leg) will apply to the entire switchboard or panelboard and that no transposition of phases B and C is needed within the switchboard or panelboard. However, beyond the service switchboard or panelboard, the basic rule of 408.3(E) must be observed to have the B phase (the middle busbar) as the high (208-V) leg, requiring phase transposition on the load side of the service switchboard or panelboard. Part **(A)(2)** is new in the 2014 **NEC** and covers dc bus arrangements for the first time. They are permitted in any order, but must be field marked as to polarity, grounding system, and nominal voltage classification.

Part **(F)**, greatly expanded in the 2014 **NEC**, requires a warning label in accordance with 110.21(B) to be posted on any switchboard, switchgear, or panelboard if it is operating on any system that is not solidly grounded or that operates with unequal voltages to ground. There are five possibilities. The first covers all switchboards or panelboards containing a high-leg delta system, and they must have a warning label to that effect, and not just rely on the color code for the phase leg with the higher voltage to ground. The marking, which is to be applied in the field, must read: "Caution: ___ Phase Has ___ Volts to Ground." The second paragraph covers ungrounded ac systems and gives notice as to the phase-to-phase voltage.

The third through fifth paragraphs were new as of the 2014 **NEC**, beginning with a notice for high-impedance grounded neutral systems. This notice must provide the phase-to-phase voltage together with the advice that the system may operate a specified voltage to ground, usually the phase-to-phase voltage, and that this operation may continue for an indefinite period during a fault. The fifth paragraph provides for a parallel warning with respect to a resistively grounded dc system. The fourth paragraph covers ungrounded dc systems and requires the same type of label as required in (2) for ungrounded ac systems.

Part **(G)** refers to the need for specific clearances in top and side gutters in both panelboards and switchboards and makes it mandatory that wire bending space at terminals and gutter spaces must afford the room required in 312.6. This is a repeated requirement throughout the Code and is aimed at ensuring safe termination of conductors as well as adequate space in the side gutters of panelboards and switchboards for installing the line and load conductors in such equipment. This concern for adequate wire bending space and gutter space is particularly important because of the very large size cables and conductors so commonly used today in panelboards and switchboards. Sharp turns to provide connection to terminal lugs do present possible damage to the conductor and do create strain and twisting force on the terminals themselves. Both of those objections can be eliminated by providing adequate wiring space.

408.4. Field Identification Required.

(A) Circuit directory or circuit identification This section specifically requires full and

legible marking of a panelboard's *circuit directory* to show the loads supplied by each circuit originating in the panel. This is similar to the rule of 110.22(A), where the Code requires thorough identification of the loads fed by all circuit breakers and switches that serve a Code-required disconnecting means. Note that the wording also calls for “clear and legible marking” of circuit modifications. This requires that any load(s) added to or deleted from the panelboard in question must be shown in an updated circuit directory. A point commonly missed in the field is that this rule also applies to “circuit modifications.” This means that any downstream rearrangement, additions, or subtractions from circuit coverage must result in an update to the circuit directory, even if the work was done without ever opening the circuit protection in the panel.

The prevalence of modern word processing software (and even circuit directory software) makes compliance with these rules far simpler than in the past ([Fig. 408-8](#)). All circuit directories, for both switchboards (labels required at each switch) and panelboards, must meet the following requirements:

WXYZ APARTMENT PANEL

(installed September 2003)

(revised August, 2004)

FED FROM WXYZ METER MAIN AT SERVICE

- | | |
|---|---|
| 1. Peninsula counter receptacle, west | 16. Overhead lights, hall receptacle, bathroom fan |
| 2. Peninsula counter receptacle, east | 17. Refrigerator; dining alcove receptacles (except NE) |
| 3. East counter receps, left half of quad | 18. Spare |
| 4. East counter receps, right half of quad dining area, NE receptacle | 19. Spare |
| 5. Garbage disposer | 20. Spare |
| 6. Dishwasher | 21. _____ |
| 7. Livingroom receps, left half of quad; south outdoor receptacle | 22. _____ |
| 8. Livingroom receps, right half of quad; entry luminaires; north outdoor recept. | 23. _____ |
| 9. Bedroom receps, right half of quad, | 24. _____ |
| 10. Bedroom receps, left half of quad single duplex in south bedroom | 25. _____ |
| 11. & Range | 26. _____ |
| 12. | 27. _____ |
| 13. Bathroom receptacle | 28. _____ |
| 14. Microwave oven receptacle | 29. _____ |
| 15. Oil burner for heat, hot water | 30. _____ |

Fig. 408-8. The particular circuit that supplies every single outlet in the occupancy can be accurately identified using this circuit directory. There are no exceptions, and every description will remain valid after a change in tenancy. Because this panel is in a multifamily building, the feeder source is entered in the circuit directory header as well. (Sec. 408.4.)

- Every circuit must have a directory entry, which must be legible.
- Every directory entry must describe a “clear, evident, specific purpose or use.”
- Every directory entry must include a sufficient degree of detail to distinguish it from all others. This could include outlet faceplate markings correlated with unique directory entries, such as “receptacle outlets in Room A identified as “Ckt ###.”
- No directory entry can use a description that depends on transient conditions of occupancy. For example, terminology such as “Ed’s bedroom” or “Annie’s Hair Salon” must be rejected in favor of handing (left or right), or points of the compass, or the use of a map with room numbers, specific receptacle locations, etc.
- Spare overcurrent devices must be identified as such on the circuit directory.
- Circuit directories must be posted on the face or inside of the panel door (panelboards) and at each switch on a switchboard.

(B) Source of supply This part requires, for all but one- and two-family housing, that the source of supply for all nonservice panelboards and switchboards be labeled as to the device or equipment where the power originates. The wording “each device” was chosen to make it clear that a description of an electrical room or switchboard was insufficient because in the first case an electrical room is not a device, and in the second case a stated switchboard, while a device within the meaning of the Code, is not the device where the feeder conductors are connected; it merely houses the relevant device. The description must uniquely describe the actual source. The word “equipment” was added because some feeders originate at generators or other sources. The 2017 NEC added requirements for durability and that at least this part of the label not be handwritten. Note that this is a requirement in (B) and not the general directory requirements in (A).

408.5. Clearance for Conductors Entering Bus Enclosures. Figure 408-9 shows the rules of this section, which are aimed at eliminating high conduit stubups under equipment containing busbars to prevent contact or dangerous proximity between conduit stubups and the busbars. On this matter, UL says that “the acceptability of conduit stubs serving unit sections with respect to wiring space and spacing from live parts can be determined only by the local inspection authorities at the final installation.”

Fig. 408-9. Conduit stub-ups must have safe clearance from busbars. (Sec. 408.5.)

408.7. Unused Openings. The rule here requires that all unused openings in panelboards and switchboards—regardless of whether the opening is inside the cover or through the enclosure—must be closed to prevent persons from coming in contact with the enclosed energized components. The means utilized to satisfy this rule must be such that the enclosure opening is effectively returned to its original integrity. The general requirement is covered in 110.12(A); the rule here is aimed at missing circuit breaker openings in a deadfront.

408.16. Switchboards and Switchgear in Damp and Wet Locations. The rules in 312.2 apply to switchboards in these locations.

408.17. Location Relative to Easily Ignitable Material. A combustible floor under a switchboard must be protected against fire hazard, usually with sheet metal.

408.18. Clearances. Although it has long been a Code rule that a clearance of at least 3 ft be provided from the top of a switchboard to a “combustible” ceiling above, the opening phrase of part (A) excludes totally enclosed switchboards from this rule. The original rule requiring a 3-ft clearance was based on open-type switchboards and did not envision totally enclosed switchboards. The sheet-metal top of such switchboards provides sufficient protection against heat transfer to nonfireproof ceilings. As a result of this rule, now there is no minimum clearance required above totally enclosed switchboards.

As covered in part (B), accessibility and working space are very necessary to avoid possible shock hazards and to provide easy access for maintenance, repair, operation, and housekeeping—as required by 110.26. It is preferable to increase the minimum space behind a switchboard where space is available or attainable.

408.20. Location of Switchboards and Switchgear. This section addresses the

permitted environment for old-style open switchboards (Fig. 408-10).

Fig. 408-10. A switchboard with “*any*” exposed live parts is limited to use in “permanently dry” locations, accessible only to qualified persons. (Sec. 408.20.)

408.30. General. The first sentence here establishes the minimum acceptable rating of any panelboard.

All panelboards—lighting and power—are required by this section to have a rating (the ampere capacity of the busbars) not less than the **NEC** minimum feeder conductor capacity for the entire load served by the panel. That is, the panel busbars must have a nameplate ampere rating at least equal to the required ampere capacity of the conductors that feed the panel (Fig. 408-11). A panel may have a busbar current rating greater than the current rating of its feeder but must never have a current rating lower than that required for its feeder. [215.2(A) notes that a feeder for a continuous load must be rated at least 125 percent of the load current, which seems to mean that the panel busbars would have to be rated for 125 percent of the continuous load current.]

Fig. 408-11. Rating of panelboard bus must at least match required feeder ampacity and circuits must be identified. (Sec. 408.30.)

Although selection of a panelboard is based first on the number of circuits that it must serve, it must be ensured that the busbars in a panelboard for any application have at least the Code-minimum circuits.

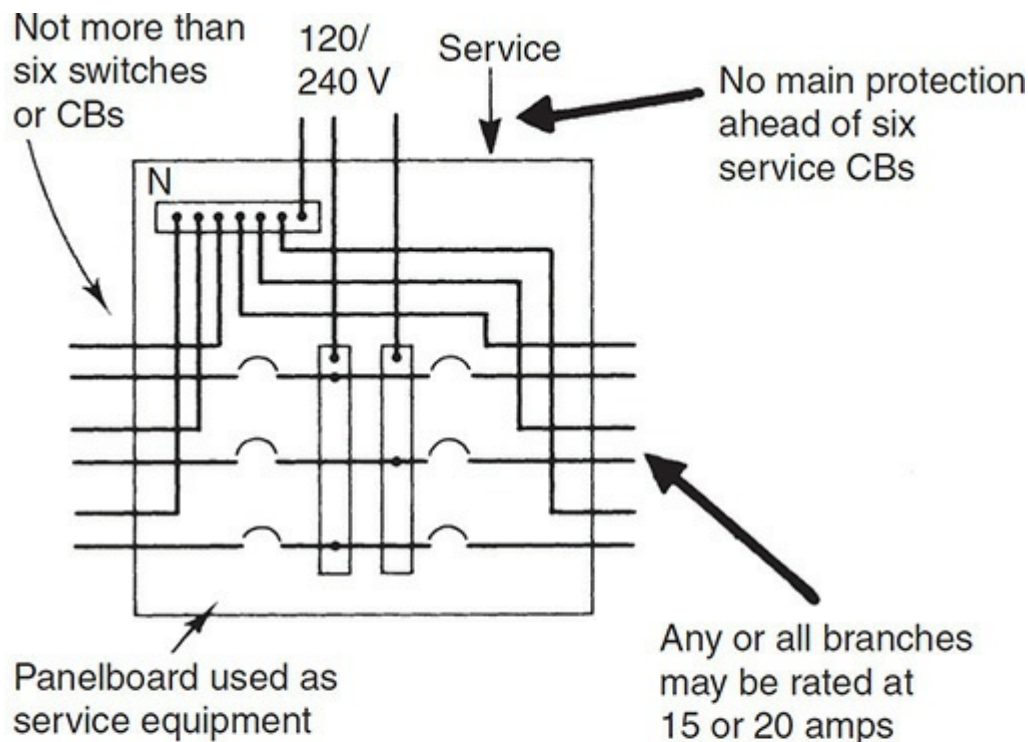

With respect to panelboards, marking may appear on the individual terminals, but terminals can often be changed in the field, and wiring space and the means of mounting the terminals may not be suitable. Therefore, panelboards should be marked independently of the marking on the terminals to identify the terminals and switch or CB units which may be used with aluminum wire. If all terminals are suitable for use with aluminum conductors as well as with copper conductors, the panelboard will be marked “use copper or aluminum wire.” A panelboard marked “use copper wire only” indicates that wiring space or other factors make the panelboard unsuitable for any aluminum conductors.

408.34. Classification of Panelboards (Deleted). For some 70 years, the **NEC** maintained special rules for a classification of panelboards described as *lighting and appliance branch-circuit panelboards*; however, effective with the 2008 **NEC**, this classification has been abolished. For example, these panelboards required individual protection in accordance with their busbar ratings, whereas power panels did not require individual protection; now all panelboards require individual protection, but the former **NEC** limit on the numbers of circuit positions (42) has been deleted. The distinctions were a response to a fire in a New York hotel in the 1930s involving large numbers of rubber-insulated wires in a panel, and no longer had technical validity with today’s

wire insulation and panel construction methods.

408.36. Overcurrent Protection. The trade-off for the elimination of rules setting a ceiling on the number of overcurrent devices permitted in a panel was changing the individual protection requirement that formerly only applied to lighting-and-appliance panelboards and some power panelboards so it now applied to all panelboards of any description. These panels are now in manufacture, including 56-circuit versions routinely shipped to Canada that never had this restriction, and there are many others, with even greater numbers of circuit positions. There are three exceptions to this general rule, as follows:

1. A panelboard with up to six circuit breakers may be installed without individual protection provided it is used as service equipment (see Fig. 408-12). In this case, with more than two main breakers installed in a new panelboard, the use of a second bus structure within the panelboard as shown in Fig. 408-14 is now expressly prohibited. This type of arrangement is common in many parts of the country, with an outdoor service panel breaking out major loads and an indoor subpanel supplying the various lighting, small appliance, and receptacle circuits. A panelboard with two main breakers is covered in the next topic.

This application prohibited for new installations if a second bus structure is supplied within the same enclosure. If a second bus structure exists, see Exception No. 2 for two-main-device applications, and see Exception No. 3 for existing dwelling unit service equipment.

Fig. 408-12. This application is permitted only where it comprises the service equipment. (Sec. 408.36, Exception No. 1.)

2. A panelboard with two main breakers, as shown in Fig. 408-13, is still permitted, provided it qualifies under the old 42-circuit limitation on numbers of circuits for lighting and appliance

branch-circuit panelboards. The combined main breaker ratings must not exceed the panel rating.

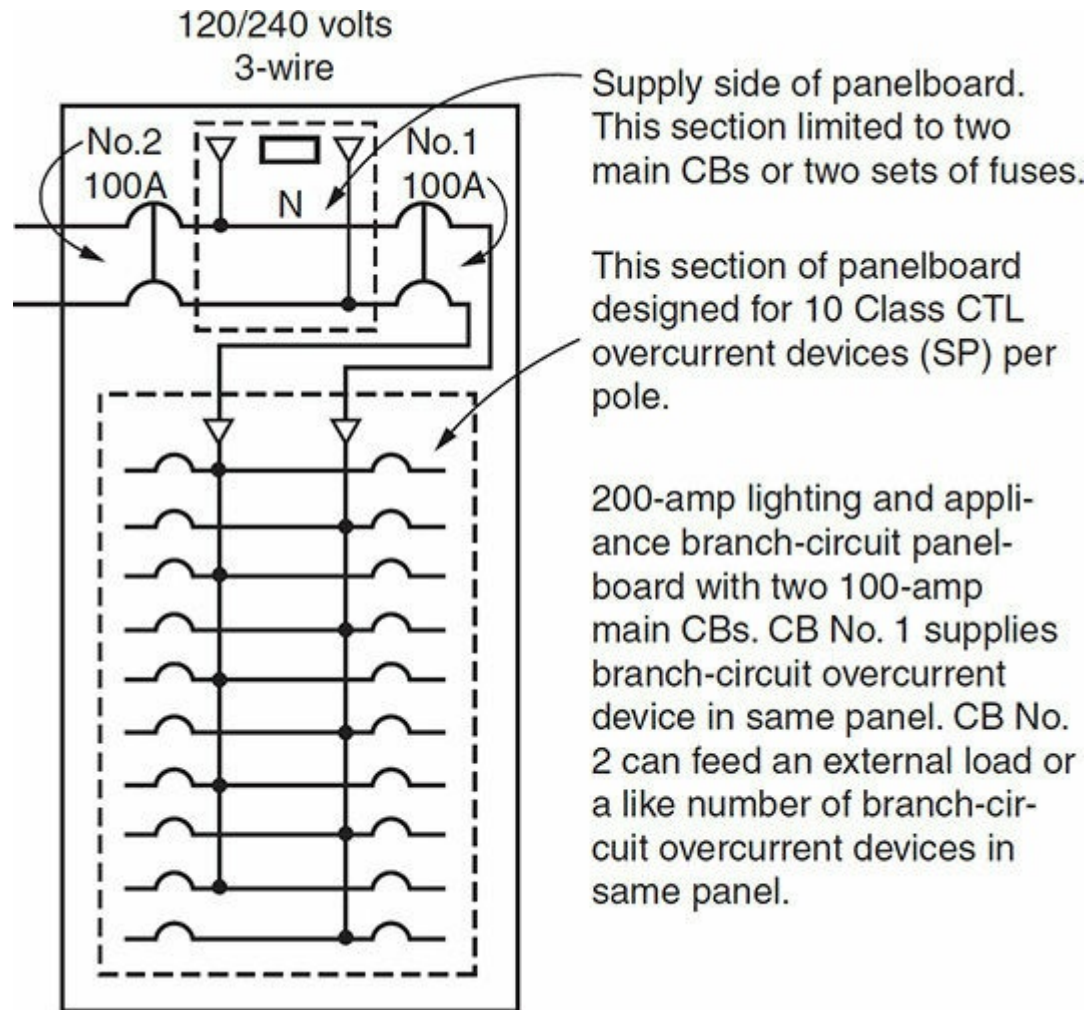

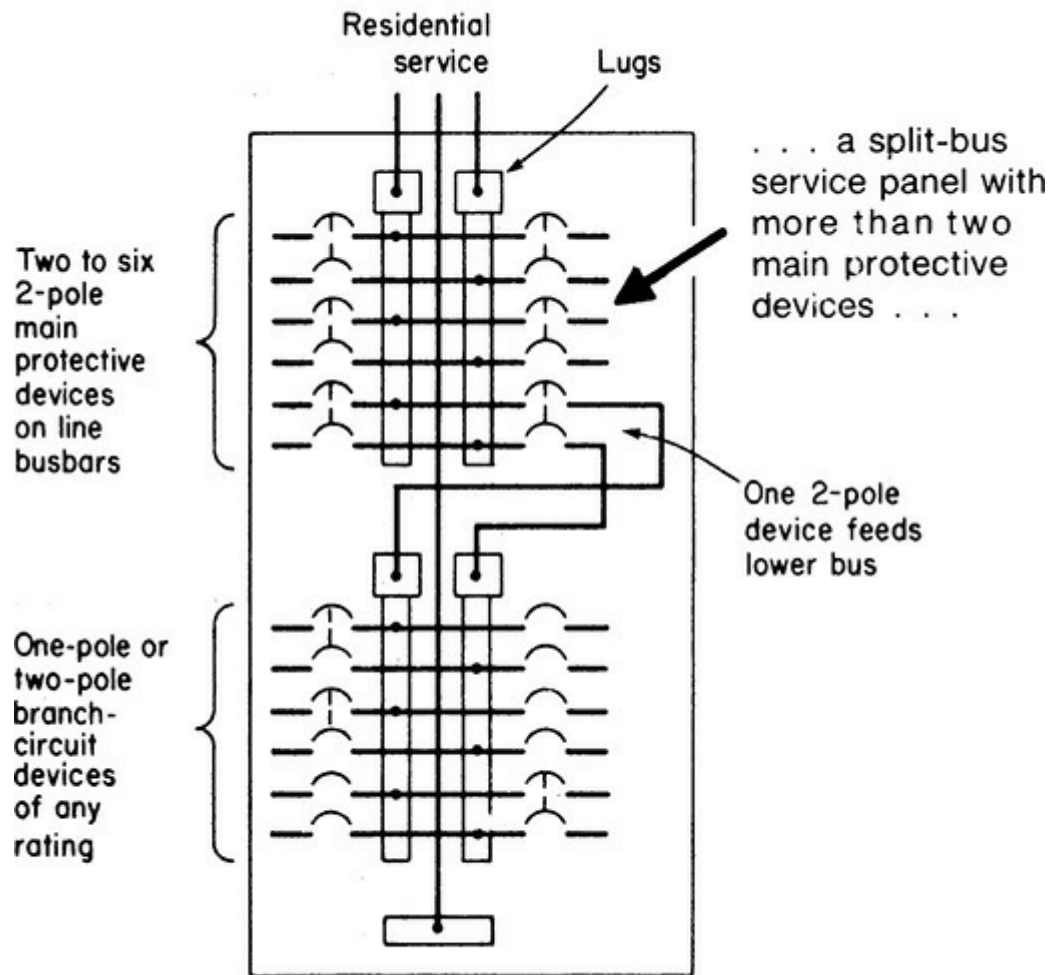

Fig. 408-13. This application is permitted, subject to the old 42-circuit limitation, which, on the literal text, includes the mains. Note that the second main circuit breaker, at the upper left, is permitted to feed a second bus structure within the common enclosure under this exception, and some designs do use this arrangement. (Sec. 408.36, Exception No. 2.)

3. An existing panelboard with up to six circuit breakers may continue to be used without individual protection, provided it is used as service equipment for an individual dwelling unit. [Figure 408-14](#) is an example of one of these old “split-bus” panels.

FOR NEW INSTALLATIONS . . .

. . . IS A VIOLATION!

Fig. 408-14. Use of a split-bus loadcenter with more than two main overcurrent devices is permitted for residential service equipment *only* in “existing installations.” (Sec. 408.36, Exception No. 3.)

The individual protection required for panelboards generally may be placed at any location, provided the buses have the required protection. [Figure 408-15](#) shows the possibilities.

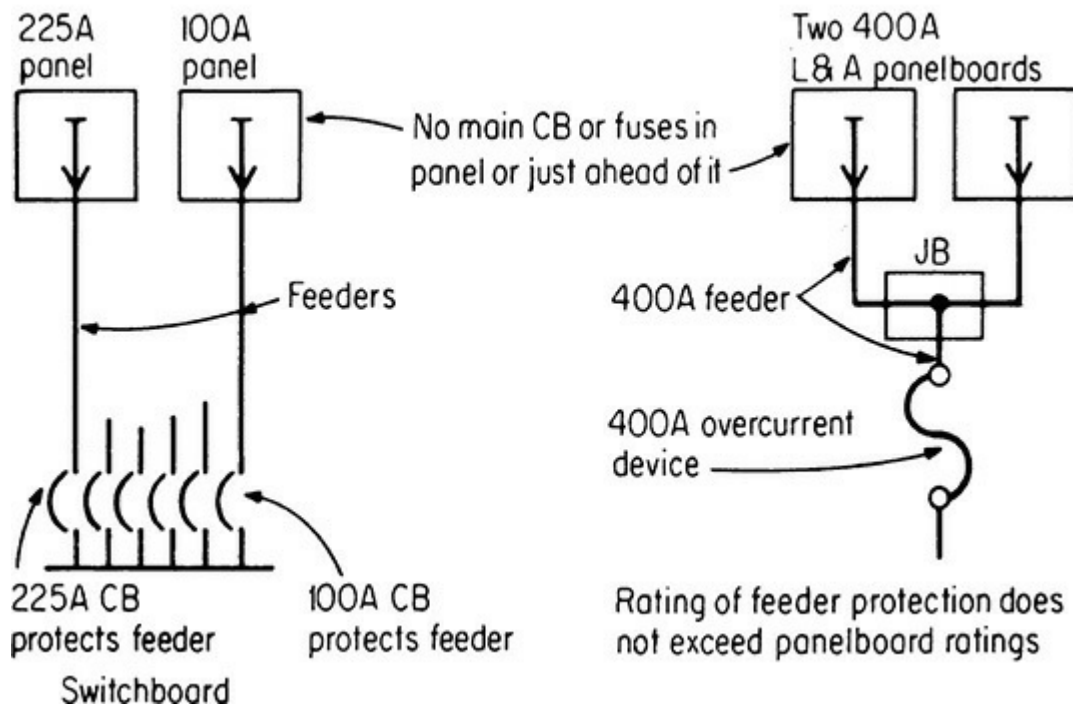

Fig. 408-15. Panel protection may be provided in a variety of ways. (Sec. 408.36.)

The rule of part (A) of this section is covered in [Fig. 408-16](#). Any panel, a lighting panel or a power panel, which contains snap switches (and CBs are not snap switches) rated 30 A or less, must have overcurrent protection and not in excess of 200 A.

Fig. 408-16. Any panelboard containing snap switches rated 30 A or less must have main or feeder protection rated not over 200 A. [Sec. 408.36(A).]

Part **(B)** of this section applies to a panelboard fed from a transformer. The rule requires that overcurrent protection for such a panel, as required in **(A)** and **(B)** of the same section, must be

located on the secondary side of the transformer. An exception is made for a panel fed by a 2-wire, single-phase transformer secondary and for “delta-delta” transformers. Such a panel may be protected by a primary-side OC device, as covered in 240.21(C)(1).

This concept of generally prohibiting use of panel protection located on the primary side of a transformer feeding the panel is consistent with the rules of 240.4, which cover conductor protection. Generally, the Code requires properly rated OC protection on the secondary side of the transformer for the secondary conductors because the primary-side device will not afford adequate protection. Similarly, the OC device on the primary side cannot adequately protect the panelboard on the secondary side. But where a delta-delta transformer is used, the per-unit current value on the secondary will be equal to or less than the per-unit current on the primary side. Therefore, with the delta-delta configured transformers, the secondary conductors and panelboard can be safely protected by the primary overcurrent protective device.

Part (C) is a rule prohibiting the installation of any 3-phase disconnect or 3-phase overcurrent device in a single-phase panelboard. It is now required that any 3-pole disconnect or 3-phase protective device supplied by the bus within a panelboard may be used only in a 3-phase panelboard. The effect of this rule is to outlaw the so-called delta breaker, which was a special 3-pole CB with terminal layouts designed to be used in a single-phase panel fed by a 3-phase, 4-wire, 120/240-V delta supply where the loads served by the panel were predominantly single-phase, but where a single 3-phase motor or 3-phase feeder was needed and could readily be supplied from this type of delta breaker. The delta CB plugged into the space of three single-pole breakers, with the high leg of delta feeding directly through one pole of the common-trip assembly. The unit was used to protect the motor branch circuit or feeder to a 3-phase panel, rated up to 100 A.

Use of delta breakers has been found hazardous. When a delta breaker is used in a single-phase panel and the main disconnect for the single-phase panel is opened, there is still the high hot leg supplying the delta breaker. These breakers were likely to backfeed voltage from their load connections into the panelboard buswork even when the panel main was off, because the main did not interrupt the third phase.

As noted in part (D), a plug-in circuit breaker that is connected for “backfeed” (with the plug-in stabs being the load side of the CB) must be mechanically secured in its installed position. This rule requires all plug-in-type protective devices (CB or fusible) and/or main lug assemblies, in panelboards, to have some mechanical means that secure them in position, requiring more than just a pull to remove the devices. This is intended to eliminate the hazard of exposed, energized plug-in stabs of a device that is readily dislodged from its plug-in or connected position (Fig. 408-17).

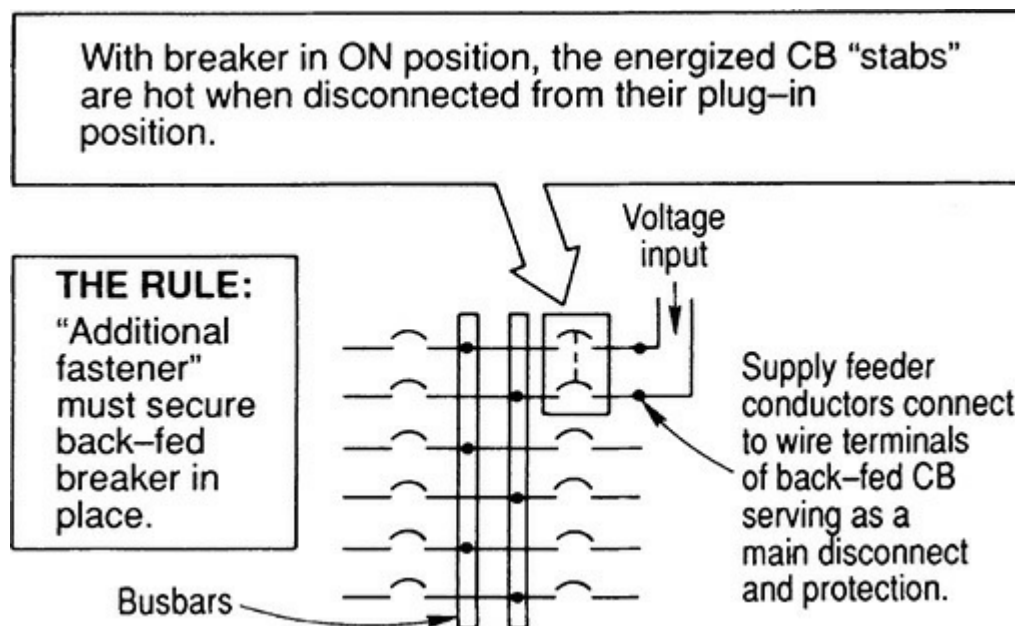

Fig. 408-17. This is an important safety rule for plug-in breakers. [Sec. 408.36(D).]

408.37. Panelboards in Damp or Wet Locations. UL data supplement the Code rules:

Enclosed panelboards marked "Raintight" will not permit entry of water when exposed to a beating rain. Enclosed panelboards marked "Rainproof" will not permit a beating rain to interfere with successful operation of the apparatus within the enclosure but may permit entry of water.

But note this carefully: In 408.37, the Code references 312.2. That rule requires that panelboard enclosures in "*damp or wet*" locations must be placed or equipped to "prevent moisture or water from *entering and accumulating* within" the enclosure, and there must be at least a 6-mm ($\frac{1}{4}$ -in.) air space between the enclosure and the wall or surface on which a metallic enclosure (or nonmetallic enclosure on an absorbent surface) is mounted. When they are installed exposed outdoors or in other wet locations, the **NEC** requires that panelboard enclosures must be weatherproof. The **NEC** definition of *weatherproof* is similar to the **NEC** and UL definitions of *rainproof*. Yet, **NEC** 312.2 requires exclusion of water entry—which clearly demands a "raintight" enclosure for outdoor, exposed panelboards (and not "rainproof"). These same considerations apply to other cabinets or enclosures used outdoors.

408.38. Enclosure. Because a panelboard (refer to Art. 100 definitions) is technically the busbar assembly and not the cabinet or cutout box in which the busbar assembly is customarily mounted, the UL Guide Card information on this category allows for field installation of panelboard bus assemblies in enclosures. This information goes on to explain that if that is how the panel was shipped, UL cannot assess gutter space within the enclosure. Therefore it would be judged by the electrical inspector in the field according to its compliance with Part IV of Art. 408 and other applicable requirements. Panelboards shipped in the usual way with enclosures bear the marking "Enclosed Panelboards."

408.39. Relative Arrangement of Switches and Fuses. For service equipment, switches are permitted on either the supply side or the load side of the fuses. In all other cases, if the panelboards are accessible to other than qualified persons, 240.40 requires that the switches shall be on the supply side so that when replacing fuses, all danger of shock or short circuit can be eliminated by opening the switch.

408.40. Grounding of Panelboards. The effect of this rule is to *require* a panelboard to be equipped with a terminal bar for connecting all equipment grounding conductors run with the circuits connected in the panel. Such a bar must be one made by the manufacturer of the panel and must be installed in the panel in the position and in the manner specified by the panel manufacturer—to ensure its compliance with UL rules, as well as the **NEC**. The terminal bar for connecting equipment grounding conductors may be an inherent part of a panelboard, or terminal bar kits may be obtained for simple installation in any panelboard. Homemade or improvised grounding terminal bars are contrary to the intent of this Code section.

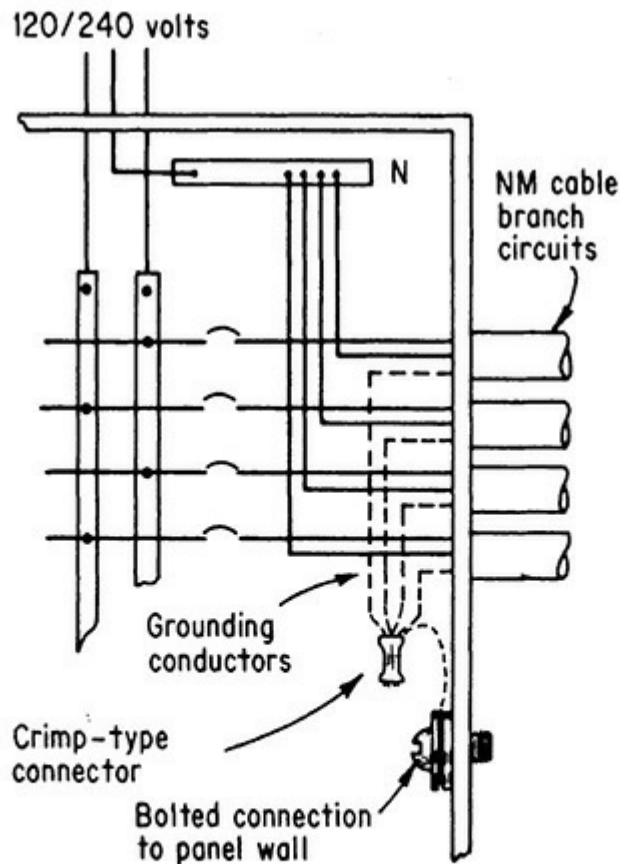

The terminal bar that is provided for connection of equipment grounding conductors must be bonded to the cabinet *and* frame of a metal panelboard enclosure. If such a panel enclosure is nonmetallic, the equipment grounding terminal bar must be connected to the equipment grounding conductor of the feeder supplying the panel.

Equipment grounding conductors must not be connected to terminals of a neutral bar—unless the neutral bar is identified for that purpose and is in a panel where Art. 250 requires or permits bonding and grounding of the system neutral (or grounded) conductor. These applications include a service panel or a panel fed from another building as part of an existing premises wiring system (250.24 or 250.32), or a panel fed from a separately derived system where the system disconnect is at the panel, and the bonding connection to the grounded circuit conductor is done at the system disconnect and not at the system source (250.30).

Figure 408-18 shows some details of grounding at panelboards. There have been many field problems relative to terminating grounding conductors in panelboards where nonmetallic wiring methods have been involved. The rule here requires an “equipment grounding terminal bar” in such panels so that these grounding conductors can be properly terminated and bonded to the panel.

AN "APPROVED" GROUNDING BAR MUST BE USED

VIOLATION ! Homemade techniques are not acceptable.

Fig. 408-18. Grounding in panelboards must use "identified" components. (Sec. 408.40.)

In other than service equipment, the grounding conductor terminal bar must not be connected to the neutral bar (i.e., the neutral bar must not be bonded to the panel enclosure). Refer to 250.32, 250.30, 250.24, and 250.142. In a service panel, with the neutral bonded to the enclosure, equipment grounding conductors may, as previously noted, be connected to the bonded neutral terminal bar (or

block). Note that manufacturers are only obliged to supply enough neutral and equipment grounding terminals to supply the minimum number of connections for an installation to meet some of the **NEC** wiring methods. Beyond that, the number of terminals supplied reflects the manufacturer's marketing goals. In other words, because a panel could be used to supply a house wired with EMT (and they do exist) which would require zero equipment grounding connections for separate wires, manufacturers are free to supply (but probably would not supply) a neutral bus that only supports white wire terminations. The field electrician must verify that the connections are sufficient and order a separate equipment grounding terminal bar of sufficient size if they are not. See also the discussion at 408.41 for more information on this topic.

The exception to this section allows an isolated ground conductor run with the circuit conductors to pass through the panelboard without being connected to the panelboard grounding terminal bar, in order to provide for the reduction of electrical noise (electromagnetic interference) on the grounding circuit as provided in 250.146(D).

In order to maintain the isolation of the grounding wire necessary for a low-noise ground, the grounding wire must be connected directly to the grounding terminal bar in the service-entrance equipment if the service equipment is within the same building. To do this it may be necessary for the grounding wires to pass through one or more panelboards, but the grounding conductor *must not* leave the building in which the isolated ground is installed. Of course, such isolated grounding conductors may be spliced together by use of a terminal block installed in the panel but insulated from conductive contact with the metal enclosure of the panel. A “quiet ground” keeps grounding conductors apart from and independent of the metal raceways and enclosures (Fig. 408-19).

Fig. 408-19. “Quiet ground” terminal block for equipment grounding conductors provides for carrying isolated grounding conductors from circuits back to service bonded neutral, with single grounding conductor connecting terminal bar back to service. Terminal block is insulated from metal panel enclosure. Check with manufacturer to assure that isolated bar is approved. (Sec. 408.40.)

408.41. Grounded Conductor Terminations. Although in a service panelboard grounded conductors (white or gray) and equipment grounding conductors (green or bare) often arrive on the same terminal bar and with identical terminating provisions, actual permitted field practice considers

them quite differently because only the grounded conductors are routinely current-carrying. The terminations for these conductors must not be opened inadvertently through service on another circuit. In addition, a terminal for a current-carrying conductor undergoes a heat-cycling test that is difficult to pass when multiple conductors are connected at the same point. For these reasons, all panelboard labels issued over the last 40 years or more have limited these current-carrying connections (but usually not small equipment grounding conductor connections) to one wire per termination. Many people never read those instructions, and so, just as 110.14(C) put termination temperature limitations that existed for decades into the **NEC** where they will be seen and enforced, 408.41 has taken similar requirements and brought them into the **NEC** where they will be seen and enforced. The exception refers to large, specially-shaped terminating openings for parallel conductors (therefore, 1/0 AWG and larger) that are specifically evaluated for such applications.

This limitation does not apply to equipment grounding terminations, because they are not current-carrying. This means, for applications where grounded and grounding conductors are permitted to be connected, that the same busbar might have one terminal with one white 14 AWG wire (and never more), and next to it an identical terminal with one, two, or three (depending on the instructions that come with the equipment; two is usual and three is common for small conductors) bare 14 AWG wires from NM cable. This is not a mistake, and the directions serve a purpose. If, after all the grounded conductor positions are used up (commonly the case) an additional equipment grounding terminal bar is necessary to comply with these rules; make sure that only equipment grounding conductors are terminated on it, even if it is in a service enclosure. Terminating a grounded conductor on a separate grounding bar forces its current to use the enclosure as a current-carrying conductor between the terminal bar and the service or system neutral. This is exactly what 200.2(B) is designed to prevent.

408.54. Maximum Number of Overcurrent Devices. Although manufacturers are now free to design panels with as many number of overcurrent device positions as they think appropriate, no manufacturer is to be responsible for field installations of more overcurrent devices than the panel was designed to hold. [Figure 408-20](#) illustrates a panelboard with a 200-A main that provides for the insertion of class CTL overcurrent devices. The top stab receivers are of an F-slot configuration. Each F slot will receive only one breaker pole. The remainder of the slots are of an E configuration, which will receive two breaker poles per slot. Thus there is provision for installing not more than 42 overcurrent devices, which does not include the main CB in this case. If tandem breakers were put in slots intended for only full-size breakers, the manufacturer's design limitations would be defeated by an untested and very likely unsafe circuit fill. This is the reason for the physical rejection rule.

Fig. 408-20. Slots for push-in CB units have different configurations to limit the total number of poles to no more than 42. This is a CTL panelboard (or loadcenter). (Sec. 408.54.)

Class CTL is the Underwriters Laboratories, Inc., designation for the Code requirement for circuit limitation within a lighting and appliance branch-circuit panelboard. It means “circuit-limiting.” The circuit-limiting (Class CTL) requirement first entered the **NEC** in its 1965 edition. In order to provide replacements for breakers already in use in panels that were installed previous to this time, UL continues to list the old designs, but they must be prominently marked to indicate that they are not CTL rated and are for replacement purposes only in non-CTL assemblies. [Figure 408-21](#) shows two tandem breakers (two breakers designed to fit in one normal circuit position) from the same manufacturer. One is CTL-rated for current panels, and has a rejection feature that only allows its use where the manufacturer intends it to be applied. The other has no rejection feature, being thereby capable of occupying any position or any number of positions within a panel, easily defeating the intent of the limitation. They should never be used except on very old panels and only to the extent absolutely necessary.

Fig. 408-21. A 20-A Class CTL tandem (left) and a non-Class CTL tandem (right) circuit breaker shown for comparison. The CTL breaker set has a restricted-height bus connection slot (compare the dimension markings) that will only mount where a bus stab has been slotted by the panelboard manufacturer. (Sec. 408.54.)

408.55. Wire Bending Space Within an Enclosure Containing a Panelboard. This section of the Code correlates wire bending space at terminals in panelboards to the basic concepts of 312.6, as follows:

The basic rule requires the wire bending space at the top *and* bottom of a panel to satisfy the distances called for in Table 312.6(B), regardless of position of conduit entries. Exceptions are:

1. For a “42-circuit (maximum) panelboard rated 225 A or less,” *either* the top *or* the bottom bending space may conform to Table 312.6(A)—but the other space at top or bottom (whichever is the terminal-lug space) must comply with Table 312.6(B).
2. For any panelboard, *either* the top *or* bottom bending space may conform to Table 312.6(A), provided that at least one of the side wiring terminal spaces satisfies Table 312.6(B), based on the largest conductor terminated in that space.
3. Depth of the wire bending space at the top and bottom of a panel enclosure may be as given in Table 312.6(A) rather than Table 312.6(B)—which is a deeper space requirement; but this may be done only where the panel is designed and constructed for a 90° bend (an L bend) of the conductors in the panel space and the panelboard wiring diagram is marked to show and describe the acceptable conditions of hookup.
4. Either the top or bottom space (but not both) can meet the more forgiving Table 312.6(A) where no conductors are terminated, in that space.

Figure 408-22 shows the basic rule and Exceptions No. 1 and No. 2. Of course, the rules of 312.6(B) must be fully satisfied in the choice of location for the wire bending space. And the size of the largest conductor determines the minimum required space for all applications of the tables. Note

that the title of this section reflects the fact that panelboards are actually contained within cabinets (refer to the Art. 100 definition) and therefore the wire bending space technically applies to the cabinet and not the panelboard.

N = NARROW SPACE, TABLE 312.6(A)
W = WIDE SPACE, TABLE 312.6(B)

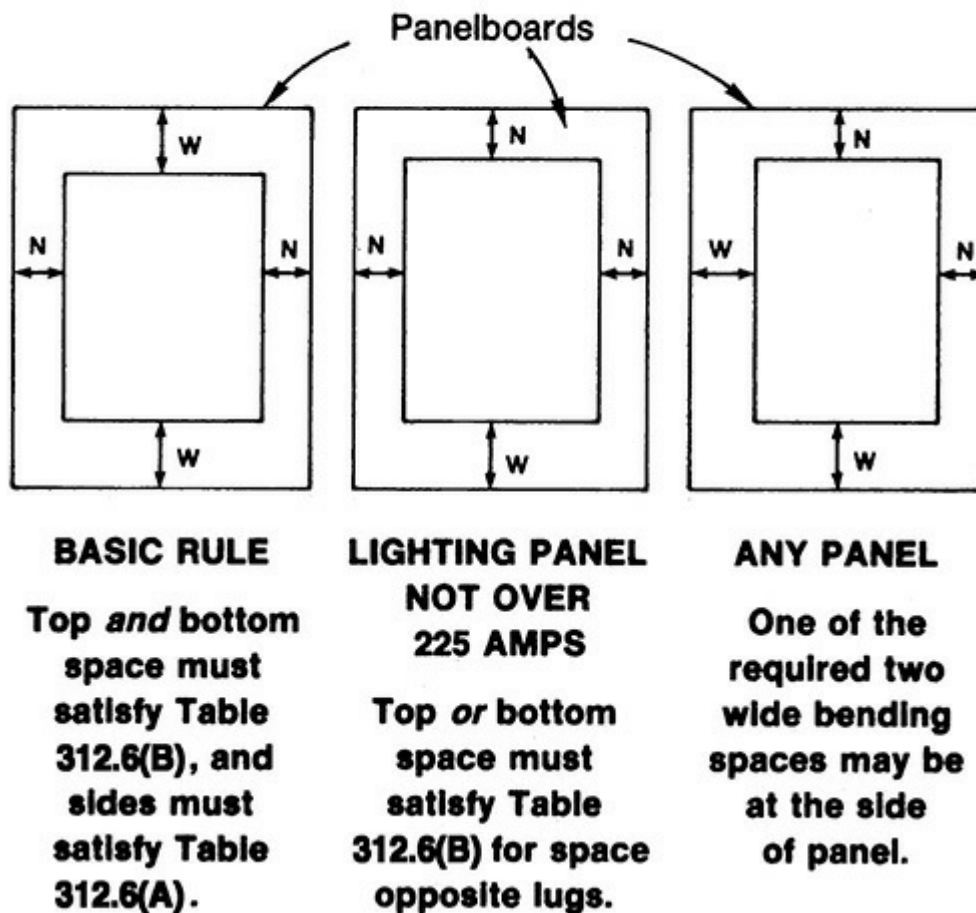

Fig. 408-22. This summarizes the requirements on wire-bending space at terminals where the feeder conductors supply a panelboard. (Sec. 408.55.) The reference to a “lighting” panel is one limited to 42 overcurrent devices.

The 2014 **NEC** has divided the rules for bending spaces in panelboards by location. The principal focus was and remains the top and bottom spaces as just covered, which are now (A). The single-side wire-bending space is now (B) and allows these gutters to have a width corresponding to the smaller dimensions of Table 312.6(A) based on the largest conductor terminated therein.

Part (C), new as of the 2014 **NEC**, is illustrated in [Fig. 408-23](#). It covers the allowable entry points at the back of a panelboard enclosure, and two dimensions need to be considered. First, the rear entry is not permitted if the depth of the panel from the back wall to the removable cover fails to meet the minimum bend radius in Table 312.6(A) for one wire per terminal. This is the same rule as the one covering comparable work in 314.28(A)(2) Exception. Second, the distance between the center of the knockout and the nearest termination point of the entering conductors must comply with that given in Table 312.6(B). Note that in this case the words “one wire per terminal” are absent; if the raceway entry is comprised of a parallel makeup, then the single-wire column in Table 312.6(B) will not apply.

Fig. 408-23. The **NEC** now addresses the permitted location of rear entries in panelboard cabinets [408.55(C)]. The drawing uses dimensions for copper wire; the 312.6(B) spacing for 4/0 aluminum would be 5½ in., and the 312.6(A) spacing would be 3½ in.

ARTICLE 409. INDUSTRIAL CONTROL PANELS

409.1. Scope. This new article covers industrial control panels, and these rules significantly impact how these panels are assembled, and by whom. Refer to the definition in Art. 100. Most of the article provisions duplicate other **NEC** rules and are covered elsewhere, primarily in Art. 430. The coverage here focuses on provisions that are unique. The terminology is consistent with that used by testing labs, such as UL, and covered by NEMA/UL Standards 508 and 508A.

409.20. Conductor—Minimum Size and Ampacity. The wording here mimics the wording of other Code rules that govern the minimum size and ampacity for feeder conductors

supplying heating and motor loads—either alone, in combination with each other, or in combination with other loads.

409.21. Overcurrent Protection. Part B gives location requirements that are the same as those for panelboards and switchboards; note that they apply to each incoming supply circuit and therefore encompass control panels with multiple supply circuits.

409.22. Short-Circuit Current Rating. Although this was certainly implied, no rule prior to the 2011 **NEC** specifically prohibited applying an industrial control panel in an environment for which it could not handle the available fault current. This, after all, was the reason 409.110(4) required the current rating to be calculated and marked. The 2017 **NEC** initiated a documentation requirement on the calculation as well.

409.110. Marking. The marking requirements will affect anyone who installs or significantly modifies these components in the field. The short-circuit current rating developed as part of this process will govern whether the industrial control panel is allowed to be installed based on the fault current that is available at its line terminals. Specifically, the label must include the following information:

1. The name of the manufacturer, or a trademark, or other descriptive marking by which the organization responsible for the product can be identified.
2. The supply voltage, number of phases, frequency, and full-load current for each incoming supply circuit.
3. If there is more than one power source and more than one disconnecting means required to fully disconnect the power, the control panel must be marked accordingly. The 2017 **NEC** clarified the requirement as pertaining to circuits of 50 volts or more, and also required that the location of these disconnects be “documented and available” so they could be operated quickly, even by someone unfamiliar with the equipment.
4. The short-circuit current rating of the panel based on one of the following:
 - a. Short-circuit current rating of a listed and labeled assembly.
 - b. Short-circuit current rating established utilizing an approved method. (An explanatory note follows, calling out *UL 508A, Suppl. SB* as an example of an approved method.)

Note: A “short-circuit current rating” is a defined term in Art. 100. It is “*the prospective symmetrical fault current at a nominal voltage to which an apparatus or system is able to be connected without sustaining damage exceeding defined acceptance criteria.*” This is a newer term for the older withstand values, and reflects an ability to continue to function after the fault.

Exception: The short-circuit current rating marking *is not required* on an industrial control panel that contains only control circuit components and no power circuit components. This exception exists for the simple reason that *short-circuit current ratings are not assigned to components that are not in the power circuit*, and therefore if a panel is assembled with no power circuits entering, there would be no basis for determining such a rating. Such control panel would still be an industrial control panel, and must otherwise meet all the marking requirements, but the short-circuit current rating would not be included in those markings.

5. If the panel will be used as service equipment, it must be evaluated and marked accordingly.

6. The panel must include an electrical wiring diagram or the identification number of a separate such diagram or a designation referenced in a separate wiring diagram.
7. The enclosure type number (Table 110.20) must be marked on the enclosure.

Most of these requirements are easily met, but the short-circuit current rating provisions are not. The wording here mimics the wording of other Code rules that govern the minimum size and ampacity for feeder conductors supplying heating and motor loads—either alone, in combination with each other, or in combination with other loads. If you are making these in the field, and industrial control electricians have been doing this every day, you will need to get a copy of *UL 508A, Suppl. SB* along with the control manufacturer’s literature in order to meet these requirements. This now crucial publication for this work exempts some components such as voltmeters and reactors from short-circuit ratings, and describes how to apply established ratings for other components. The object is to assure that the components are not subjected to fault currents that will result in catastrophic failures. There are several pages of flow sheets that must be carefully followed in order to correctly arrive at a short-circuit current rating for one of these panels. Our sister book, the *American Electricians’ Handbook*, contains copies of the three principal flowcharts, rearranged and reformatted to fit in this size book, but unchanged in terms of technical content.

ARTICLE 410. LUMINAIRES, LAMP HOLDERS, AND LAMPS

410.2. Definitions. This section includes definitions of “closet space” (applied in 410.16) and “lighting track” (applied in Part XV). These definitions are not new, but they were relocated because the **NEC** is moving toward standardized locations for certain material. Because it is more clear to discuss these terms in context, they will not be further discussed here. Note that the parenthetical expressions “(fixture)” or “(fixtures)” or “(lighting fixture)” have been dropped in this edition of the **NEC**, leaving “luminaire” as the correct terminology.

410.6. Listing Required. All luminaires must now be listed. This may turn out to be a major impediment to many historical reproductions of period lighting by small firms unable to afford the listing process, but it may assist overall quality. Time will tell whether this is a workable restriction, or overkill. The 2014 **NEC** has added retrofit kits to the listing requirement. Because these may involve extensive rearrangements of internal components, the directions that come with the listing must be followed and enforced.

410.8. Inspection. This was relocated from a subsection in the support section (now Sec. 36) because it applies to all luminaires, and therefore belongs to the general part of the article. The connections between the branch-circuit wiring and the luminaire supply conductors must be open for inspection without “requiring the disconnection of any part of the wiring” unless the luminaire is cord-and-plug-connected.

410.10. Luminaires in Specific Locations. Part (A) covers the kind of installations shown in [Fig. 410-1](#). At left, the luminaire on the covered vehicle-loading dock is in a damp location and must be marked “SUITABLE FOR DAMP LOCATIONS” or “SUITABLE FOR WET LOCATIONS.” At right, the luminaires at a vehicle-washing area are in a wet location and must be marked “SUITABLE FOR WET LOCATIONS”—unless the luminaires are so high mounted or otherwise protected so that there is no chance of water being sprayed on them.

Fig. 410-1. Luminaires must be marked as suitable for their place of application. (Sec. 410.10.)

An enclosed and gasketed luminaire would fulfill the requirement that water shall be prevented from entering the luminaire, although under some conditions water vapor might enter and a small amount of water might accumulate in the bottom of the globe.

Luminaires in the form of post lanterns, luminaires for use on service-station islands, and luminaires that are marked to indicate that they are intended for outdoor use have been investigated for outdoor installation.

An example of luminaires in “damp” locations would be those installed under canopies of stores in shopping centers, where they would be protected against exposure to rain but would be subject to outside temperature variation and corresponding high humidity and condensation. Thus, the internal parts of the luminaire need to be of nonhygroscopic materials, which will not absorb moisture and which will function under conditions of high humidity.

Part (C) recognizes use of luminaires in commercial and industrial ducts and hoods for removing smoke or grease-laden vapors from ranges and other cooking devices. The rule spells out the conditions for using luminaires and their associated wiring in all types of nonresidential cooking hoods. The requirement that such a luminaire be “identified for use” may be taken as listed by UL for such use, in view of 410.6. In fact, this is probably a misuse of the term “identified” and probably the intent is to require a marking on the product by its manufacturer, indicating suitability for this use. Note that in addition to the requirement for special luminaires, the wiring method must not be exposed within the hood. Hoods wired properly have flush openings the size of outlet boxes so the boxes and the raceways with the high-temperature branch-circuit conductors are completely out of the air stream within the hood, and only the special luminaires remain exposed in the hood. See also the discussion at 402.11 on this point.

Part (D) covers the use of chandeliers, swag lamps, and pendants over bathtubs, which could pose a potential hazard. Although there is no Code prohibition on use of luminaires over tubs and although a bathroom generally is not technically a damp or wet location, there is considerable concern over exposing persons in water to possible contact with energized parts. Where installed over a tub, a hanging luminaire or pendant must be at least 8 ft (2.5 m) above “the top of the tub.” In addition, hanging luminaires must be excluded from a zone 3 ft (900 mm) horizontally and 8 ft (2.5 m) vertically from the top of a bathtub rim. This defines the volume of space from which a chandelier-

type luminaire is excluded above and around a bathtub. This excludes the entire luminaire and its cord or chain suspension. Such application is difficult, if not impossible, in most interiors.

Part (E). Metal halide or mercury vapor luminaires subject to damage and used in sports venues or mixed-use facilities, whether over the court or over spectator seating area, must be designed to protect the lamp with a glass or plastic lens. Additional protection in terms of a wire or other guard is also permitted. This rule protects spectators and players from shards of broken glass and direct UV exposure that is radiated from the inner arc containment when the outer bulb is broken if the lamp continues to operate.

Part (E) is new as of the 2014 **NEC** and requires luminaires mounted under roof decking to be spaced at least 1½ in. below the low point on the decking to the top of the luminaire. This rule, which mirrors the one in 300.4(E), will help prevent damage from the widespread indiscriminate usage of long decking screws during reroofing operations.

410.11. Luminaires Near Combustible Material. This section provides the basis for an inspector to review a luminaire placement in cases where adjacent combustibles might become overheated. Note that this section does not literally apply to a lampholder. For that reason, the 2011 **NEC** inserted a new section (410.97) covering lampholders and imposing this requirement. The burn radius of a 60-W incandescent lamp is about 100 mm (4 in.).

410.12. Luminaires Over Combustible Material. This refers to pendants and fixed lighting equipment, not to portable lamps. Where the lamp cannot be located out of reach, the requirement can be met by equipping the lamp with a guard.

410.16. Luminaires in Clothes Closets. The intent is to prevent lamps from coming in contact with cartons or boxes stored on shelves and clothing hung in the closet, which would, of course, constitute a fire hazard. Use of luminaires in clothes closets is covered by this section, with specific rules based on the definition of “storage space” in a closet as given in 410.2 and the associated isometric drawing that illustrates the locations and dimensions of regulated space within the closet. [Figure 410-2](#) shows the default storage space dimensions in one dimension. There are some aspects to the definition that are not widely appreciated and require emphasis:

Fig. 410-2. These clearances apply to luminaires in closets. (Sec. 410.16.)

1. The lower storage space (600 mm [2 ft] deep) does not simply run from right to left along the back closet wall, even if that is the only location of a closet pole. This space also covers both side walls of the closet, extending all the way to the front. It also covers from the floor to the height of the highest closet pole if one exists and to a height of 1.8 m (6 ft) if there is no pole.
2. The upper storage space (300 mm [2 ft] deep) sits above all applicable lower storage spaces, running from the rear and side walls out 300 mm (1 ft), and all the way up to the ceiling

however high that may be. It begins 1.8 m (6 ft) up from the floor whether or not a shelf is provided. If shelving is provided and is deeper than 300 mm (1 ft), then the upper storage space deepens to the same extent.

3. If the closet has doors on both sides so there is no rear wall, the lower space is 300 mm (1 ft) on both sides (i.e., front and back) of the closet pole, with all other dimensions being the same.

This section presents rules that can be divided into two categories as follows:

1. Parts (A) and (B) describe the kind of luminaires that may be used and the kinds that are prohibited from use in closets. Incandescent or LED luminaires with lamps that are not completely enclosed, or any pendant luminaire or lampholder, are excluded regardless of the size of the closet and the position of the light source. Although not quite properly worded, it appears the same is intended to apply to an incandescent lampholder that is not part of a pendant, and such lampholders do not appear in the list of permitted locations in (C) following. On the other hand, both surface-mounted and recessed incandescent luminaires with completely enclosed lamps are permitted, along with fluorescent luminaires, either recessed or surface mounted, and whether or not the lamps are exposed. In addition, there is a new allowance for fluorescent and for LED luminaires to be accepted even within a storage area, but only if so “identified” (probably intended to mean “marked” because all luminaires must now be listed and any listed luminaire for some purpose automatically meets the definition of “identified” in Art. 100).
2. Part (C) defines four permitted locations for luminaires that depend on spacing from the storage area and on the type of luminaire. A fifth location, new in 2008, is in the storage area and will be discussed last. Because the defined storage areas extend to the closet ceiling on both side walls and the rear wall, the only possible locations left for luminaire positions are over the door (or just to either side if spacing to the side wall is available) or on the ceiling. The possibilities, expressed as clearances between the outer margins of the luminaires and the storage areas, are as follows:
 - a. For surface-mounted incandescent (or LED) luminaires with a completely enclosed light source, 300 mm (12 in.)
 - b. For surface-mounted fluorescent luminaires, 150 mm (6 in.)
 - c. For recessed incandescent (or LED) luminaires with a completely enclosed light source, 150 mm (6 in.)
 - d. For recessed fluorescent luminaires, 150 mm (6 in.)

The last possibility is the LED or fluorescent luminaire specifically rated to actually be installed within a storage space; if such a luminaire is developed, this language provides the authorization for testing laboratories to proceed with a listing.

For small clothes closets, proper lighting may be achieved by locating luminaires on the outside ceiling in front of the closet door—especially in hallways where such luminaires can serve a dual function. Flush recessed luminaires with a solid lens are considered outside of the closet (but still subject to the spacing rules) because the lamp is recessed behind the wall or ceiling line.

410.18. Space for Cove Lighting. Adequate space also improves ventilation, which is equally important for such equipment. This rule has been pushed beyond all reason by some installations. There are well-documented reports of fluorescent luminaires in cove lighting applications for which special tools and mirrors are required to service the ballasts, clearly amounting to a violation of this rule.

410.21. Temperature Limit of Conductors in Outlet Boxes. Luminaires equipped with incandescent lamps may cause the temperature in the outlet boxes to become excessively high. The remedy is to use luminaires of improved design, or in some special cases to use circuit conductors having insulation that will withstand the high temperature.

The first sentence of this rule is related to the rule of 410.11. Figure 410-3 shows how a luminaire may be “installed so” that the branch-circuit wires are not subjected to excessive temperature. That hookup relates to 410.117(C) for recessed luminaires, which requires a 1½- to 6-ft length of flex with high-temperature wire (say, Type FEP) to connect the hot luminaire junction point (150°C) to the lower-rated branch-circuit wires. These hookups are almost obsolete. Refer to the discussion at 410.117(C). However, the rule is very much alive in other ways. Refer to the discussion at 402.11 and 410.10(C) for one good example of this rule at work. Another frequent issue is the relative rarity today of luminaires that are not marked for 90°C supply connections. This is a real problem on rehab work where the NM cable was installed before the product standard revision in the 1980s and all the branch-circuit wiring is only rated 60°C. Any luminaire with a required supply conductor temperature rating above 60°C must be marked with the required temperature rating, in accordance with 410.74(A).

Fig. 410-3. Flex “whip” may be used to keep 60°C or 75°C wire away from 150°C terminal space in luminaires. (Sec. 410.21.)

The second paragraph of this section applies to *prewired* recessed incandescent luminaires, which have been designed to permit 60°C (or 75°C, depending on the marking) supply conductors to be run into an outlet box attached to the luminaire. Such luminaires have been listed by UL on the basis of the heat contribution by the supply conductors at *not more than* the *maximum* permitted lamp load of the luminaire. Some luminaires have been investigated and listed by UL for *feed-through* circuit wiring. This does not mean what it may appear to mean, and a recent **NEC** change clarified how the luminaire industry, and this Code rule, use the terminology “through-wiring.” It is frankly counterintuitive. “Through wiring” suitability is *not required* to daisy chain multiple luminaires together on the same branch circuit, or even on the same multiwire branch circuit. As long as the volume of the wiring compartment and the conductor fill markings accommodate the number of

conductors required to go from one luminaire to the next on the circuits as described, no special marking is required. Only when yet an additional circuit, such as an unrelated lighting circuit or even a receptacle circuit passes through the luminaire wiring box is the “identified for through-wiring” provision activated (Fig. 410-4).

Not “through wiring” because the fixture is connected to the circuit, whether two-wire or multiwire.

Fig. 410-4. Care must be exercised in hooking up *prewired* types of luminaires. (Sec. 410.21.)

The current UL Luminaire Marking Guide includes the following information under the heading “Branch Conductors in Box”:

THROUGH CONDUCTORS IN A WIRING COMPARTMENT—A luminaire that is suitable for use with through branch conductors is marked “MAXIMUM OF ___NO. ___AWG THROUGH BRANCH CIRCUIT CONDUCTORS SUITABLE FOR ___°C PERMITTED IN BOX.

Note the word “THROUGH.” This label applies to the number of “through” conductors (if any) and not the supply conductors. The branch-circuit conductors supplying the luminaire, including the associated conductors of a multiwire circuit, are not “through” conductors as defined in 410.21. The current **NEC** wording amended the 1996 **NEC** wording that said “Branch-circuit wiring shall not be passed through an outlet box that is an integral part of an incandescent fixture unless the fixture is identified for through-wiring.” The substantiation for the proposal, which came from a panel member and manufacturer of these luminaires, stated in part:

[This section] is commonly misinterpreted as applying to both branch circuits passing through a junction box and branch circuits supplying the fixture. This is a problem because the number of permitted through-branch-circuit conductors is reduced by the number

of wires in the circuit supplying the fixture. This negates the usefulness of the through-branch-circuit rating.

The proposal also broadened the applicability of the rule to other styles of luminaire beyond just incandescent luminaires because other types were being manufactured with the same provisions.

410.22. Outlet Boxes to Be Covered. This rule is similar to that of 314.25. The canopy may serve as the box cover, but if the ceiling or wall finish is of combustible material, the canopy and box must form a complete enclosure. The chief purpose of this is to require that no open space be left between the canopy and the box edge if the finish is wood or fibrous or any similar material.

410.23. Covering of Combustible Material at Outlet Boxes. If a luminaire canopy encloses over 180 sq. in. of a combustible surface, then that surface must be covered with noncombustible material. Prior to the 2014 **NEC** any such material had to be covered and this was a real problem. Because 180 sq. in. corresponds to a canopy (after allowing for about 10 sq. in. for the box at the center) of about 15-½ in. diameter, this problem has effectively disappeared. If the canopy is larger than this, then there aren't many good options short of visiting a sheet metal shop. Some manufacturers have round decorative backers (often for vinyl siding) or ceiling medallions that, depending on the canopy diameter, may fit acceptably.

Fig. 410-5. A combustible mounting surface above a luminaire canopy must be protected if over 180 sq. in. is exposed to the inside of the canopy (410.23).

410.24. Connection of Electric-Discharge and LED Luminaires. As 410.24 is worded, the rules presented apply to *both* indoor and outdoor applications of electric-discharge luminaires. The rules cover general lighting in commercial and industrial interiors as well as all kinds of outdoor floodlighting and area lighting. Part (A) of this section covers *only* connection of electric-discharge luminaires “... supported independently of the outlet box.” Chain-hung luminaires, luminaires mounted on columns, poles, structures, or buildings, and any other luminaire that is not supported by the outlet box that provides the branch-circuit conductors to feed the luminaire are covered by part (A).

The basic rule requires a fixed or permanent wiring method to be used for supply to all “electric-discharge luminaires,” which includes all luminaires containing mercury-vapor, fluorescent, metal-

halide, high-pressure sodium, or low-pressure sodium lamps. BUT *incandescent* luminaires are *not* covered by 410.24. As a result, incandescent luminaires using cord connection are regulated only by 400.10(A)(2), 400.12(1), and 410.62(B).

Part (B) applies to surface-mounted fluorescent (and LED) luminaires where the ballast channel is not mounted *on* the box, and not designed to be supported solely by the box, but rather the luminaire is mounted *over* a concealed outlet box. Full access to the box must be afforded by opening the luminaire ballast channel. Usually this involves field punching the luminaire at the appropriate location with a metric designator 53 or 63 (trade size 2 or 2½) punch, depending on the box opening size. It does not mean relying on a metric designator 16 (trade size ½) knockout with a federal bushing to let the branch-circuit wiring into the ballast channel. In such a case the only access to the box is through completely removing the luminaire from the ceiling, in violation of this requirement.

410.30. Supports. Figure 410-6 shows a 3-kg (7-lb) luminaire shade that is 432 mm (17 in.) in diameter and supported by the screw-shell of the lamp and holder, on both counts violating the rule of part (A).

Fig. 410-6. Luminaire shade assembly may be supported from a screw-shell lampholder if it is not too heavy or too big in diameter. [Sec. 410.30(A).]

In part (B) the rules cover use of metal poles for supporting luminaires. A metal pole supporting a luminaire must have a readily accessible handhole (minimum 2 by 4 in. [50 by 100 mm]) to provide access to the wiring within the pole or its base. A grounding terminal for grounding the metal pole must be provided and be accessible through the handhole. Any metal raceway supplying the pole from underground must be bonded to the pole with an equipment grounding conductor. And conductors run up within metal poles used as raceway must have vertical supports as required by 300.19 (Fig. 410-7).

410.30(B)(1) Exception No. 1. This type of fixture-on-post does not need an access handhole at base of pole.

Fig. 410-7. Metal pole must provide access handhole and internal terminal for connecting grounding wire to metal of pole. [Sec. 410.30(B).]

As noted in Exception No. 1 to **(B)(1)**, a metal pole supporting a luminaire does not have to have an access handhole at its base if the pole is not over 8 ft (2.5 m) in height (such as a common post light) and the enclosed wiring is accessible at the luminaire end. This rule excludes the typical short

(not over 8 ft [2.5 m] high) post light from the need for a wiring access handhole at its base. That handhole is important for higher poles used on commercial and industrial properties and does add safety. But it is unnecessary for a post light, and this exception allows omission of the handhole where the wiring runs “without splice or pull point” to a luminaire mounted on a metal pole not over 8 ft (2.5 m) high and where splices of the luminaire wires to the branch circuit supply conductors are accessible by removal of the luminaire. And, as noted in Exception No. 2, where the pole is provided with a hinged base and is *not* over 20 ft (6.0 m) tall, then the handhole may also be omitted. Such poles have the equipment grounding terminal in the base.

The effect of these rules is to recognize the pole as a raceway. Where such poles are used to also support power-limited circuits such as for the video signal from a camera, and where the power circuit is run as individual conductors and not a [Chap. 3](#) wiring method, full system separation must be maintained between the systems as required in 725.136 and other comparable requirements. Frequently this is addressed through the use of a flexible nonmetallic conduit to sleeve the power-limited wiring, because system separation in such cases must never depend on wire insulation alone.

410.36. Means of Support. A luminaire may be supported by attachment to an outlet box that is securely mounted in position (see 314.23), or a luminaire may be rigidly and securely attached or fastened to the surface on which it is mounted, or it may be supported by embedment in concrete or masonry. As shown in [Fig. 410-8](#), heavy luminaires must have better support than the outlet box.

Fig. 410-8. Any luminaire over 50 lb (22.7 kg) must be supported from the structure or some other means than the outlet box. (Sec. 410.36.)

Various techniques are used for mounting luminaires independently of the outlet box, depending somewhat on the total weight of the individual luminaires. In general, pipe or rods are usually used to

attach the luminaires to the building structure, and the electrical circuit is made by using flex between the luminaire and the outlet box concealed in the ceiling cavity. If provision is made for lowering the luminaire, by means of winch or otherwise, provision must also be made for disconnecting the electrical circuit.

The most common method of supporting luminaires is by means of fixture bars or straps bolted to the outlet boxes, as shown in Fig. 410-9. A luminaire weighing over 50 lb (23 kg) can be supported on a hanger such as is shown for boxes under 314.27 for a tile-arch ceiling. Care should be taken to see that the pipe used in the construction of the hanger is of such size that the threads will have ample strength to support the weight.

Fig. 410-9. Luminaires must be supported by approved methods. (Sec. 410.36.)

Any luminaire may be attached to an outlet box where the box will provide adequate support, but,

as noted in 410.30(A), units that weigh more than 6 lb (3 kg) or exceed 16 in. (400 mm) in any dimension “shall not be supported by the screw-shell of a lampholder.”

A normal method of securing an outlet box in place is to use strap iron attached to the back of the outlet box and fastened to studs, lathing channels, steel beams, and the like nearby. Lightweight units are sometimes attached to outlet box by means of screws passing through luminaire canopy, that thread into outlet box ears, or flanges, tapped for this purpose. For heavier luminaires, fixture studs, hickies, tripods, or crowfeet are normally used.

Part **(B)** covers the support of luminaires installed in suspended ceilings. The Code rule wording was based on the following:

SUBSTANTIATION: The Uniform Building Code requires that suspended ceilings be adequately supported. This is usually in the form of an iron wire support attached to the structural ceiling members and the other end of the wire attached to the suspended ceiling frame members. The luminaires are then laid in the openings and secured only by light metal clips. There have been numerous accidents occur when these metal clips have been dislodged causing luminaires to fall to the floor. There have been several instances, where luminaires are installed in end-to-end rows, when one luminaire becomes dislodged from construction vibration causing the entire row to also fall to the floor.

There is also the danger of luminaires being shaken loose by seismic disturbances—Los Angeles, Oroville and Santa Rosa areas, to mention a few locations.

Having these luminaires attached to the framing members also becomes a severe problem to firemen. When the ceiling area becomes involved in a fire or enough heat generated from the fire, the framing members distort and cause the luminaires to fall through the openings.

The last sentence of part **(B)** does clearly recognize support of luminaires by means of “clips” that are listed for use with a particular framing member and type of luminaire. However, many jurisdictions across the country do *not* recognize the use of suspended-ceiling-supported luminaires—even where a ceiling system is specifically listed to provide such support. Check with your local inspector to determine the acceptability of ceiling-supported luminaires. Further, note that the rule requires the luminaire to be attached to the framing for the suspended ceiling, even if the luminaire is entirely supported to the building structure. This rule makes certain that in the event of a seismic disturbance, the ceiling and the luminaires move together. Otherwise luminaire movement out of step with the ceiling could easily result in the luminaires battering the ceiling to the point of causing it to fail. However, it must also be noted that UL, with respect to the T-bar clips mentioned here, makes the following statement: “The ability of these clips to withstand seismic disturbances has not been evaluated.”

Part **(G)** correlates to 225.26, which prohibits trees from being used to support conductor spans, but, this rule specifically permits outdoor luminaires and their boxes and support means to be mounted on trees. Needless to say, branch-circuit wiring supplying such luminaires may also be supported by the tree. Note that 300.5(D) requires protection where such wiring emerges from grade and up the initial 2.5 m (8 ft).

410.42. Luminaires with Exposed Conductive Parts. Part **(A)** says all exposed metallic components of the luminaire—other than trim pieces, and so forth, which are exempted by the next sentence—must be grounded. This can be accomplished by connection of the luminaire to an equipment grounding means—metal raceway, metal cable armor, or a ground wire in NM cable.

410.44. Methods of Grounding. Luminaires must be mechanically connected to the equipment grounding system, with three exceptions. The first covers luminaires made of insulating material and with no exposed conductive parts, which are suitable for mounting to a wiring method such as concealed knob-and-tube wiring, that does not provide ready means for an equipment

grounding connection. The other two cover replacements.

The first (Exception No. 2) recognizes the installation of what amounts to an “external” equipment ground, as described in 250.130(C), to provide the desired safety grounding of a noninsulating material luminaire where no equipment grounding means exists within the outlet box. The second (Exception No. 3) permits installation of metallic luminaires, provided the circuit supplying the luminaire is GFCI protected.

410.46. Equipment Grounding Conductor Attachment. This rule requires luminaires to have some terminal or other connection for an equipment grounding conductor when such luminaires have exposed metal parts and are supplied by NM cable or nonmetallic raceway, which must carry an equipment grounding conductor for grounding metal parts of the luminaire (Fig. 410-10). For luminaires supplied by metal raceway, proper connection of the raceway to the metal of the luminaire provides an equipment ground return path through the raceway, in accordance with 250.118.

Fig. 410-10. Exposed metal parts of luminaires must incorporate some suitable means for connecting the equipment grounding conductor of a nonmetallic-enclosed supply circuit. (Sec. 410.46.)

410.50. Polarization of Luminaires. This method of wiring luminaires is required in order to ensure that the screw shells of sockets will be connected to the grounded circuit wire. This is extremely important because luminaires with multiple lamps are often relamped hot in order to simplify choosing the correct lamp to replace. If the screw shell is hot, the skirt of the burned-out lamp will be hot as it is unscrewed until it is entirely separated from its socket. And the skirt of the new lamp will be hot as soon as it touches the screw shell going in. At either stage, it is very easy to have a finger touch the screw shell of the lamp. If the person’s other hand is braced on any grounded object, or perhaps bracing a chain-supported chandelier, the full voltage to ground will be present in a path running directly across the heart.

410.56. Protection of Conductors and Insulation. As noted in part (E), a luminaire fed by a conduit stem suspended from a threaded swivel-type conduit body must be supplied by stranded, not solid, wires run through the conduit stem—because the swivel fitting permits movement of the conductors.

410.59. Cord-Connected Showcases. Figure 410-11 shows an arrangement of cord-supplied illuminated showcases in a store. The details of this layout are lettered, with dimensions as given in the answers and involve the following rules:

Fig. 410-11. Hookup of lighted showcases must satisfy a number of rules. (Sec. 410.59.)

- The first showcase is supplied by flexible cord plugged into grounding-type receptacle rated 20 A. And that is permitted by part **(B)**.
- Flexible cord feeds the second showcase; the cord is spliced in JBs in each showcase. That is a clear violation of the requirement that in such connections, separable locking-type (twist-type) cord connectors must be used, and spliced cord connections would be a violation of the wording used in the first paragraph of 410.59.
- Cord is 14 AWG, hard-service type. That is a violation because the cord conductors must be 12 AWG, the size of the branch-circuit conductors for the 20-A circuit, as required in part **(A)**.
- Showcases are separated by 2 in. (50 mm). That is okay, but it is the maximum permitted separation, as noted in part **(C)**.
- The first case is 14 in. (350 mm) from the supply receptacle. No good! The maximum permitted distance is 12 in. (300 mm), as given in part **(C)**.
- The second showcase feeds a spotlight. Violation! Part **(D)** says no other equipment may be connected to showcases.

410.62. Cord-Connected Lampholders and Luminaires. Part **(B)** recognizes the use of a fixed-cord connection for energy supply to luminaires that require aiming or adjustment after installation (Fig. 410-12). Use of a cord supply to luminaires has been a recurring controversial issue, although 400.10 has permitted cord supply to luminaires for a long time. 410.30(C) has required that electric-discharge luminaires, if suitable for supply by cord, must make use of plug-and-receptacle connection of the luminaire to the supply circuit. The rule here in part **(B)** permits floodlights—such as those used for outdoor and indoor areas for sporting events, for traffic control, or for area lighting—to have a fixed-cord connection from a bushed-hole cover of the branch-circuit outlet box to the wiring connection compartment in the luminaire itself. This rule gives adequate recognition to the type of cord connection that has long been used on floodlights, spotlights, and other luminaires used for area lighting applications.

Fig. 410-12. Cord connection—either fixed cord or cord with plug cap—is permitted for adjustable luminaires. [Sec. 410.62(B).]

Prior to the 2017 **NEC**, Part (C)(1) was one of the most convoluted, poorly worded, and difficult to follow provisions in the entire **NEC**, but it has been completely rewritten and is now greatly improved in understandability. First, there are three global conditions that must be met for any of the permitted applications. First, the electric discharge luminaire (and not, therefore, an incandescent luminaire) must be directly below the outlet or busway. This last word correlates with 368.17(C) Exception No. 2 that recognizes busway connections to cord-and-plug-connected luminaires with fuses in the cord cap. “Directly below” clearly does not allow for cord to be run below (at a lower level) but swagged way off to the side. The second global condition is that the cord be visible over its entire length, and the third is that it not be subject to strain or damage.

If these three conditions are met, then there are three possibilities expressed in three separated paragraphs that are far more comprehensible than the 62-word run-on sentence that preceded the 2017 edition. The first is the oldest use, that of a cord-and-plug connection for the luminaire with the receptacle directly over the luminaire (Fig. 410-13). The original concept here is that maintenance personnel would unplug the luminaire, unhook some jack chain, and take the luminaire to the bench for work or cleaning.

THIS IS OK

410.30(C) permits such applications if the conditions in parts (C) (1) and (2) are satisfied.

Fig. 410-13. Cord-and-plug luminaire supply is okay only if cord is “continuously visible.” The suspended ceiling application would normally violate (C)(2)a and not be acceptable. (Sec. 410.62.)

The next possibility is extensively used in upscale lighting designs with rows or other patterns of fluorescent luminaires suspended from aircraft cable capable of height adjustment so the luminaires can be precisely positioned. At a convenient point in the lineup, the canopy supplied with the luminaires is connected to the branch circuit using flexible cord between the canopy and the luminaire (Fig. 410-14). Some box manufacturers make outlet boxes with T-bar knockouts on the sides at right angles so the box can straddle the supports on a hung ceiling and mount flush with the ceiling tiles, and then this canopy can be mounted without further ado. However, a 2008 **NEC** amendment also recognizes a riser nipple from the canopy not over 150 mm (6 in.) long, allowing the cord to pass through the ceiling plane and connect to an outlet box just above the ceiling. The last possibility correlates with 604.100(A)(3) (requiring 12 AWG hard usage cord minimum) and uses the proprietary receptacle configurations covered in 604.100(C) that are uniquely polarized and locking for this purpose as part of a manufactured wiring system.

Fig. 410-14. This listed cord-connected luminaire lineup is arranged for precise vertical positioning. [Sec. 410.62(C)(1).]

Part (C)(2) of this section permits electric-discharge lighting with mogul-base screw-shell lampholders (such as mercury-vapor or metal-halide units) to be supplied by branch circuits up to 50 A with the use of receptacles and caps of lesser ampere rating if such devices are rated not less than 125 percent of the luminaire full-load current. Note that there are no limitations placed on the length of the cord or the position of the receptacle relative to the luminaire under this provision, short of the generic wording in 400.12(1) prohibiting the use of cord as a substitute for fixed wiring.

Unlike part (C)(2), paragraph (3) applies to fluorescent luminaires as well as HID applications. This rule essentially reverses the cord direction as covered in 410.62(C)(1)(c) (first clause) by using a flanged inlet in the back of the luminaire connected to a receptacle cord body fed by a drop from an unspecified source (Fig. 410-15). Here again there are no limitations placed on the length of the cord or the position of the cord connection to the branch circuit relative to the luminaire short of the generic wording in 400.12(1) prohibiting the use of cord as a substitute for fixed wiring. The use of a connector body and flanged inlet supply affords greater ease in maintenance of the luminaire, because maintenance people can disconnect the luminaire at the lower end of the cord to remove it for cleaning or repair.

Fig. 410-15. This is another method recognized for cord supply to luminaires. [Sec. 410.62(C)(3).]

410.64. Luminaires as Raceways. This Code rule has long stated basically that luminaires shall not be used as a raceway for circuit conductors (Fig. 410-16) unless “listed and marked for use as a raceway.” Note the correct use of the term “marked” in this rule. When a luminaire is specifically approved as a raceway, any number of branch-circuit conductors may be installed within the capacity of the raceway. When housings are approved as raceways, luminaires carry an Underwriters Laboratories label that states “Suitable for Use as Raceway.” Any type of circuit may be run through the luminaire in such a case, provided listing limitations are met. UL rules require that luminaires that are suitable for use as raceway—that is, for carrying circuit wires other than the wires supplying the luminaires—must be so marked and must show the number, size, and type of conductors permitted.

Fig. 410-16. Use of wiring through luminaires is clearly limited. (Sec. 410.64.)

(C) Luminaires connected together This paragraph permits limited use of luminaire wiring compartments, even where such luminaires are *not* listed and marked for use as raceways, to carry through the circuit that supplies the luminaires. This allowance applies if the luminaires are designed for end-to-end assembly to form a continuous raceway or the luminaires are connected together by recognized wiring methods (such as rigid conduit and EMT). Most self-contained fluorescent luminaire units now available are designed for end-to-end assembly. Each luminaire contains a metal body, or housing, which serves as the structural member of the luminaire and provides a housing for the ballast, wiring, and so forth, and which is of sufficient size to permit running the branch-circuit wiring through the unit. Each luminaire is then tied to the branch circuit by means of a single tap (Fig. 410-17).

Fig. 410-17. Only luminaires approved as “raceway” may be used for carrying through circuit wires that supply any load other than the luminaires. (Sec. 410.64.)

It should be noted that in 410.64(C) the permitted luminaire layouts may carry only conductors of either a 2-wire or a multiwire branch circuit where the wires of the branch circuit supply only the luminaires through which the circuit conductors are run. Thus, it is permissible to use a 3-phase, 4-wire branch circuit through luminaires so connected, with the total number of luminaires connected from all the phase legs to the neutral; that is, with the luminaire load divided among the three phase legs. But the last sentence limits such use to a single 2-wire or multiwire branch circuit.

This section also permits one additional 2-wire branch circuit to be run through such luminaires (connected end-to-end or connected by recognized wiring methods) in addition to the 2-wire or multiwire branch circuit previously recognized. This additional 2-wire branch circuit may be used only to supply one or more of the connected luminaires throughout the total luminaire run supplied by the other branch circuit run through the raceway (Fig. 410-18). This was added to permit separate control of some of the luminaires fed by the additional branch circuit, providing the opportunity to turn off some of the luminaires for energy conservation during the night or other times when they are not needed.

This may now be done:

But the *Code* rule accepts one more circuit—only a **2-wire** circuit—run through the row. But this additional circuit **must** supply one or more of the fixtures in the row, such as night lighting by, say, every fifth fixture, to enable the others to be turned off for energy conservation.

And the same permission applies in this case—

Fig. 410-18. Expanded use of luminaires as raceways provides better control for conservation. (Sec. 410.64.)

410.68. Feeder and Branch-Circuit Conductors and Ballasts. The sentence of this section regulates use of wires run through or within luminaires where the wire would be exposed to possible contact with the ballast, which has a hot-spot surface temperature of 90°C. Thus, such wires must be rated at least 90°C—which is the temperature at which the wire will operate when carrying its rated current in an ambient not over 30°C (which is 86°F). Note that LED drivers, and associated power supplies and transformers, are potent heat sources and they are now grouped with ballasts as requiring equivalent separation from lower-temperature wiring. The use of conductors with lower-rated insulation is permissible only where the luminaire is specifically listed and marked for use with the lower-temperature insulation within 3 in. (76 mm) of the ballasts, or the specific wiring

arrangement in the ballast channel precludes the lower-rated conductors from getting near the ballast. For example, if the outlet is 300 mm (12 in.) from the ballast, and only 200 mm (8 in.) of Type TW branch-circuit wire enters the channel, obviously this section is not in play because the branch-circuit wiring cannot get close enough to the ballast.

The question often arises, “May 150°C fixture wire be used for circuiting through end-to-end connected continuous-row fluorescent luminaires?” 402.10 permits “fixture wires” to be installed “in luminaires” where they will not be subject to bending or flexing in normal use. That would seem to approve fixture wire through the luminaires connected in a row. But, 402.11 prohibits fixture wires used as branch-circuit conductors. The conductors installed in the luminaire “ballast compartment” are referred to as “conductors of a . . . branch circuit” in 410.64, because they feed directly from the branch circuit and are tapped at each luminaire to feed each luminaire. The branch circuit extends from the point where it is protected by a CB or fuse to the last point where it feeds to the final outlet, device, apparatus, equipment, or luminaires. Under these conditions, it seems clear that the wiring must be that approved for branch circuits. Any fixture wires are not approved for branch-circuit wiring.

To satisfy 410.68, any of the 90°C-rated conductor insulations, such as Type RHH, Type THHN, or even 75°C-rated Type THW under the special 90°C allowance, must be installed. No fixture wire is permitted to be installed as branch-circuit conductors.

410.74. Luminaire Rating. This section specifically requires that any luminaire be suitably marked to indicate the need for supply wires rated higher than 60°C to withstand the heat generated in the luminaire. Such marking must be prominently made on the luminaire itself and also on the shipping carton in which the luminaire is enclosed (Fig. 410-19). This makes the information available to the consumer at the time the luminaire selection decision is being made. The label must include a statement that a qualified electrician should be consulted to determine the suitability of the branch-circuit wiring, or at least a warning label will require consultation with a qualified person. Most residential branch-circuit wiring installed prior to late 1983 is rated 60°C at best.

If heat developed in fixture wiring box requires wire rated over 60°C—the required temperature rating of supply wire must be marked in the fixture and on shipping carton.

Fig. 410-19. Where high-temperature wire is needed, the luminaire must be marked. [Sec. 410.74(A).]

410.82. Portable Luminaires. Part (A) requires portable lamps (table lamps and floor lamps) to be wired with flexible cord approved for the purpose and to be equipped with polarized- or grounding-type attachment plugs. Two-prong nonpolarized attachment plugs are no longer permitted. Polarized-type plug caps permit a single orientation of the plug for insertion in the receptacle outlet. Such polarizing of the plug will provide for connecting the grounded conductor of the circuit to the screw shell of the lampholder in the lamp.

In part (B), five specific rules are given on the use of portable handlamps, as shown in Fig. 410-20. All the requirements of part (A), including the need for polarized- or grounding-type attachment plugs, also are made applicable to portable handlamps.

Portable lamps

Portable hand lamps

Fig. 410-20. NEC rules aim at greater safety in use of portable lamps and portable handlamps. (Sec. 410.82.)

410.90. Screw-Shell Type. This warns against the previously common practice of installing screw-shell lampholders with screw-plug adapters in baseboards and walls for the connection of cord-connected appliances and lighting equipment, and thereby exposing live parts to contact by persons when the adapters were moved from place to place. See also 406.2(B).

410.93. Double-Pole Switched Lampholders. On a circuit having one wire grounded, the grounded wire must always be connected to the screw shell of the socket, and sockets having a single-pole switching mechanism may be used. (See 410.102.) On a 2-wire circuit tapped from the outside (ungrounded) wires of a 3-wire or 4-wire system, if sockets having switching mechanisms are used, these must be double-pole so that they will disconnect both of the ungrounded wires.

410.97. Lampholders Near Combustible Material. This rule prohibits, using identical language as in 410.11 for luminaires, the placement of a lampholder (unless provided with construction features or shades or guards) where adjacent combustible material will be heated above 90°C. A bare incandescent lamp in a plain vanilla lampholder can be one of the most potent heat sources available, and on the literal text of prior Codes there were no placement restrictions, because they are not luminaires.

410.104. Electric-Discharge Lamp Auxiliary Equipment. Part (B) requires that a

switch controlling the supply to electric-discharge-lamp auxiliary equipment must simultaneously disconnect both hot conductors of a 2-wire ungrounded circuit. This is required to prevent an energized screw shell where only one circuit wire is disconnected—which would be a hazard during relamping. Note that this may require a relay in the event a conventional single-pole photo-control is used for this application.

410.110. General. Underwriters Laboratories rules comment on use of luminaires installed in hung ceilings, as follows:

All recessed luminaires, except those marked for use in concrete only, are suitable for use in suspended ceilings and may be marked “SUITABLE FOR SUSPENDED CEILING.” Note that this is not a mandatory marking for this use. However, luminaires mounted in such locations are subject to the requirements of Parts X and XI of Art. 410, that is, from this section through Sec. 410.122. There was a very long-standing formal interpretation on this point. When a formal interpretation issues, **NFPA** regulations require that the committee responsible for the text that prompted the request for interpretation amend the text so as to avoid the lack of clarity in the future. Incorporating the words “including suspended ceilings” finally addresses that lack of clarity, and now that old formal interpretation can be officially “retired.”

Air-handling luminaires must be used fully in accordance with the conditions marked on the luminaires. When used in fire-rated partitions, such luminaires must be specifically covered in the applicable listed design in the *UL Fire Resistance Directory*.

410.115. Temperature. Heat is a major problem in lighting system design, and with the trend to the use of recessed luminaires and equipment, the problem is increased. In the case of luminaires using incandescent lamps, the problem is primarily the prevention of concentrated spots of heat coming into contact with the building structure. In the case of fluorescent luminaires, the major heat problem is related to the ballast, which can build up severely high temperatures when not properly ventilated, or designed for cooler operation through adequate radiation and convection. These are problems that must be solved (1) through proper luminaire design, and (2) through proper installation methods and techniques (Fig. 410-21).

Luminaires shall not subject adjacent combustible material to a temperature in excess of 90°C (194°F).

Fig. 410-21. Recessed luminaires must not threaten combustion of building materials. (Sec.

410.115.)

The rule of part (C) requiring thermal protection of recessed incandescent luminaires is intended to prevent fires that have been caused by overlamping or misuse of insulating materials. (See Fig. 410-22.) Exception No. 1 covers an installation with the luminaire embedded in poured concrete; no thermal protection is required for this application. As noted in Exception No. 2, a nonthermal-protected recessed incandescent luminaire may be used in direct contact with thermal insulation if it is listed as suitable by design for performance equal to thermally protected luminaires and is so identified. There are presently available recessed incandescent luminaires of such design as to prevent overheating even when installed in contact with thermal insulation. Such luminaires cannot be overlamped or mislamped to cause excessive temperature and are listed and marked for such application.

Fig. 410-22. Recessed incandescent luminaires that incorporate thermal protection must be “identified as thermally protected,” but a luminaire without thermal protection may be used if listed and identified for use as “inherently protected.” [Sec. 410.115(C).]

410.116. Clearance and Installation. As covered in part (A)(1), where “Non-Type IC” recessed luminaires are used with thermal insulation in the recessed space, thermal insulation must have a clearance of at least 3 in. (75 mm) on the side of the luminaire and at least 3 in. (75 mm) at the top of luminaire and shall be so arranged that heat is not trapped in this space. Free circulation of air must be provided with this 3-in. (75-mm) spacing. If, however, the luminaire is approved for installation with thermal insulation on closer spacing, it may be so used (Fig. 410-23). In parts (A)(2) and (B), the Code recognizes recessed incandescent luminaires in contact with thermal insulation or combustible material. Recessed incandescent luminaires must be listed and identified for use in contact with thermal insulation.

Fig. 410-23. Clearance of recessed luminaire from thermal insulation is required unless luminaire is UL-listed for use in direct contact with insulation. (Sec. 410.116.)

In the past, thermal insulation has been installed in direct contact with recessed luminaires not approved for that use and has caused overheating in luminaires with resulting failures and fires. Obviously, the installer of thermal insulation will have to be educated on this subject, because electrical installers have little control over how the insulation will be applied.

Figure 410-24 shows an application that involves the $\frac{1}{2}$ -in. clearance covered in the first sentence of this section. It shows two 40-W fluorescent strips installed in a residential kitchen ceiling. The ceiling has been furred down on all sides of the 4- by 4-ft (1.22- by 1.22-m) luminaire area as shown. The question arises: Is this a “recessed” installation according to the Code? How small or large must such an enclosed space be to be considered a recess? The Code does not mention “recessed installations” but refers to “recessed luminaires.” The installation as shown is basically a field-fabricated recessed luminaire. With only two 40-W lamps in this space, it is not likely there will be much of a heat problem. But sufficient information on the total construction of the cavity would be needed for an inspector to make an evaluation. The temperature limitations of 410.11 and 410.115 must be observed, and wiring must be in accordance with 410.117.

Fig. 410-24. Clearances on custom recessed lighting applications must be evaluated carefully. (Sec. 410.116.)

The next question is: Must a ½-in. (13-mm) clearance be maintained between the luminaires and the Sheetrock? Sheetrock is fire-rated by UL but is not fireproof. It is unlikely that inspectors would require the ½-in. (13-mm) spacing between the luminaires and the Sheetrock because the paperboard surfaces of the Sheetrock are still part of a rated material and 314.20 and many other Code rules treat it comparably to other noncombustible surfaces. Although the paper will char, the water of hydration in the substrate, when heated, will prevent transmission of fire, hence the rating. The local inspector would, of course, have the final say on this.

410.117. Wiring. Supply wiring to recessed luminaires may be the branch-circuit wires, if their 60°C, 75°C, or 90°C temperature rating at least matches the temperature that will exist in the luminaire splice compartment under operating conditions. Typically, fluorescent luminaires do not have very high operating temperatures where the branch-circuit wires splice to the luminaire wires, and branch-circuit conductors may be run right into the luminaire. But incandescent luminaires develop much higher localized heat because all the wattage is concentrated in a much smaller lamp, thereby requiring higher-temperature wire where the branch circuit splices to the luminaire leads.

The rules of part **(B)** and part **(C)** of this section are related to the details discussed under 410.21. [Figure 410-25](#) shows branch-circuit wires rated at 75°C coming out of ceiling boxes (left) and then connecting directly to fluorescent strip units mounted over the boxes and attached to the ceiling (right). The 75°C THW branch-circuit wires are generally recognized as rated at 90°C for use within the fluorescent units [Table 310.104(A), THW properties row]. Therefore, this installation fully complies with 410.117(B).

Fig. 410-25. Branch-circuit wires rated at 75°C are brought out of ceiling boxes (left) and then connected to luminaire leads within the relatively cool wiring compartment of the fluorescent units. (Sec. 410.117.)

Figure 410-26 is an old photo taken prior to the advent of 90°C Type NM-B cable, and so it shows 60°C branch-circuit wiring run directly to integral junction boxes of prewired incandescent luminaires. The box protects the branch-circuit wires from the heat generated within the luminaires. Therefore, this installation fully complies with 410.117(A). Note that these luminaires are used for supply and feed-through of the branch-circuit wires. There are no tap conductors wired in the field, the junction box is not “placed” in position in the field, and the raceway, all 75 mm (3 in.) of it, is provided by the manufacturer and is certainly not “at least 450 mm (18 in.) but not more than 1.8 m (6 ft) long.”

Fig. 410-26. Prewired recessed incandescent luminaires may have 60°C branch-circuit wiring run directly into their junction boxes. (Sec. 410.117.)

Figure 410-27 is another old photo that predates the requirement in 410.130(F)(1) for thermal protection on recessed HID luminaires, and for this reason required the field-wired cold lead as shown. This, in its day, was a completely legitimate application of 410.117(C), where a luminaire wiring compartment operates so hot that the temperature exceeds that of the branch-circuit-rated value, and high-temperature fixture wires must be run to the unit. The circuit outlet box supplying the luminaire must be “placed” in the field not less than 1 ft (300 mm) away. The flex whip may be metric designator 12 (trade size 3/8) flex for the number and type of luminaire wires as specified in Table 348.22. If the branch circuit supplying the luminaire is protected at 20 or 15 A, 18 AWG fixture wires may be used for luminaire loads up to 6 A, or 16 AWG fixture wires may be used for loads up to 8 A (402.5), and the metal flex may serve as the equipment grounding conductor (250.118). The flex may not be less than 18 in. (450 mm) and not more than 6 ft (1.8 m) long. This length assures enough of a loop to minimize convection of heat into the branch-circuit connections. The fixture wires could be Type PF for conditions requiring a 200°C rating or could be another type

of adequate temperature rating for the luminaire's marked temperature, selected from Table 402.3.
For flex, refer also to 348.12.

This is an alternative to tap conductors run in metal flex or liquidtight metal flex.

Fig. 410-27. For luminaires with circuit-connection compartments operating very hot, high-temperature wires must be run in flex (other metal raceway or Type AC or MC metal armored cable) between 1½ and 6 ft (0.45 and 1.8 m) from an outlet box at least 12 in. (300 mm) away. [Sec. 410.117(C).]

The 1½- to 6-ft (0.45- to 1.8-m) luminaire whip may be Type AC or Type MC cable, if ever such cables are manufactured with conductors rated higher than 90°C.

Having fully covered the requirements in 410.117(C), this subsection needs to be put in perspective. The rule is about wiring cold leads, and nothing else. If you don't need a cold lead, you don't need this rule. This rule has absolutely nothing to do with prewired luminaires like those shown in Fig. 410-26. Luminaires like the one shown in Fig. 410-27 have not been manufactured for many years. There is only one application where a cold lead might be necessary and that is for luminaires that will be embedded in poured concrete, and therefore exempt from thermal protection rules by 410.115(B) or 410.130(F)(3). Although there are references to 410.117(C) all over the **NEC**, they are usually erroneous. They generally describe taps that are not taps (whips above hung ceilings made up with branch-circuit wiring methods using the same size conductors are not taps) run to luminaires that are prewired and suitable for ordinary branch-circuit connections.

410.130. General. Paragraph (E) pertains only to fluorescent lamp ballasts used indoors. The protection called for must be a part of the ballast. Underwriters Laboratories, Inc., has made an extensive investigation of various types of protective devices for use within such ballasts, and ballasts found to meet UL requirements for these applications are listed and marked as “Class P.” The protective devices are thermal trip devices or thermal fuses, which are responsive to abnormal heat developed within the ballast because of a fault in components such as autotransformers, capacitors, reactors, and the like.

Simple reactance-type ballasts are used with preheat-type fluorescent lamp circuits for lamps rated less than 30 W. Also, a manual (momentary-contact) or automatic-type starter is used to start the lamp. The simple reactor-type ballast supplies one lamp only, has no autotransformer or capacitor, and is exempted from the protection rule of part (E).

The thermal protection required for ballasts of fluorescent luminaires installed indoors must be within the ballast. Previous wording permitted the interpretation that the supplementary protection for the ballast could be in the luminaire and not necessarily within the ballast.

Note that part (4) of this rule prohibits the use of thermal protectors for emergency luminaires where such luminaires are energized only during an emergency. This rule presents a requirement similar to the concept of prohibiting overload protection on fire-pump motors. The prohibition of thermal and overload protection for emergency egress luminaires and fire-pump motors, respectively, is intended to ensure maximum operating continuity of the equipment during an emergency. It makes little sense to automatically de-energize such equipment under overload conditions during an emergency. Why save the luminaires or fire-pump motors from destruction at the risk of leaving people in the dark or cutting off the fire main's pressure? During an emergency, saving people and the building outweigh any concerns for the emergency luminaires or fire-pump motors. They are to be allowed to continue operating while overloaded, right to the point of failure.

Part (F) requires that recessed HID luminaires used *either* indoors or outdoors must have thermal protection. The luminaire—and not just the ballast—must be thermally protected and so identified.

All *indoor, recessed* luminaires using mercury-vapor, metal-halide, or sodium lamps must be thermally protected. If remote ballasts are used with such luminaires, the ballasts must also be thermally protected. Paragraph (5) requires luminaires using metal halide lamps to provide secondary containment around the lamp to protect against what the industry euphemistically describes as “nonpassive end-of-life failures” where the inner arc tube ruptures with enough force to break the outer bulb. Several fires have been reported from the hot lamp fragments falling on combustible materials. The other permitted approach is to use a specially engineered lamp with an internal shroud around the arc tube, designated “Type O” (for open). Luminaires that use this approach have a screw shell that is deeper than conventional screw shells. The “O” lamps have an extended Edison base that will hit the center contact when screwed all the way in; other lamps will run out of thread before being energized.

In part (G) the Code requires, for nonresidential occupancies, a disconnecting means for fluorescent luminaires that are equipped with double-ended lamps and feature in-place replacement of ballasts. The location of this disconnecting means may be inside or outside of each such luminaire, and such a disconnect must simultaneously open all conductors to the ballast—including the grounded (neutral) conductor, if it is supplied by a multiwire branch circuit. The disconnect’s line-side terminals must be guarded, and it must be accessible either in the ballast channel or mounted on or within sight of the luminaire while maintenance is being performed. In general these are usually small, pull-apart two-pole units that fit easily in the ballast area. They avoid the possibility of shock and/or open multiwire neutral failures when working a luminaire hot, which is the usual approach because the light from other luminaires avoids the necessity of additional portable illumination.

Watch Out! Effective with the 2011 **NEC**, when a ballast that would be covered by this rule if it were being wired new is replaced, the disconnect required by this rule must be retrofitted if it is not already present.

Exceptions apply for hazardous (classified) locations, for two-wire circuiting with adjacent luminaires arranged to stay lit, and for emergency lighting. A cord-and-plug connection is recognized as well for obvious reasons. However, because manufacturers do not really know where their luminaires will end up, and because the little two-pole devices cost only pennies, the trend is to simply include these arrangements in most of the conventional luminaires sold today. The 2014 **NEC** has removed the prior exception for qualified industrial occupancies.

410.135. Open-Circuit Voltages Exceeding 300 Volts. This rule, limiting luminaires in dwelling occupancies with open circuit voltages above 300 unless special construction features are in place, may be dated. The only dwelling-unit location limitation markings in the current UL Luminaire Marking Guide are those that prohibit open circuit voltages over 1000 [and thereby enforce 410.140(B)] and those that prohibit luminaires marked for supply wiring rated over 90°C. The section is being retained, however, because it provides a basis for requirements in the relevant product standards, particularly as applicable to cold-cathode electric discharge lighting systems being listed for use in dwelling units.

410.136. Luminaire Mounting. Paragraph (B) of this section has been essentially unchanged for over 50 years, but remains valid although there are no luminaires now listed that qualify for such a marking. Until 2000, the UL Guide Card data on this product category read as follows: “Fluorescent luminaires suitable for mounting on combustible low-density cellulose fiberboard ceilings which have been evaluated for use with thermal insulation above the ceiling and which have been investigated for mounting directly on combustible low-density cellulose fiberboard ceilings are

“marked ‘Suitable for Surface Mounting on Combustible Low-Density Cellulose Fiberboard’” (Fig. 410-28). With no listings in sight, UL has dropped this explanation from its Guide Card information. This type of ceiling is not common, but if it is encountered, the spacing rule given here must be applied because no listed luminaire will likely be available to mount against this material.

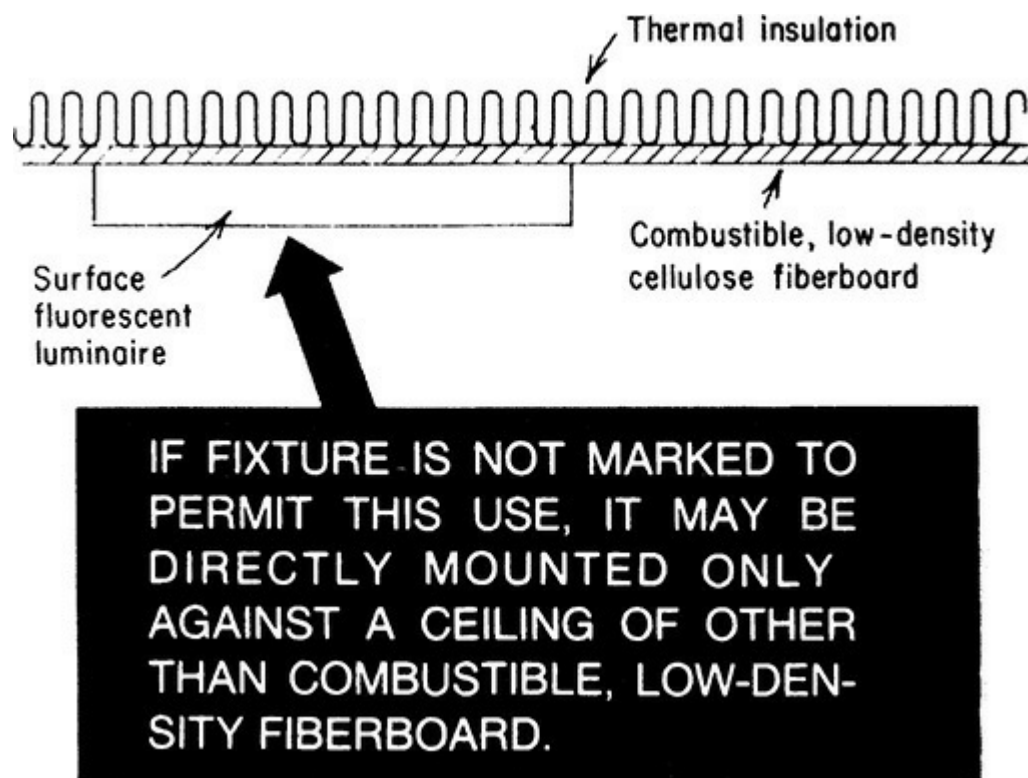

Fig. 410-28. There are no luminaires currently listed for this use. [Sec. 410.136(B).]

410.137. Equipment Not Integral with Luminaire. Part (C) covers interconnection of “paired” luminaires, with a ballast supplying a lamp or lamps in both, using up to a 25-ft (7.5-m) length of metric designator 12 (trade size $\frac{3}{8}$) flexible metal conduit to enclose the circuit conductors. Lighting manufacturers have been making UL-listed pairs of luminaires for use with each other. Because some inspection agencies have questioned use of this equipment, this section describes Code-conforming use of such equipment to thereby resolve field controversy. Two-lamp ballasts are more efficient than one- or three-lamp versions, and the paired luminaire concept allows a two-lamp ballast in one luminaire to feed the odd lamp in its paired section.

410.138. Autotransformers. This rule ties in with the rules of 210.6 on voltage of branch circuits to luminaires. On neutral-grounded wye systems (such as 120/208 or 277/480) incandescent, fluorescent, mercury-vapor, metal-halide, high-pressure sodium, and low-pressure sodium equipment can be connected from phase to neutral on the circuits. If fluorescent or mercury-vapor luminaires are to be connected phase to phase, some Code authorities contend that autotransformer-type ballasts cannot be used when they raise the voltage to more than 300 V, because, they contend, the reference to “a grounded system” in this rule of 410.138 calls for connection to a circuit made up of a grounded wire and a hot wire (Fig. 410-29). On phase-to-phase connection they would require use of 2-winding (electrically isolating) ballast transformers. The wording of 410.138 does, however, lend itself to interpretation that it is only necessary for the supply system to the ballast to be grounded—thus permitting the two hot legs of a 208- or 480-V circuit to supply an autotransformer because the

hot legs are derived from a neutral-grounded “system.” Further, the rule in 210.9 restricts the use of autotransformers as a supply point for branch circuits. Because a luminaire ballast has no field wiring connected to its load side, it is difficult to see how this is a significant problem.

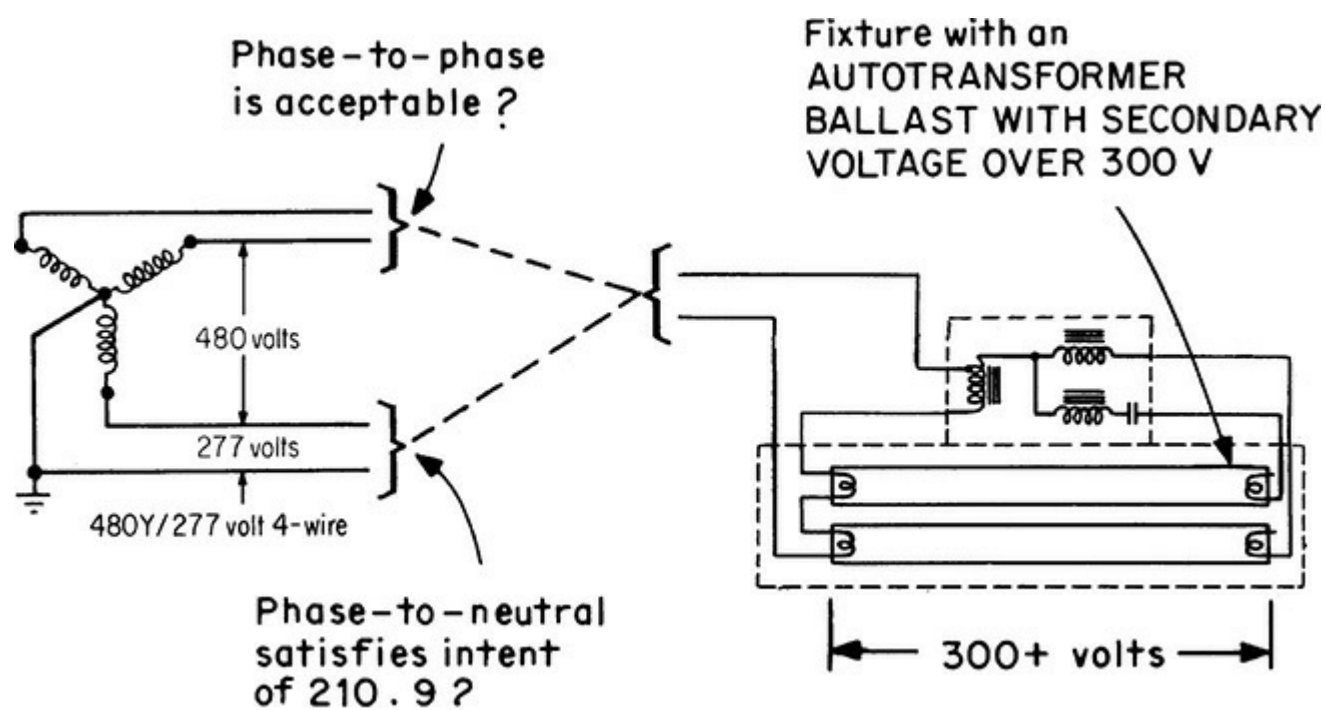

Fig. 410-29. Intent of 210.9 raises questions about connection of autotransformer ballasts. (Sec. 410.138.)

410.140. General. These sections apply to interior neon-tube lighting for general illumination, lighting with long fluorescent tubes requiring more than 1000 V, and cold cathode fluorescent-lamp installation arranged to operate with several tubes in series. Note that as soon as the neon tubing “outline[s] or call[s] attention to certain features such as the shape of a building or the decoration of a window” or if it conveys information in the form of a sign, then it is covered as outline lighting or as a sign, respectively, under the applicable provisions of Art. 600. As noted in part (B), electric-discharge lighting equipment with open-circuit voltage exceeding 1000 V shall not be installed in dwelling occupancies. This is correlated with the UL marking requirements, as discussed at 410.135. Note that (C) specifically requires that electric discharge lamp terminals are to be considered live parts, by which it is presumably intended to indicate “uninsulated live parts.”

410.141. Control. When any part of the equipment is being serviced, the primary circuit should be opened and the servicers should have assurance that the disconnecting means will not be closed without their knowledge.

410.143. Transformers. See comments following 600.23.

410.144. Transformer Locations. In part (B) the Code addresses secondary conductors used with neon lighting. This type of cable is not included in the table in [Chap. 3](#) listing various types of insulated conductors, but Underwriters Laboratories, Inc., have standards for such cables. It is now called out in 600.32(B) as Type GTO cable and is discussed at that location.

410.151. Installation. This covers the very popular and widely used track lighting (defined in Art. 100) made by a number of manufacturers and used so commonly today in residential and commercial interiors. In 410.151 through 410.155, extensive rules cover applications of track lighting

mounted on ceilings or walls, while the rules for conductor sizing and overcurrent protection are given in 220.43(B). Specifically, these rules cover the installation and support of lighting track used to support and supply power to luminaires designed to be attached to the track at any point along the track length (Fig. 410-30). Unless otherwise specifically designed, lighting track must be supported at least every 1.2 m (4 ft) and it must be mounted at least 1.5 m (5 ft) above the elevation of the finished floor, although that distance can be lowered if there is appropriate protection from damage, or on low-voltage applications.

Fig. 410-30. Part XV of Art. 410 contains rules on installation, application, fastening, and circuit loading for standard and heavy-duty track lighting. However, rules for calculating required feeder circuit capacity are covered in 220.43(B). The rules in 220.43(B) are for feeders and do not limit the length of track connected to a single-branch circuit or the number of luminaires on a track. (Secs. 410.151 through 410.155.)

410.160. Decorative Lighting. Decorative lighting, such as holiday lighting in bushes, trees,

and on architectural elements, must be listed even though it will only be used for temporary purposes pursuant to the 90-day limitation in 590.3(B).

ARTICLE 411. LOW-VOLTAGE LIGHTING

411.1. Scope. This article, which was new in the 1996 **NEC**, covers the installation of so-called low-voltage lighting. This lighting, although power limited, is not necessarily power limited to the same degree as Class 2 or Class 3 circuits in Art. 725. For example, the upper limit on voltage is 30, but the upper limit on current is 25 A, making the potential available power roughly 6 times that of a Class 2 signaling circuit. Recent changes, largely driven by LED technology, have resulted in extensive systems covered by this article that operate entirely within Class 2 limits, and the article title now simply refers to low voltage. Generally the specified limits are 30 volts ac and 60 volts dc, but if wet contact is likely, then the voltage limits drop by half. A new informational note points to Art. 680 as the source of rules applicable to submersion.

411.3 Low-Voltage Lighting Systems. This sets the minimum components for these systems. They must have an isolating power supply, they must employ low-voltage luminaires, and any associated equipment must be identified for the application. The power supply output circuits must not exceed 25 amps under any load condition.

411.4. Listing Required. Effective with the 2008 **NEC**, there are two options regarding listings on these systems. The first option, is 411.4(A). Under this procedure the entire setup with all the components has to be listed as part of a complete system. The second option allows for a field assembly of listed parts, including the cord, cable (or other wiring method), luminaires and fittings, and the power supply. However, if the setup involves exposed bare wire as the system arrangement, then the luminaires and their associated fittings, along with the power supply, must all be listed for use as part of the same lighting system. An important clarification is that “fixed wiring method” (2014 **NEC**) is now “fixed [Chap. 3](#) wiring method” with respect to the secondary circuit.

411.5. Specific Location Requirements. These systems must not encroach on the 3.0-m (10-ft) boundary around a swimming pool or similar location unless installed in accordance with a specific allowance in Art. 680. In other locations the conductors must not be concealed or run through partitions unless one of two approaches is taken. The first is to convert to a [Chap. 3](#) wiring method. The second is to live within a Class 2 power limitation, in which case the low-voltage conductors can be concealed. Now that LED technology is steadily advancing, this is often feasible.

411.6. Secondary Circuits. These systems are a rare example in the **NEC** of a system that is forbidden to be grounded; neither of the two conductors on the load side of the transformer may be connected to the ground.

ARTICLE 422. APPLIANCES

422.1. Scope. See the definition of *appliance*, Art. 100. For purposes of the Code, the definition of an appliance indicates that it is utilization equipment other than industrial, which generally means small equipment such as may be used in a dwelling or office (clothes washer, clothes dryer, air conditioner, food mixer, coffee maker, etc.). See also the definition of *utilization equipment* in Art. 100.

422.5. Ground-Fault Circuit Interrupter (GFCI) Protection for Personnel. This

new section as of the 2014 **NEC** requires that GFCI devices used to meet requirements in this article be readily accessible, correlating with the rule in 210.8. This is of particular importance to GFCI receptacles that supply older vending machines per 422.51(A), many of which are very difficult to move out of the way and provide access to the test buttons on the device. A GFCI circuit breaker may be the only practical option. This section now (2017 **NEC**) centralizes in one location appliance GFCI requirements in the article. As a result, former Sec. 23 on tire inflation and also automotive vacuum machines for public disappears, along with former Sec. 49 on spray washers, Sec. 51 on vending machines, and Sec. 52 on drinking water coolers (here renamed to match the product standard) all disappeared. The parent language in (A) sets consistent coverage limits for everything, namely, 250 volts or less, 60 amps. or less, and both single and three-phase. Part (B) on location, focusing on the actual equipment, allows the protection at the branch-circuit OCPD, or downstream in the supply circuit, or as an integral part of an attachment plug.

422.6. Listing. As of the 2017 **NEC**, if an appliance operates at 50 volts or more, it must be listed. This includes vending machines, for which the former definition was deleted. Instead, the **NEC** is, in effect, deferring to the product standard to define the term. There appear to be three UL Guide Card designations that apply to this equipment, and that may serve as a starting point to get a handle on what is included. The category that generally applies to vending machines is YWXV. Additionally, there are food and beverage applications covered under the TSYA designation, and if such dispensing is refrigerated, then the SQMX designation applies.

422.10. Branch-Circuit Rating. Part (A) states that the amp rating of an individual branch circuit to a single appliance must not be less than the marked ampere rating of the appliance.

422.11. Overcurrent Protection. The second sentence of part (A) presents a rule based on the fact that some appliances are marked to indicate the maximum permitted rating of a protective device (fuse or CB) for the branch circuit supplying that appliance.

The rule in part (G) requires application of the overload protection provisions of 430.32 and 430.33 to motors of motor-operated appliances. And overload protection for sealed hermetic compressor motors must satisfy 440.52 through 440.55. But motors that are not continuous-duty motors—and most appliances have intermittent, short-time, or varying-duty types of motor loads—do not require running overload protection. The branch-circuit protective device may perform that function for such motors. See 430.33.

Part (E) sets limits on the maximum permitted branch-circuit protection for an individual branch circuit supplying a single nonmotor-operated appliance. This rule is aimed at providing overcurrent protection for appliances that would not be adequately protected if too large a branch-circuit protective device were used ahead of them on their supply branch circuits.

The basic rule says that if a maximum rating or branch-circuit protective device is marked on the appliance, that value must be observed in selecting the branch-circuit fuse or CB. If, however, a particular appliance is *not* marked to show a maximum rating of branch-circuit protection, the values specified in this section must be used as follows:

For an appliance drawing more than 13.3 A—the branch-circuit fuse or CB must not be rated more than 150 percent (1½ times) the full-load current rating of the appliance. For an appliance drawing up to 13.3 A—the branch-circuit fuse or CB must not be rated over 20 A.

Those values were chosen to limit the maximum rating of protection to not over 150 percent of the appliance rating to afford greater protection to the appliance, as well as to provide for continuous-

load appliances (that operate for 3 h or more continuously). In the latter case, 210.20(A) requires that a continuous load not exceed 80 percent of the branch-circuit fuse or CB; that is, the protective device is rated not less than 125 percent of the continuous-load current.

An appliance drawing 13.3 A must have protection of not over 150 percent of that value ($1.5 \times 13.3 = 20$ A), which sets 20 A as the maximum protection. And 80 percent of a 20 A rating is 16 A—so that the 13.3-A load does not exceed that value for a continuous load. For appliances drawing more than 13.3 A, the exception says that if 150 percent of the appliance current rating does not correspond to a standard rating of protective device (from 240.6), the next standard rating of protective device above that value may be used even though it is rated more than 150 percent of the appliance current rating.

Electric water heaters are typical nonmotor-operated appliances rated over 13.3 A, and 422.13 (see Fig. 422-1) says such water heaters of 120-gal (450-L) capacity or less must be classified as continuous loads, which means branch-circuit overcurrent device will be rated not less than 125 percent of the unit's current rating. And 422.11(E)(3) says the same branch-circuit device must not be rated more than 150 percent of the unit's current rating. So, for a 4500-W hot water tank on a 240 V system, the current draw will be $4500 \text{ VA} \div 240 \text{ V} = 19 \text{ A}$, 125 percent of that is 24 A and 150 percent of that is 28 A with the next higher standard size overcurrent device permitted. Therefore, in standard sizes the smallest size permitted is 25 A and the largest size is 30 A.

Fig. 422-1. Any fixed storage water heater with capacity of 120 gal (450 L) or less must be treated as a “continuous duty load” that does not load the circuit to more than 80 percent of its capacity. (Sec. 422.13.)

Part (F) of this section covers electric heating appliances using resistance-type heating elements. It requires that, where the elements are rated more than 48 A, the heating elements must be subdivided. Each subdivided load shall not exceed 48 A and shall be protected at not more than 60 A.

The rules of this section are generally similar to the rules contained in 424.22 for fixed electric space heating using duct heaters as part of heating, ventilating, and air-conditioning systems above suspended ceilings. But 422.11(F)(2) applies to commercial kitchen and cooking appliances using sheath-type heating elements. This section permits such heating elements to be subdivided into circuits not exceeding 120 A and protected at not more than 150 A under the conditions specified.

422.11(F)(3) of this same section permits a similar subdivision into 120-A loads protected at not more than 150 A for elements of water heaters and steam boilers employing resistance-type immersion electric heating elements contained in an ASME rated and stamped vessel. The 2014 NEC has broadened the scope of this allowance to include listed instantaneous water heaters and also water heaters incapable of building steam pressure. These include vented industrial process tanks (“low-pressure water heater tanks”) or tanks directly connected to vented containers with no valves or restrictions (“open-outlet water heater vessels”) separating the water from the atmosphere.

422.12. Central Heating Equipment. This rule requires a dedicated (individual) branch circuit to supply the electrical needs of “Central Heating Equipment” other than fixed electric space heating. This requires a separate circuit for the electrical ignition, control, fan(s), and circulating pump(s) of gas- and oil-fired central heating plants. The exception notes that auxiliary equipment “such as a pump, valve, humidifier, or electrostatic air cleaner directly associated with the heating equipment” *may* be connected to the same branch circuit (or another branch circuit). Using the noncoincident load concept of 220.60, permanently connected air-conditioning equipment can also be connected to the same circuit if desired.

The purpose of this rule is to prevent loss of heating when its circuit is opened due to a fault in a lamp or other appliance that is connected on the same circuit with the heater, as was permitted in the 1987 NEC and previous editions. All heating equipment should be supplied by one or more individual branch circuits that supply nothing but the heater and its auxiliary equipment.

422.13. Storage-Type Water Heaters. Water heaters with a capacity equal to or less than 450 L (120 gal) must be considered to be continuous loads. The branch-circuit overcurrent protective device (unless rated for full continuous loading) must be rated for not less than 125 percent of the water heater rating, and due to the operation of 210.19(A)(1) the sizing of the branch-circuit conductors (prior to the application of ampacity adjustment factors) follows the same procedure.

422.14. Infrared Lamp Industrial Heating Appliances (Deleted). This section now resides in Sec. 425.14 as part of the new article on industrial process heating equipment.

422.15. Central Vacuum Outlet Assemblies. This rule allows a local lighting circuit to supply the beater bar attachment or other accessories to a central vacuum system, in accordance with 210.23(A). Note that that reference carries with it the mandatory exception that disallows other connections to the dedicated appliance circuits. For example, if there is a central vacuum system outlet in a dining room, the local receptacle circuit is off-limits for this connection.

422.16. Flexible Cords. This section sets the rules for connecting certain appliances to their outlets through the use of a cord-and-plug connection. This is often a desirable design objective because when an appliance needs service, it can be disconnected without crossing trades. There are four specific headings in (B) that follow the general boilerplate rules in (A) that reiterate 400.10 and

12. Note that this language with respect to large appliances fastened in place specifically requires appropriate mechanical connections. This was aimed at disallowing cord-and-plug-connected hot water tanks.

Part **(B)(1)** covers “in-sink” waste disposers, as shown in [Fig. 422-2](#). The designation shift from “kitchen” to “in-sink” reflects the fact that these appliances should follow the rules in this part whether or not they are located in a kitchen. There are four requirements for the arrangement, including receptacle accessibility, location to avoid cord damage, permitted cord length [450 to 900 mm (18 in. to 3 ft)] and grounding or double insulation provisions. The parent language also requires that the cord set be identified in the installation instructions, so this is not an item that can be made in the field.

Fig. 422-2. Code rules aim at proper cord connections for in-sink garbage disposers. [Sec. 422.16(B)(1).]

Part **(B)(2)** covers built-in dishwashers and trash compactors. The same conditions apply here, with two differences. The receptacle for a compactor must be in the same space, or it can be adjacent thereto, which is why these receptacles often end up in the sink base. This is often preferable in terms of design, because a receptacle under the sink is usually easier to get at quickly, and as of the 2017 **NEC** this is now mandatory. Make sure that the hole in the sink base to accommodate the cord is big enough, even after plumbing connections are in place, to pass the cord cap without having to unwire it. If the cord has to be unwired, it certainly takes on the flavor of permanent wiring, contrary to 400.12(1). The second difference is the cord can be longer, to better accommodate the adjacent receptacle. These cords can be 0.9 to 1.2 m (3 to 4 ft) long in the case of a compactor, and 0.9 to 2.0 m (3 to 6½ ft) for a dishwasher, and actually longer than that because the dimension is measured from

the back plane of the appliance. Some modern kitchen designs place the dishwasher remote from the sink, which will make these rules challenging. One option always available is to hard-wire the appliance. Beyond that, ingenuity must prevail. The author once placed a receptacle behind a nearby filler panel spacing installed to accommodate a non-standard wall spacing dimension. With hidden hinges and a hidden latch the receptacle was easily accessible by a pull from the toe space. As always, communication with other trades is essential.

Part **(B)(3)** covers wall-mounted ovens and counter mounted cooking units. They are permitted to be cord-and-plug-connected, using either a receptacle or a mating cord body, but the assembly must be approved for the temperature of its location.

Part **(B)(4)** covers range hoods, including built-in microwave ovens with range hoods incorporated underneath them and installed as a single appliance. Historically range hoods could only be hard-wired; however, with the advent of these combined appliances, the **NEC** now allows for either a hood or a combination microwave and hood to be cord-and-plug-connected. The conditions are similar to the ones for waste disposers (the cord can be a foot longer), with one major additional requirement. The receptacle must be connected as an individual branch circuit, even if the original connection is to a 3-A range hood only. The intent is to prepare for a microwave oven combination later. And as discussed at the definition of “individual branch circuit” in Art. 100, a circuit supplying both halves of a duplex receptacle is not an individual branch circuit in most cases, because each half of the duplex is classified as a separate device.

422.18. Support of Ceiling Fans. This section has been rewritten to simply refer to 314.27(C) because this Code panel does not have the relevant technical jurisdiction. These rules have very little to do with paddle fans as appliances, and everything to do with how a box designed for a static load will respond to a dynamic load. Permission to use a locking support and mounting receptacle (see [Fig. 100-28](#)) is now recognized here for use with paddle fans, as covered in 314.27(E).

422.19. Space for Conductors. This rule correlates this article’s coverage of paddle fans with 314.16(B)(1), which contains within it and its exception all the relevant requirements.

422.20. Outlet Boxes to be Covered. This rule correlates paddle fan requirements with 314.25.

422.21. Covering of Combustible Material at Outlet Boxes. This rule, new for the 2014 edition, was supposed to correlate the paddle fan rules with equivalent exposures for luminaires in Sec. 410.23. However, (refer to the discussion and drawing at that section) the luminaire rule no longer has any relevance to a paddle fan canopy given the new sizing threshold. The 2017 **NEC** now correlates the requirement here with 410.23, which as a practical matter removes the requirement from the Code entirely. No paddle fan canopy will be that large.

422.30. General. Appliances must be wired on the load side of a disconnecting means in accordance with Part **III** of the article, and if multiple disconnecting means are required for a given appliance, then those disconnecting means must be grouped and “identified” as such, with each disconnecting means simultaneously disconnecting the conductors it controls. The word “identified” here is incorrect and should say “marked.”

422.31. Disconnection of Permanently Connected Appliances. This section divides the universe of permanently connected appliances into three parts. In part **(A)** lower-rated appliances

(not over 300 VA or $\frac{1}{8}$ hp) may use the “branch-circuit overcurrent device” as their disconnect means and such a device could be a plug-fuse or a CB. However, as of the 2017 **NEC** even such a trivial appliance must either be in sight of the overcurrent device, or the device must have a lock-open capability. In other words, there is no longer any operational difference between (A) and (B). This is somewhat at odds with customary **NEC** requirements. For example, 430.109(B) maintains the recognition of branch-circuit protective devices generally at $\frac{1}{8}$ hp and below. In addition, 422.31(C) Exception grants relief to permanently connected appliances over $\frac{1}{8}$ hp with unit switches; no such relief applies to smaller appliances. In part (B) higher-rated nonmotor-operated appliances does not permit use of a plug-fuse as the disconnect but requires a definite switch-action device—a switch or CB. A permanently connected nonmotor-operated appliance rated over 300 VA may use its branch-circuit switch or CB as the required disconnecting means *if* the switch or CB is within sight from the appliance or it can be locked in the open position. For 2008 in this and in countless other locations, additional language has been inserted clarifying that the lockout mechanism must be a permanent feature that stays with the switch or circuit breaker even when the lock is removed. Note that this section applies *only* to permanently connected appliances—that is, those with fixed-wiring connection (so-called hard wired) and not cord-and-plug connection.

In part (A), the overcurrent device for the circuit to the appliance is not required to be “within sight”—that is, visible and not more than 50 ft (15.0 m) away. But the switch or CB in part (B) must be within sight or must be capable of being locked open.

Part (C) covers permanently connected appliances having motor loads rated over $\frac{1}{8}$ hp. The branch-circuit switch or circuit breaker is permitted to be used as the disconnect if it is in sight of the appliance, or equipped with a lock-open capability or it can also be out of sight if the appliance has a qualifying unit switch as covered in 422.34 ([Fig. 422-3](#)).

Fig. 422-3. Toggle switch in outlet box on this central vacuum cleaner serves as the disconnecting means within sight from the motor controller installed in the top of the unit. [Sec. 422.31(C).]

According to the exception in this rule, the branch-circuit switch or CB serving as the other disconnect required by 422.34(A), (B), (C), or (D) is permitted to be out of sight from the motor controller of an appliance that is equipped with a unit switch that has a marked OFF position and opens all ungrounded supply conductors to the appliance, as shown in [Fig. 422-4](#).

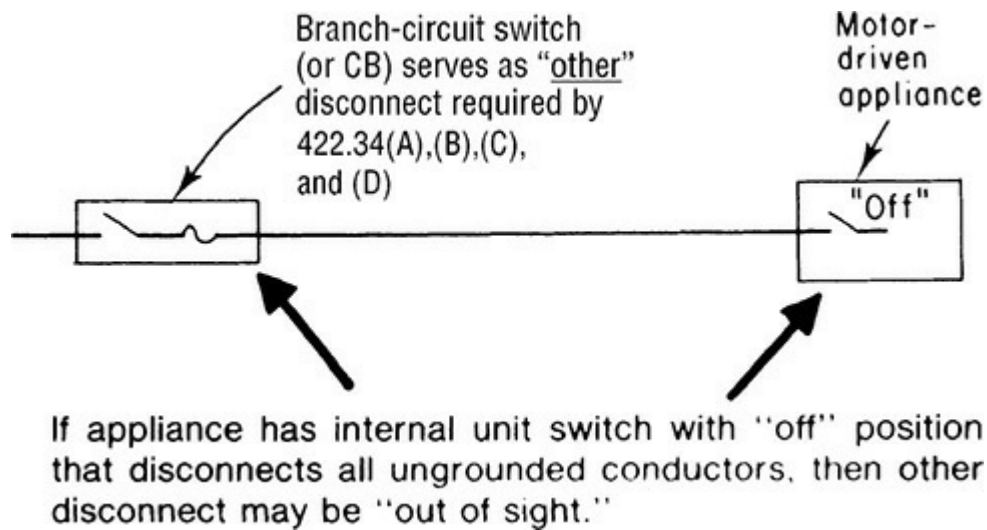

Fig. 422-4. Disconnect for motor-driven appliance may be "out of sight from the motor controller." [Sec. 422.31(C) Exception; Sec. 422.34.]

422.33. Disconnection of Cord-and Plug-Connected Appliances. Examples of the application of this section to disconnecting means for appliances are found in the installation of household electric ranges and clothes dryers. The purpose of these requirements is to provide that for every such appliance there will be some means for opening the circuit to the appliance when it is to be serviced or repaired or when it is to be removed. This section also comprehensively recognizes the receptacle and locking attachment fittings shown in [Fig. 100-28](#) and covered in 314.27(E).

In part (B), household electric ranges may be supplied by cord-and-plug connection to a range receptacle located at the rear base of the range. The rule permits such a plug and receptacle to serve as the disconnecting means for the range if the connection is accessible from the front by removal of a drawer.

This rule refers to electric ranges but the concept also applies to gas ranges. For instance, there have been 115-V receptacle outlets installed behind gas ranges in mobile homes. Such a receptacle is used only as an outlet for the oven light and clock on the range and is not accessible after the range is installed. In order to disconnect the attachment plug or plugs from the receptacle, the range gas supply pipe has to be disconnected, the frame of the range has to be disconnected from its floor fastening, and then the range has to be moved in order to reach the receptacle outlet where the cords are plugged in ([Fig. 422-5](#)). Is such an installation in conformity with the intent of the Code? The answer seems surely to be No. The inaccessibility of the receptacle would be objectionable.

Fig. 422-5. Rule on receptacle behind electric ranges could be applied to gas ranges. (Sec. 422.33.)

422.34. Unit Switch(es) as Disconnecting Means. As shown in Fig. 422-6, the ON-OFF switch on an appliance, such as a cooking unit in a commercial establishment, is permitted by part (D) to serve as the required disconnecting means if the user of the appliance has ready access to the branch-circuit switch or CB. Note that the wording does not recognize simply “the branch-circuit overcurrent device,” and a plug-fuse in the circuit to the appliance would not, therefore, be acceptable as the additional means for disconnection.

Fig. 422-6. An ON-OFF switch on an appliance must be supplemented by an additional disconnect means. (Sec. 422.34.)

For residential occupancies the rules vary by the number of units. A single-family home may simply rely on its service disconnect; in a two-family home the disconnect can be within or without and may consist of a feeder disconnect that disconnects other loads. It can be a service disconnect if the two-family dwelling is equipped with multiple service disconnects such that opening the disconnect amounts to the opening of an “individual switch or circuit breaker for the dwelling unit.” For multifamily applications an individual dwelling feeder disconnect is also permitted, but must be within the dwelling or on the same floor.

422.41. Cord-and-Plug-Connected Appliances Subject to Immersion. This is the rule that mandates the in-cord protection for hair dryers and portable hydromassage units.

422.42. Signals for Heated Appliances. The standard form of signal is a red light so connected that the lamp remains lighted as long as the appliance is connected to the circuit. No signal lamp is required if the appliance is equipped with a thermostatic switch that automatically opens the circuit after the appliance has been heated to a certain temperature. This rule does not apply in dwelling occupancies.

422.49. High-Pressure-Spray Washers. As required by this rule, a portable high-pressure-spray washing machine is required to have a “factory-installed” GFCI. *And* this factory-installed device *must* be “an integral part” of the plug cap or in the cord itself no more than 12 in. (300 mm) from the plug cap. As of the 2014 **NEC**, the rule now also applies to 3-phase equipment rated 208Y/120V and 60 A (or less), but it does not apply to washers operating over 250 V.

422.51. Cord-and-Plug-Connected Vending Machines. This rule requires an integral GFCI protector for all cord-and-plug-connected vending machines “manufactured or re-manufactured on or after January 1, 2005.” This GFCI protection must be installed by the manufacturer within 12 in. of the plug cap and be identified for portable use, which means it will have open neutral protection. For nonintegral-GFCI-protected vending machines, a GFCI-protected receptacle must be used. The term “vending machine” now has a formal definition in 422.2. As of the 2014 **NEC**, circuit-level GFCI protection for hard-wired vending machines is now a requirement.

422.52. Electric Drinking Fountains. GFCI protection is now mandated for these units, either as part of the appliance, or at or on the line side of the outlet. In other words, if it is not built into the drinking fountain, then there must be a GFCI receptacle or GFCI circuit breaker on the line side. Note that this rule does not apply to bottled water coolers.

ARTICLE 424. FIXED ELECTRIC SPACE-HEATING EQUIPMENT

424.3. Branch Circuits. The basic rule of part (A) limits fixed electric space-heating equipment to use on 15-, 20-, 25-, or 30-A circuits, *if the circuit has more than one outlet*. The second sentence of the paragraph applies only to fixed infrared equipment on industrial and commercial premises, permitting use of 40- and 50-A circuits for multioutlet circuits to *fixed* space heaters.

The continuous load requirement in paragraph (B) means that branch circuits for electric space heating equipment cannot be loaded to more than 80 percent of the branch-circuit rating. Even though electric heating is thermostatically controlled and is a cycling load, it must be taken as a continuous load for sizing branch circuits.

The three parts of this rule are as follows:

1. The branch-circuit wires must have an ampacity not less than 1.25 times the total amp load of the equipment (heater current plus motor current).
2. The overcurrent protective device must have an amp rating not less than that calculated for the branch-circuit wires.
3. If necessary, the rating or setting of the branch-circuit overcurrent device may be sized according to part (B) of 240.4. That is, if the ampacity of the selected branch-circuit wires does not correspond to a standard rating or setting of protective device (240.6), the next higher

standard rating or setting of protective device may be used. This accommodates those applications of large unit heaters, where often there is not agreement in ampacity of wires and ratings of standard fuses or CBs.

Figure 424-1 shows an example of branch-circuit sizing for an electric heat unit.

**Fuses or CB must be rated not less than
 1.25×73.7 , or 92 amps.**

**NEXT STANDARD RATING ABOVE 95-AMP
RATING OF No. 2 TW OR THW IS 100 amps**

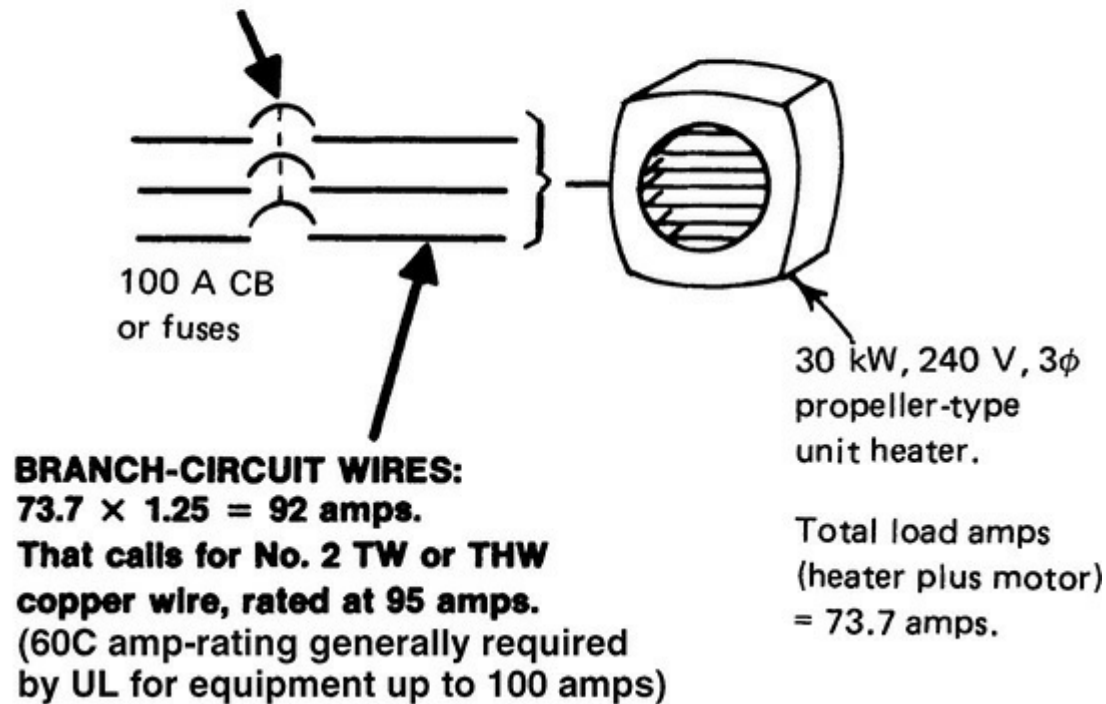

Fig. 424-1. Branch-circuit conductors and overcurrent protection must be rated not less than 125 percent of heater unit nameplate current. (Sec. 424.3.)

Many line thermostats and contactors are approved for 100 percent load, and derating of such devices is not required.

Section 220.51 covers sizing of feeders for electric space-heating loads. The computed load of a feeder supplying such equipment shall be the total connected load on all branch circuits, with an exception left up to the authority enforcing the Code, which allows permission for feeder conductors to be of a capacity less than 100 percent, provided the conductors are of sufficient capacity for the load serving units operating on duty-cycle, intermittently, or from all units not operating at one time.

424.6. Listed Equipment. Baseboard heat, duct heaters, radiant heating systems, etc. must now be listed.

424.9. General. For instance, heating cable designed for use in ceilings may not be used in concrete floors and vice versa.

This rule ties into that of 210.52(A). The note that follows says that UL-listed baseboard heaters must be installed in accordance with their instructions, which *may* prohibit installation below outlets. This applies to all occupancies— residential, commercial, institutional, and industrial.

In buildings warmed by baseboard heaters, the question arises: How can wall receptacles be

provided to satisfy the requirement of **NEC 210.52(A)** that no point along the floor line be more than 6 ft (1.8 m) from an outlet? Should the receptacles be installed in the wall above the heaters? The answer is that receptacles should not be placed above the heaters unless they have been designed to anticipate such usage, and such heaters probably don't exist. Fires have been attributed to cords being draped across heaters. Continued exposure to heat causes the cord insulation to become brittle, leading to possible short circuits or ground faults. Note that this limitation applies to electric baseboard heaters, and not to conventional central heating radiators configured as baseboard heating units using circulating hot water supplied by a furnace.

Article 210 does not specifically prohibit installation of receptacles over baseboard heaters, and Art. 424 does not specifically prohibit installation of baseboard heaters under receptacles. However, 110.3(B) says:

Installation and Use. Listed or labeled equipment shall be used, installed, or both, in accordance with any instructions included in the listing or labeling.

Underwriters Laboratories requires a warning that a heater is not to be located below an electrical convenience receptacle. A similar statement is included in the *UL Guide Card information* [see discussion at 110.3(B) for details]:

To reduce the likelihood of cords contacting the heater, the heater should not be located beneath electrical receptacles.

This instruction and the provisions of 110.3(B) make it very clear that installation of electric baseboard heaters under receptacles may be a Code violation.

Receptacles can be provided in electrically heated (baseboard-type) occupancies as required by 210.52 by making use of the receptacle accessories made available by baseboard heater manufacturers. These units are designed to be mounted at the end of a baseboard section or between two sections. Or, one could opt to utilize floor-mounted receptacles as described in 210.52(A)(3).

424.19. Disconnecting Means. The basic rule requires disconnecting means with all poles functioning simultaneously and rated for 125 percent of the total load for the heater and motor controller(s), plus supplementary overcurrent protective devices for all fixed electric space-heating equipment. If multiple circuits supply the equipment, then there will be multiple disconnects, and they must be grouped. As in other locations, the disconnects must be lockable and the locking provisions must not be removable when the lock itself is removed, as required in 110.25.

Part (A) of this section applies to heating equipment provided with supplementary overcurrent protection (such as fuses or CBs) to protect the subdivided resistance heaters used in duct heating, as required by 424.22. The basic rules are shown in [Fig. 424-2](#). The disconnect in that drawing must comply with the following:

Fig. 424-2. Rules on disconnects for heating equipment demand careful study for HVAC systems with duct heaters and supplementary overcurrent protective devices. (Sec. 424.19.)

The disconnect must be “within sight from” the supplementary overcurrent panel. If circuit breakers are used as the supplementary overcurrent protective devices for the subdivided electric heating loads [424.22(B)], the circuit breakers may constitute the disconnects required by this section if they have the required locking provisions. This rule has to be correlated with the parent language and other rules based on whether there is a motor over $\frac{1}{8}$ hp. If there isn't (or the motor is smaller), then the disconnects in (A) are acceptable as the heater disconnects. If there is, then the disconnects qualify if one of four options is in place. However, because of the lock-open amendments in the 2008 **NEC** in the parent language of 424.19, the disconnects for (or constituting in the case of circuit breakers) the supplementary heat and other loads are guaranteed to meet (2) that covers, among other options, a lock-open disconnecting means, and it is pointless to review the other options in detail. Note that the options in 424.19(A)(2) now line up with 422.31(C), which is sensible given the nature of the loads. However, the disconnect in 424.19 appears to make these requirements superfluous.

Part (B) applies to heating equipment *without* supplementary overcurrent protection.

Care must be taken to evaluate each of the specific requirements in this Code section to actual job details involved with electric heating installations. For room thermostats, see the discussion at 424.20.

Figure 424-3 shows two conditions that relate to the rules of part (B) of this section. For the two-

family house, the service panel is located in a rear areaway and is accessible to both occupants. Circuit breakers in the panel constitute suitable means of disconnect for heaters in both apartments —*but* only if they are lockable. If the house uses baseboard heaters without motors in them, lockable breakers would be acceptable as the disconnects in accordance with the rule of **(B)(1)**. For the four-family house (a “multifamily dwelling”), the service panels accessible to all tenants are grouped in the hallway under the first-floor stairway in this four-family occupancy. If lockable, the switches in the panels may constitute suitable means of disconnect for heaters in all apartments, under the rule of **(B)(1)**. It should be noted that if the CBs are *not* capable of being locked open, then another disconnect that *is* lockable *or* within sight of the heater must be provided. And in either case, the locking provision must meet the requirements in the parent language in 424.19. But note that plug-fuses (without switches) on branch circuits to the heaters would not satisfy **(B)(1)**.

Fig. 424-3. For nonmotored electric heating units, a branch circuit switch or CB that is “within sight” from the heater or lockable may serve as disconnect. (Sec. 424.19.)

Note that **(B)(2)** requires a disconnect “within sight from” a motor controller serving a motor-operated space heater with a motor over $\frac{1}{8}$ hp, while permission is also given to use the rule of 424.19(A)(2).

Part **(C)** permits the ON-OFF switch on the heating unit to be used as the disconnecting means where “other means for disconnection” are provided, depending on the occupancy.

424.20. Thermostatically Controlled Switching Devices. Figure 424-4 shows a hookup

of duct heaters that are controlled by a magnetic contactor that responds to a thermostatic switch in its coil circuit. The subdivided heater load of 48 A per leg satisfies the rule of 424.22(B), *but* the contactor does not constitute a combination controller-and-disconnect means because it does not open all the ungrounded conductors of the circuit. And because the heater contains the 60-A supplementary overcurrent protection, a disconnect ahead of the fuses would be required by 424.19(A) even if the contactor did open all three ungrounded conductors of the circuit. Note that the usual across-the-line room heating thermostats with a marked OFF position that open all ungrounded conductors in that position qualify as disconnects for baseboard heaters within sight of the thermostat, and thereby meet 424.19(B)(1) without further action to provide lockout mechanisms to circuit breakers, etc., elsewhere in the circuit.

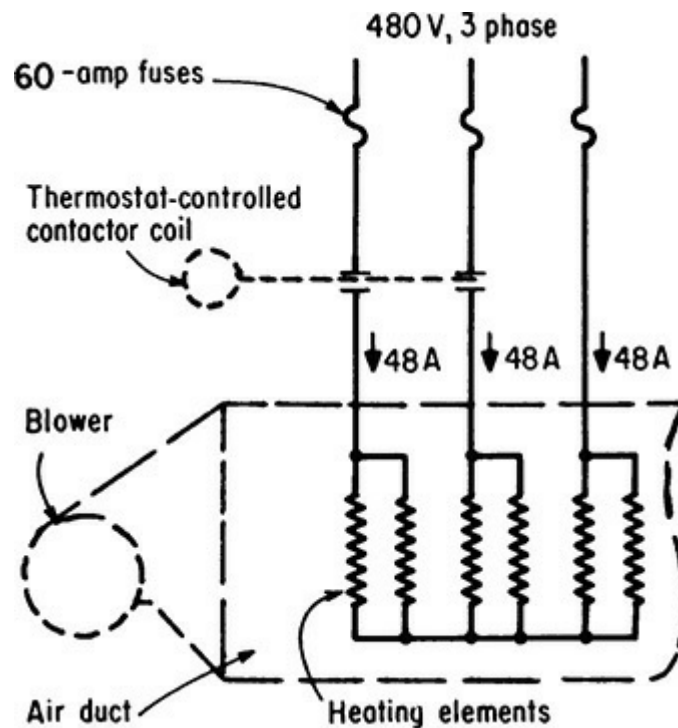

Fig. 424-4. This contactor may not serve as both controller and disconnect. (Sec. 424.20.)

424.22. Overcurrent Protection. Heating equipment employing resistance-type heating elements rated more than 48 A must have the heating elements subdivided, with each subdivided circuit loaded to not more than 48 A and protected at not more than 60 A. And each subdivided load must not exceed 80 percent of the rating of the protective device, to satisfy 424.3(B). Such a 60-A circuit could be classed as an individual branch circuit supplying a “single” outlet that actually consists of all the heater elements interconnected. By considering it as an “individual branch circuit” there is no conflict with 424.3(A), which sets a maximum rating of 30 A for a multioutlet circuit. The resistance-type heating elements on the market are not single heating elements in the 48-A size. They are made up of smaller wattage units in a single piece of equipment. The Code rule states that this single piece of equipment made up of smaller units must not draw more than 48 A and must be protected at not more than 60 A. Thus a heater of this type is limited to 48 A for each subdivided circuit. The subdivision is usually made by the manufacturer in the heater enclosure or housing.

Part (B) points to 424.3(B), whose continuous load requirement effectively requires that a resistance load less than 48 A have protection rated not less than 125 percent of heater current. The sentence at the end of this paragraph covers overcurrent protection sizing for subdivided resistance-

heating-element loads that are less than 48 A.

Figure 424-5 shows an example of subdivision of heater elements in a heat pump with three 5-kW strip heaters in it. At 240 V, each 5-kW strip is a load of about 21 A. Two of them in parallel would be 42 A and that is not in excess of the 48-A maximum set by part (B) of this section. The three heaters would be a load of 63 A in parallel. There are a number of ways the total load might be supplied, but the Code rules limit the actual permitted types of hookup:

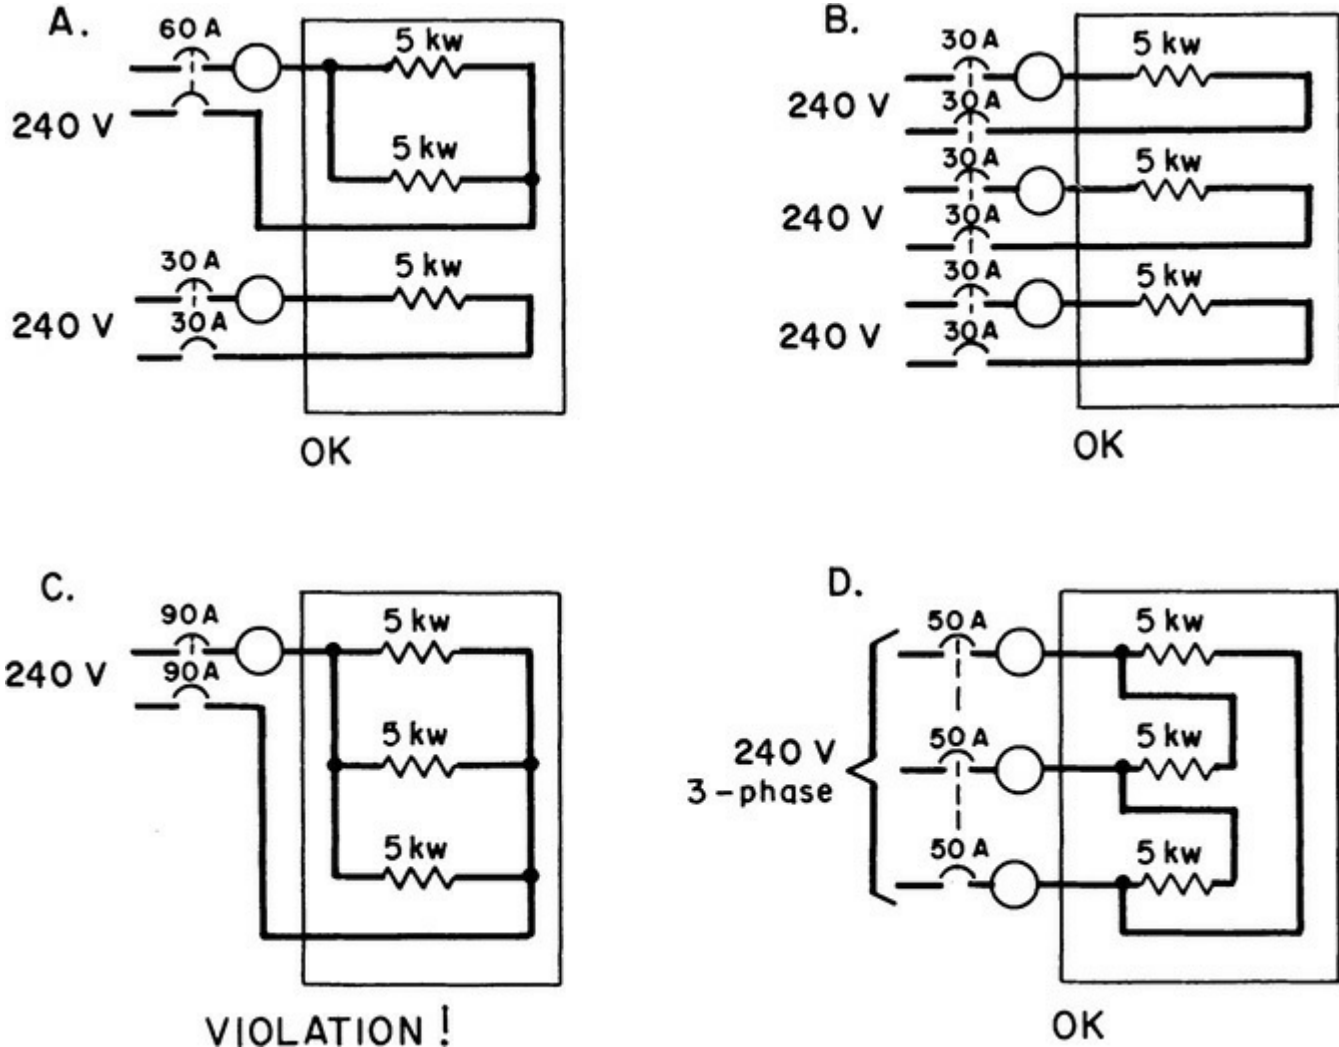

Fig. 424-5. Heater units must be limited to 48-A load with protection not over 60 A. (Sec. 424.22.)

Section 424.3(A) states that an individual branch circuit may supply any load, but that permission is qualified by part (B) of this section, which requires resistance heating loads of more than 48 A to be subdivided so that no subdivided heater load will exceed 48 A, protected at not more than 60 A. As shown at A, one possible way to hook up the heaters is to use two strips on one circuit for a connected load of 2×21 , or 42 A, and the other on one circuit with a connected load of 21 A. The two heaters would require a minimum ampacity for overcurrent protection of 42×1.25 , or 53 A, calling for a 60-A overcurrent device. For the other circuit, 21×1.25 equals 26 A, requiring a 30-A fuse or breaker. Both circuits would thus be within the limits of a 48-A connected load and 60-A protection. As shown at B, it would also be acceptable to use a 30-A, 2-wire, 240-V circuit to each heater. But use of a single circuit sized at 1.25×63 A (79 A) and protected by 80-A fuses or breaker would clearly violate the Code rule of 60-A maximum protection, as at C.

Another possibility that would give a better balance to the connected load would be to feed the

load with a 3-phase, 3-wire, 240-V circuit, if available. For such a circuit, the loading would be:

$$\frac{15,000}{1.732 \times 240} = 36 \text{ A}$$

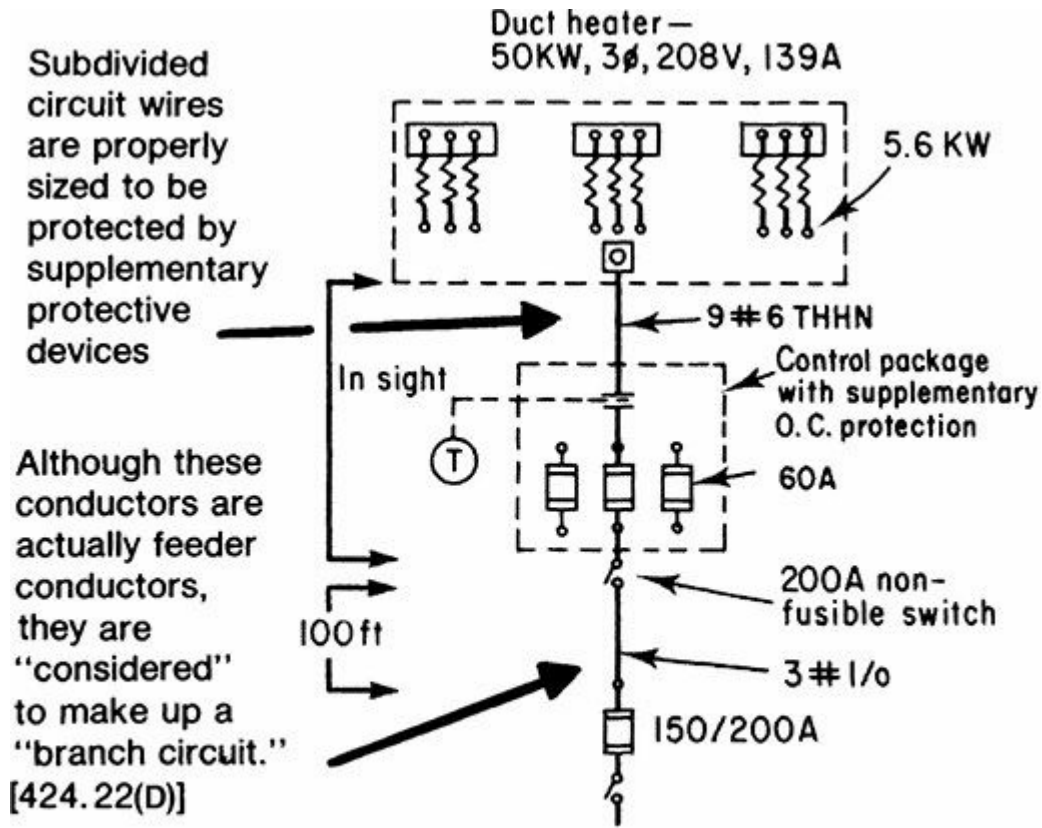

The minimum rating would be $36 \text{ A} \times 1.25$, or 45 A, which calls for 45-A overcurrent protection. Since 50 A protective devices are more common, and since such a rating is still below the 60 A maximum for resistance elements, the 50 A rating in *D* is OK. Note that if the same furnace were connected to a 208 V 3-phase circuit, the lower voltage across the same resistance would lower the current to 31 A. Don't make the mistake of simply plugging 208 V into the above formula and expecting the current draw to be 42 A.

It should be noted that the rule of part **(B)** in this section applies to *any type* of space-heating equipment that utilizes resistance-type heating elements. The rule applies to duct heaters (as in [Fig. 424-4](#)), to the strip heaters in [Fig. 424-5](#), and to heating elements in furnaces.

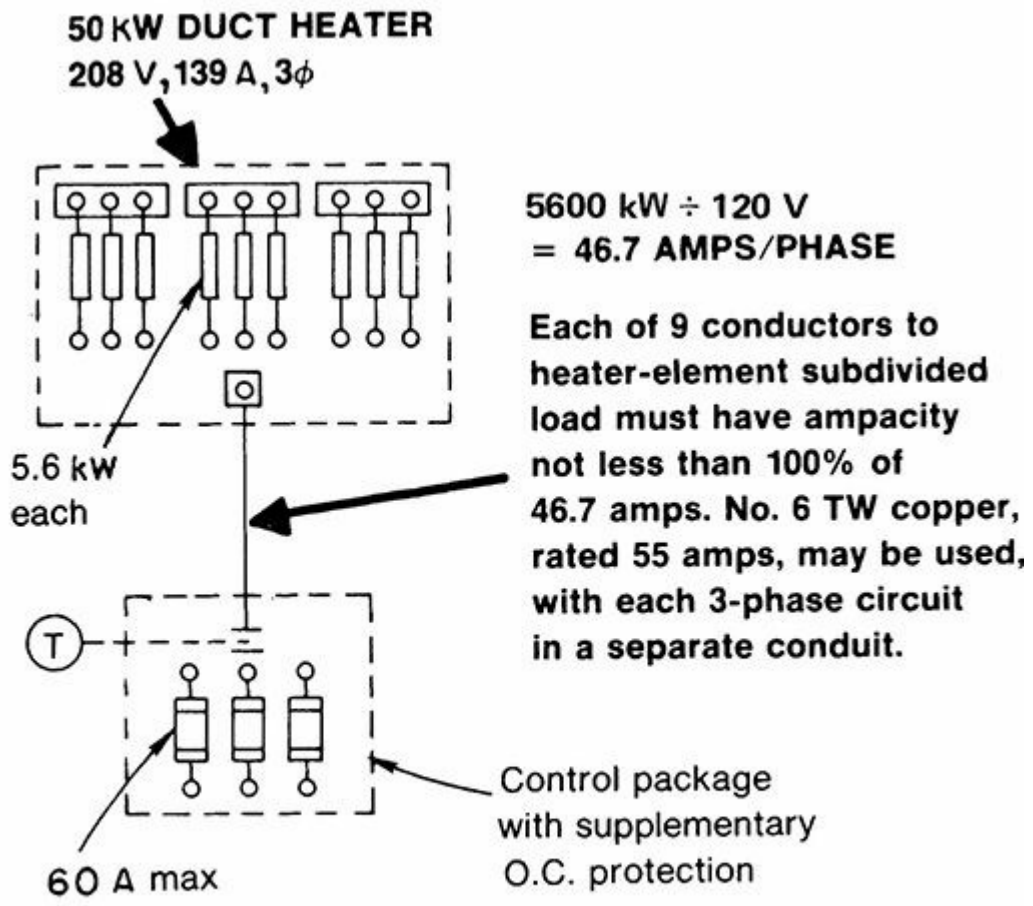

The purpose of paragraph **(C)** of this section is to require the heating manufacturer to furnish the necessary overcurrent protective devices where subdivided loads are required.

Per Part **(D)**, main conductors supplying overcurrent protective devices for subdivided loads are considered as branch circuits to avoid controversies about applying the 125 percent requirement in 424.3(B) to branch circuits *only*. It is not the intent, however, to deny the use of the *feeder tap* rules in 240.21 for these *main* conductors.

Paragraph **(E)** requires that the conductors used for the subdivided electric resistance-heat circuits specified in 424.22(C) must have an amp rating not less than 125 percent of the rating or setting of the overcurrent protective device protecting the subdivided circuit(s) ([Fig. 424-6](#)). The last paragraph provides what amounts to an exception to the basic rule, for heaters rated 50 kW or more where under the conditions specified it is permissible for the conductors to have an ampacity not less than the load of the respective subdivided circuits, rather than 100 percent of the rating of the protective devices protecting the subdivided circuits.

NOTE: There are exceptions for certain equipment.

NOTE: Conditions (1), (2), and (3) of Part (D) must be satisfied.

Fig. 424-6. Conductors for subdivided heater circuits must fully match overcurrent device rating. (Sec. 424.22.)

The wording of part (E) clarifies the need for field-wired conductors rated not less than 125 percent of the load-current rating, which must not exceed 48 A. The rating of supplementary overcurrent protection must protect these circuit wires at their ampacity, although the next higher standard rating of protection may be used where the ampacity of the circuit wires does not correspond to a standard protective device rating.

For instance, if the subdivided resistance-heating load is 43 A per phase leg, the branch-circuit conductors must have an ampacity at least equal to 1.25×43 , or 53.8 A. That would call for No. 6 TW with an ampacity of 55 A. The next standard rating of protection is 60 A, and that size protection may be used, although 60 A is the maximum size permitted for the subdivided load. The rule of the last paragraph is shown in the bottom part of Fig. 424-6.

424.35. Marking of Heating Cables. As of the 2017 NEC, the former color coding for voltage ratings table has been deleted; however, the marking for volts and either amperes or watts still applies.

424.36. Clearances of Wiring in Ceilings. Figure 424-7 shows the details of this rule. The wire at *a* is okay because it is not less than 2 in. (50 mm) above the ceiling, but it must be treated as operating at a 50°C ambient. The same is true of the wire at *c*, because it is within the insulation. The correction factors in Table 310.15(B)(2)(a) show that TW wire (60°C-rated wire) must be derated to 58 percent (0.58) of its normal table ampacity when operating in an ambient of 41°C to 50°C.

Fig. 424-7. Wiring above a heated ceiling may require derating because of heat accumulation. (Sec. 424.36.)

424.38. Area Restrictions. Figure 424-8 shows installations of heating cables and their relation to Code rules. The blanket prohibition against heating cables leaving the room from which they originate, formerly in (A), has been removed in the 2017 NEC in favor of more targeted limitations in (B) that address the real issues.

VIOLATION — cable extends beyond room and is installed in the closet. Cable in foyer is OK

OK — this cable is permitted in closet. Single cable runs that are embedded may cross partition.

THIS IS OK Clearance from top of cabinet to ceiling is at least equal to the cabinet's minimum horizontal dimension (12 in.). Cable may extend over the cabinet.

Fig. 424-8. Layouts of heating cables must generally be confined to individual rooms or areas. (Sec. 424.38.)

Heating cables shall not be installed under or through walls. They must not pass over the top of walls where the wall “intersects” the ceiling, but the single isolated run of embedded cable is still permitted to pass over a “partition” that extends to the ceiling.” The intent here is to avoid repeated crossings of cable over (or under) partitions, because radiation from these sections would be restricted or the cable would be unnecessarily exposed to possible physical damage. While the Code specifically speaks of partitions, the same reasoning would apply to arches, exposed ceiling beams, and so forth. The prohibitions now also include tub and shower walls, and under cabinets, etc. with no floor clearance.

However, there are times when a small ceiling area (such as over a dressing room or entryway) is separated from a larger room by such an arch or beam, yet it is impractical to install a separate heating cable and control. The rule of part (3) was intended as a solution to this problem. A typical floor plan of such a situation is shown in Fig. 424-9, with two methods of getting the heating cable past the partition or beam. In the upper drawing the cable is brought up into the attic space, through a porcelain tube, and back down through the gypsum board. Plaster is then forced into the tube and

puddled over the exposed cable and tube in the attic. This should be the same plaster or joint cement that is used between the two layers of gypsum board.

Fig. 424-9. Part (B)(3) of rule permits single runs across partitions. (Sec. 424.38.)

In the lower drawing a hole is drilled through the top plate of the partition (or beam) and a porcelain tube is pressed into the hole. Plaster is packed into the tube after the cable has been passed through. In both cases, the plaster serves to conduct heat away from the cable, avoiding hot spots and possible burnouts.

424.39. Clearance from Other Objects and Openings. Figure 424-10 shows application of the specified clearance distances for different conditions. Although frequently within the scope of other trades and being therefore unenforceable, no surface-mounted equipment, whether electrical or not, is permitted to cover ceiling cables.

Fig. 424-10. Heating cables installed in ceilings must be kept clear of equipment. (Sec. 424.39.)

424.41. Installation of Heating Cables on Dry Board, in Plaster, and on Concrete Ceilings. All heating cables must observe these application methods. [Figure 424-11](#) shows the rules of paragraph (B) and paragraph (F).

Fig. 424-11. The prescriptive rules on routing adjacent runs of cable ($\leq 2\frac{3}{4}$ watts/ft to be $\geq 1\frac{1}{2}$ in. on centers) have been removed in the 2017 **NEC** in favor of a simple reference to the manufacturer's instructions. [Sec. 424.41(B).]

Figure 424-12 shows the rule of paragraph **(D)** and ties into the rule of 424.43(C) at the outlet box.

Fig. 424-12. Ends of nonheating leads must be embedded in ceiling material. (Sec. 424.41.)

Heating cable installed in plaster or between two layers of gypsum board must be kept clear of ceiling luminaires and side walls. In drywall construction, cable must be embedded in mastic or plaster. Without it, dead air space between the cable runs acts as a heat reservoir, increasing the possibility of cable burnouts (Fig. 424-13). Cable movement caused by the expansion and contraction accompanying temperature changes is also prevented. Laboratory tests on cable used without mastic have found properly spaced adjacent cable runs actually making contact with each other, producing a hot spot and subsequent burnout. The plaster and sand mixture normally used as a mastic is a good conductor of heat and thus accelerates the dissipation of heat from the entire circumference of the cable. In addition, it improves the conductance from the cable to the gypsum board where the cable does not make direct contact. Even in the most careful installations small irregularities in construction and material prevent perfect contact between the cable and both layers of gypsum board throughout the entire cable length. In no case should an insulating plaster be used. Thickness of the plaster coat should be just sufficient to cover the cable. Installations have been made, unfortunately, with plaster thickness as great as $\frac{3}{4}$ in. (19 mm). Nails are not capable of supporting the resulting excessive weight, and such ceilings have collapsed. Figure 424-14 shows rules that apply to installation of heating cables in drywall ceilings. Similar to in the case of 424.41(B), the 2017 **NEC** also recognizes alternatives as covered in the manufacturer's instructions, particularly when coping with metal lath or other conductive surfaces.

Fig. 424-13. In a drywall ceiling, the heating cable must be covered with a thermally conductive mastic before second course of gypsum board is applied to the ceiling, over the heating cable. (Sec. 424.41.)

Fig. 424-14. Additional rules apply only to drywall ceiling construction. (Sec. 424.41.)

Where the cable is to be embedded between two layers of gypsum board (dry-wall construction), after the cable is stapled to the layer of gypsum lath, it is covered with noninsulating plaster or gypsum cement, and a finishing layer of gypsum board (Sheetrock) is screwed in place covering the cable and plaster. To make sure that screws driven to secure this gypsum board to the ceiling joists do not penetrate the cable, a clear space at least 2½ in. (65 mm) wide must be left between adjacent cable runs immediately beneath each joist. That is, while adjacent cable runs must in general be at least 1½ in. (38 mm) apart, the spacing beneath joists must be increased to at least 2½ in. (65 mm). This means, of course, that the cable must be run parallel to the joists, as in part (I).

Part (J) requires that heating cables in ceilings must cross joists only at the ends of the room, except where necessary to satisfy manufacturer's instructions. If manufacturer's instructions advise the installer to keep the cable away from ceiling penetrations and light luminaires, the exception here will permit crossing joists at other than the ends of the room.

424.43. Installation of Nonheating Leads of Cables. Part (C) of this rule prohibits cutting off any of the length of heating leads that are provided by the manufacturers on the ends of heating cable. Any excess length of such leads must be secured to the ceiling and embedded in plaster or other approved material.

424.44. Installation of Cables in Concrete or Poured Masonry Floors. Details of these rules are shown in [Fig. 424-15](#).

Fig. 424-15. Specific rules apply to heating cable in concrete floors. The drawing shows traditional heat density and spacing values; the 2017 NEC has removed these prescriptive requirements in favor of reliance on the manufacturer instructions. (Sec. 424.44.)

Paragraph **(B)** requires cables to be secured in place by nonmetallic frames or spreaders or other approved means. Metallic supports such as those commercially available for use in roadways or sidewalks are not to be used in floor space-heating installations. Lumber is often used, although a more common method is to staple the cable directly to the base concrete after it has set about 4 h. It was not the intention that this Code paragraph prohibit the use of metal staples. The object was to reduce the possibility of short circuits because of continuous metallic conducting materials spanning several adjacent cable runs.

The former requirement for spacing between the cables and metal embedded in the floor has been deleted in the 2017 **NEC**. Current product standards require a grounded braid or sheath over the cable as part of the assembly; this was not the case when the requirement first entered the Code.

Paragraph **(C)** requires leads to be protected where they leave the floor, and paragraph **(D)** adds that bushings shall be used where the leads emerge in the floor slab. These provisions refer to the nonheating leads that connect the branch circuit homerun to the heating cable. The splices connecting the nonheating leads to the cable are always buried in the concrete. About 6 in. (152 mm) of leads is left available in the junction box; any remaining length of nonheating leads is buried in the concrete.

The last part, part **(E)**, presents a general rule covering in-the-floor heating leads in kitchens (new as of the 2011 edition), bathrooms and hydromassage bathtub “locations.” Here the Code mandates GFCI protection for the supply circuits to the heating elements in such equipment. With electrically heated bathroom floors, the GFCI required will be in addition to any others required. Note that for pool areas, 680.27(C)(3), and as extended for spa and hot tub areas by 680.43, radiant cable heating is not permitted in floor decks in either location.

424.45. Installation of Cables Under Floor Coverings. This section, new in the 2107 **NEC**, recognizes the use of heating cables for under floor coverings, such as ceramic tile (popular in bathroom areas, and also under laminate flooring or even carpeting). The installation requirements, as reflected in installation instructions, clearly parallel heating panels, as have been recognized in Sec. 424.99 since the 1987 **NEC**. The installations must be done in accordance with the product listing and instructions, which account for and evaluate the risks associated with these installations. However, because Part V of Art. 424 did not specifically mention under floor coverings for cables, it was unclear if these applications were permissible. The new section clarifies the acceptability of the heating method. The specific requirements match up to 424.99 almost exactly. The only minor difference is the requirement in 424.99 for the floor substrate to be flat and smooth; this does not occur in 424.45, which makes sense because cables will be more forgiving of minor floor irregularities than panels.

424.47. Label Provided by Manufacturer. This requirement, which correlates with 424.92(D) for heating panels, augments the circuit directory rules in 408.4(A) and requires labels to be provided by the manufacturer that will adhere to branch-circuit panelboards and other circuit sources and provide prominent notice as to the existence of space heating cables and the identities of the branch circuits supplying those cables. A label need not be posted in the event the cables are visually evident after the installation is complete.

424.57. General. The rules of Part VI of Art. 424 apply to heater units that are mounted in air-duct systems, as shown in [Fig. 424-16](#).

Fig. 424-16. Electric heaters designed and installed to heat air flowing through the ducts of forced-air systems are covered by Secs. 424.57 through 424.66. (Sec. 424.57.)

424.70. Scope. In applying Code rules, care must be taken to distinguish between “resistance-type” boilers and “electrode-type” boilers (Fig. 424-17).

Fig. 424-17. Electric boilers with resistance-type heating elements are regulated by Secs. 424.70 through 424.74. (Sec. 424.70.)

Fig. 424-18. Electric boiler contains subdivided heating-element circuits, totalling 360 kW. Fuses protect the subdivided circuit loads. (Sec. 424.72.)

424.72. Overcurrent Protection. Heating elements of resistance-type electric boilers must be arranged into load groups not exceeding the values specified in paragraph (A) or (B). [Figure 424-18](#) shows a 360-kW electric boiler used to heat a large school.

Part (E) requires that the ampacity of conductors used between the heater and the supplementary overcurrent protective devices for the subdivided heating circuits within such boilers must not be less than 125 percent of the load served. Again, however, the last paragraph permits conductors rated at 100 percent of the load for heaters rated 50 kW or more under certain given conditions.

424.80. Scope. This part of the article covers electrode-type boilers. The requirements are the same as for resistance-type boilers with the major exception that the requirement to subdivide load over 48 A is not present.

424.90. Scope. The rules of 424.91 through 424.98 apply to radiant heating panels and heating panel sets. Rules on electric radiant heating panels are separated from the rules on heating cables. The **NEC** at one time did cover both heating cables and heating panels within the same set of rules. Panels are generically different from cables and require separate specific rules on installation and layout details essential to safety.

424.95. Location of Branch-Circuit and Feeder Wiring in Walls. When electric heating panels are mounted on interior walls of buildings, any wiring within the walls behind the heating panels is considered to be operating in an ambient of 40°C rather than the normal 30°C for which conductors are rated. Because of this, the ampacity of such conductors in wall spaces behind electric heating panels must be reduced in accordance with the correction factors given as part of Table 310.15(B)(2)(a) [424.95(B)] ([Fig. 424-19](#)). Exterior walls have no such prescriptive rule, only a reference to 310.15(A)(3). If the walls are uninsulated, the factor would be based on an

analysis of climate extremes. The data discussed at 310.15(B)(2)(c) would be a good place to start. If the walls are insulated, then the quality of the insulation has a dramatic effect on how potential-derating factors might be assigned. Refer to the discussion at 310.15(A)(3) for an actual example and a general discussion of the impact of insulation on wiring.

Fig. 424-19. Wiring in walls behind heating panels must have ampacity corrected for more than 30°C. (Sec. 424.95.)

424.97. Nonheating Leads. Excess length of the nonheating leads of heating panels may be cut to the particular length needed to facilitate connection to the branch-circuit wires (Fig. 424-20).

Fig. 424-20. The rule permits cutting of nonheating leads for “panels.” (Sec. 424.97.)

424.100. Scope. This introduces a new Part X in Art. 424 in the 2017 **NEC** to cover “Low-Voltage Fixed Electric Space-Heating Equipment.” The panel has made the assumption that these systems will operate in dry locations. This equipment must include an isolating power supply that will result in an ungrounded system in accordance with 424.103(B). The power supply must also be limited to maximum current of 25 amps at 30 volts ac or 60 volts dc, parameters that exactly coincide with those for low-voltage lighting in Art. 411. The entire system (424.102) including the heaters must be listed as a complete system and not, in contrast to Art. 411, as an assembly of listed parts.

One of the more intriguing aspects of Part X is 424.101(A), which clearly anticipates such applications as off-grid powering directly from wind or solar sources. Any power conversion equipment must meet the “applicable section” of the **NEC** for the source used; the source being limited to the general system limits covered above. Although this is extremely vague, the universal listing requirement will undoubtedly bring with it a plethora of installation specifications by the equipment manufacturer. The part omits any specific requirements for overload protection for the wiring. The substantiation indicated that the listing process would generate those parameters, which should then be followed. It also noted that the currents that could be generated may be enough to compromise the wiring, but the substantiation then continued to rely on the listing. This is not really a problem for a [Chap. 4](#) (equipment) article; other rules in [Chaps. 1](#) through [3](#) will still apply. If one of these systems is truly operating in a stand-alone mode, it will also be subject to the requirements of the new Art. 710, and 710.15(B) would require the wires to be sized based on the output rating, and that would avoid the need for overload protection.

ARTICLE 425. FIXED RESISTANCE AND ELECTRODE INDUSTRIAL PROCESS HEATING EQUIPMENT

425.1 Scope. This article, new in the 2017 **NEC** covers fixed electrically powered industrial process heating using resistance or electrode technology. The article does not cover, for obvious reasons, technology for personnel comfort, including heating processes only designed for residential spaces. Specifically, the following Art. 424 provisions have no counterpart in Art. 425:

424.19(C)(1 through 4) on residential unit switches

424.20 on environmental air thermostats

424.34 through 424.47 on space heating cables

424.61 and 424.62 on duct heaters with air conditioners

424.90 through 424.99 on radiant heating panels

424.100 through 424.104 on low-voltage electric space heating

After the remainder of Art. 424 is essentially cut and pasted as Art. 425 and carefully analyzed, the results are disturbing. The article is approximately 68 column inches long. Of that text, a careful comparison, after correcting what will almost certainly be acknowledged as formatting errors that failed to record carriage returns and in one case took normal text and converted it into an exception, shows that only 6 of the roughly 68 column inches occupied by the new article actually creates substantively different rules than what is already required in Art. 424, about 9 percent. The remainder of this analysis will be confined to offering background information on the areas that differ. Any section not included in the two mentioned here is substantively covered in Art. 424, and addressed in this book to the extent appropriate to its scope in the coverage of that article.

425.8 General. Part (A) is the duct heater installation language in 424.66 made broadly

applicable to equipment covered in the article. See [Fig. 424.16](#) for an example of cramped spaces often encountered about this equipment. The working space rules in (B) reiterate 110.26 and 110.34 based on whether or not the voltage exceeds 1000 volts. Part (C) sets practical rules for common industrial circumstances requiring working from ladders.

425.9. Approval. This topic is taken from Art. 424 and won't be analyzed here, but it does provide a basis to make an interesting observation about the new article. Art. 424 includes a wide-ranging listing requirement in 424.6. Article 425 does not have such a section, although some of its provisions use the term. This reflects the reality that a great deal of electrical equipment in the industrial environment is uniquely assembled for a complex task, and listing is impracticable. What is here, in this section (as in 424.5) is a simple requirement that covered equipment be installed in an approved manner, acceptable to the inspector.

ARTICLE 426. FIXED OUTDOOR ELECTRIC DEICING AND SNOW-MELTING EQUIPMENT

426.1. Scope. In addition to covering the longtime standard methods and equipment for electric deicing and snow melting, this article gives detailed coverage of *skin-effect heating*—a system for utilizing the alternating-current phenomenon of skin effect, which derives its name from the tendency of ac current to flow on the outside (the skin) of a conductor. This action is produced by electromagnetic induction, which has an increasing opposition to current flow from the outside to the core of the cross section of a conductor.

In the layout of the article, separate coverage is given to “Resistance Heating,” “Impedance Heating,” and “Skin-Effect Heating.”

426.4. Continuous Load. This basic rule requires that where electric deicing or snow-melting equipment is connected to a branch circuit, the rating of the branch-circuit overcurrent protection and the branch-circuit conductors must be not less than 125 percent of the total load of the heaters ([Fig. 426-1](#)).

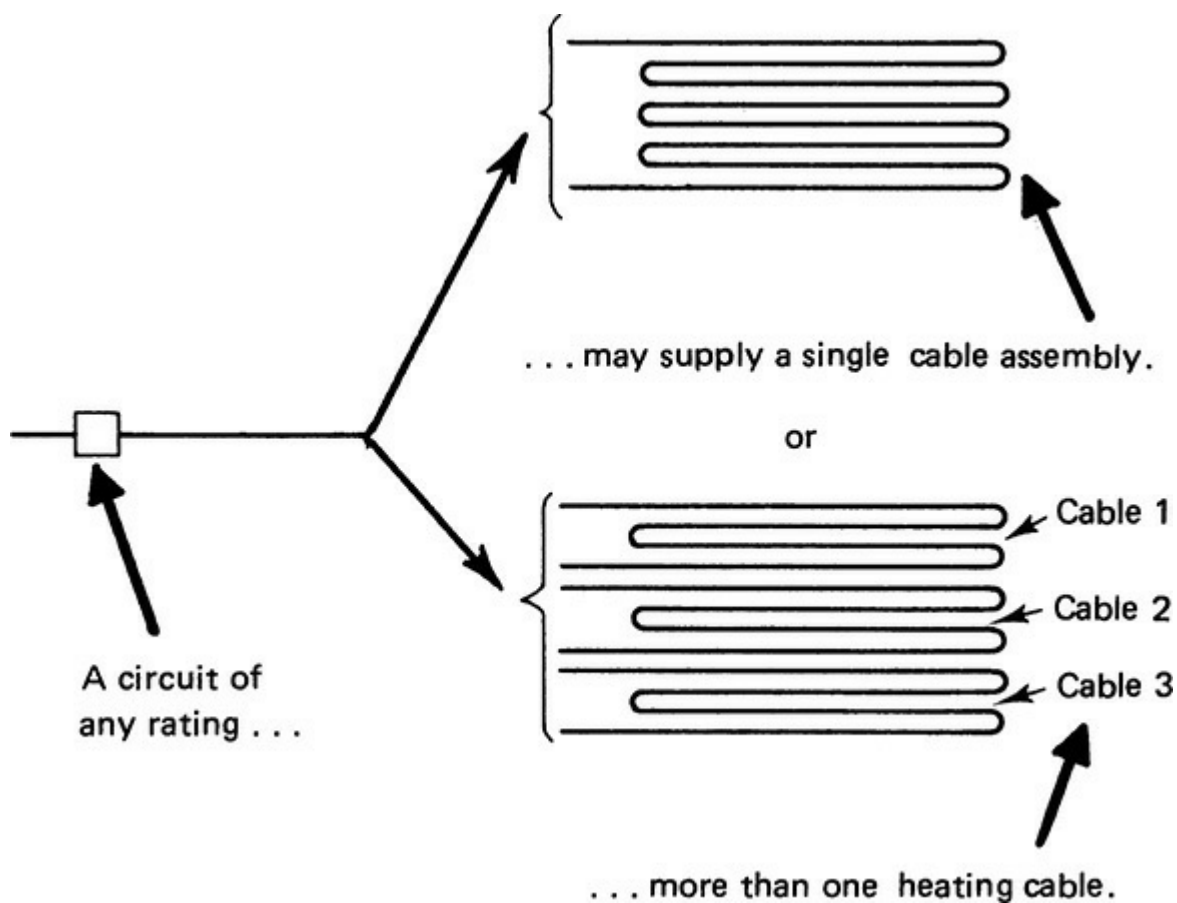

Fig. 426-1. Electric deicing or snow-melting equipment may be fed by a circuit of any rating, provided it is sized for a “continuous” load. (Sec. 426.4.)

Both the circuit conductors and the overcurrent protection must be rated so the load is not over 80 percent of their amp rating. When the branch-circuit conductors are selected to have ampacity of at least 125 percent of the amp value of connected snow-melting and/or deicing load equipment, it is permissible to go to the next higher amp value of overcurrent protection where the ampacity of the conductors does not correspond to a standard rating of protective device from 240.6.

426.11. Use. Whether used in concrete, blacktop, or other building material, any deicing or snow-melting cable, panel, mat, or other assembly must be properly recognized (as by UL) for installation in the particular material. One key installation detail concerns concrete embedment in terms of whether a single or a double pour is required. If the installation instructions are silent on this topic then either method is acceptable, but if a double pour is intended, then the instructions will so state.

426.13. Identification. This rule requires the presence of a deicing or snow-melting installation to be effectively indicated to ensure safety and to prevent disruption.

After a snow-melting installation is made, some type of caution sign or other marking must be posted “where clearly visible” to make it evident to anyone that electric snow-melting equipment is present.

426.23. Installation of Nonheating Leads for Exposed Equipment. Part (A) of this rule permits cutting (shortening) of the nonheating leads provided the required marking on the leads (catalog numbers, volts, watts) is retained. That is not permitted for space-heating cables, which may not be cut [424.43(C)]. The marking on the nonheating leads of snow-melting cable must be within 3 in. (75 mm) of *each* end of the lead. The wording appears to permit cutting the nonheating leads back to the marking closest to the connection to the heating cable—which would mean a length of 3 in. (75

mm) plus needed for the marking is all that would be required. Or a length could be cut out between the two markings, provided that any splicing that would necessitate is made in boxes, as specified in 426.24(B). (The rule of 426.22 is shown in Figs. 426-2 and 426-3.)

Fig. 426-2. Detailed rules cover installation of heating and nonheating conductors. (Secs. 426.20, 426.21, and 426.22.)

COMPLIES WITH RULES — Nonheating leads with copper grounding braid may have any length embedded in concrete.

VIOLATION — Excessive length of nonheating leads without a grounding sheath or braid.

Fig. 426-3. Installation of nonheating leads must observe all the rules. (Sec. 426.22.)

426.28. Ground-Fault Protection of Equipment. Resistance snow-melting cables for rooftops typically involve long lengths of two-wire cable in a semiconductive filler that, when energized, results in a diffuse passage of current along the cable length. The actual wires embedded in the cable construction are quite small, and if the cable is damaged, any ground fault will result in a

very low current event due to the overall resistance. These faults are far too low to open an overcurrent device; however, the sputtering arc can easily create fires because the damaged cable can restrike the arc due to the semiconductive nature of the surrounded cable filler. The solution is a residual current device similar to a GFCI, but with a 30-mA trip setting (manufacturers vary somewhat). These devices are a form of low-level ground-fault protection of equipment (GFPE), configured as molded-case circuit breakers. They are not GFCIs, but look and act very similarly. In fact a GFCI would provide the required protection, but they are set in the 4- to 6-mA range, and would likely nuisance trip on an extensive layout. However, for a short run they have been known to work without incident. Some inspectors still fail them, because they don't want to sign off on a likely source of nuisance trips. Note that Type MI cable is now (as of the 2011 edition) subject to this requirement. MI cable can be made with several different sheaths, which vary in their ability to return fault current.

426.32. Voltage Limitations. The allowance for the voltage to be from 30 to 80 volts in systems using impedance heating if protected by GFCI has been deleted in the 2017 **NEC**. This equipment has too much leakage current and is not compatible with conventional GFCI protection. Note that the grounding rule in Sec. 426.34 still requires a grounding connection for such circuits, although the permission to use them no longer exists.

426.50. Disconnecting Means. For outdoor deicing and snow-melting equipment, the CB or fusible switch for the branch circuit to the equipment is adequate disconnecting means as long as it is readily accessible to the user. It must simultaneously open all ungrounded conductors. The cord-plug of plug-connected equipment rated up to 20 A and 150 V may serve as the disconnect device; this is the upper limit for UL on the cord-and-plug ratings in this area. The disconnecting means does not have to be in sight of the equipment, but it must be indicating and include a "positive lockout" which is understood to mean that it can be locked in the open position.

ARTICLE 427. FIXED ELECTRIC HEATING EQUIPMENT FOR PIPELINES AND VESSELS

427.22. Ground-Fault Protection of Equipment. Electric heating equipment applied to pipelines or vessels must be supplied by a branch circuit with ground fault protection. This is extensively covered for similar equipment in the discussion about deicing and snow-melting equipment; see 426.28 for the analysis.

427.23. Grounded Conductive Covering. These rules require an overall grounded metal jacket on any heating cables intended to be installed on pipelines or vessels. In addition, for heating panels, only the side that is *not* in contact with the pipe or vessel must have a grounded metal covering. The outer metal covering serves as an equipment ground-return path for fault current in the event of failure of the insulation on the heating conductors. Proper grounding will trip open the faulted circuit due to unbalanced current flowing through the grounded path and prevent the type of fires that have been reported—as well as provide greater personnel safety. Here again, the reason for the rule is protection against fire resulting from sputtering, uncleared arcing faults that require a residual current detector such as this to detect.

Although this article is generally thought of as an industrial article relevant to chemical process industries and oil refineries, it also applies to everyday frost protection applied to even residential water lines. A 6-m (20-ft) run of heat tracing on a length of water pipe at a single-family house lands

you right here. Make sure to get cable with the grounded braid on the outside, and then make sure that the overcurrent device for the branch circuit has the low-level GFPE (~30 mA) built in. Also, don't forget the disconnection rules in 427.55, which are the same as for 426.50 and discussed at length there.

427.27. Voltage Limitations. The default secondary voltage limit is 30 volts. The 2017 **NEC** reevaluated the utility and practicality of conventional Class A GFCIs for personnel protection on this equipment, and concluded that a more practical approach was to ask for GFPE instead, together with rules for qualified access. The former second paragraph on 30-80 volts is now the first exception, and the former exception for industrial applications up to 132 volts is now the second exception, with a guarding specification added.

ARTICLE 430. MOTORS, MOTOR CIRCUITS, AND CONTROLLERS

430.1. Scope. Two articles in the **National Electrical Code** are directed specifically to motor applications:

1. Article 430 of the **NEC** covers application and installation of motor circuits and motor control hookups—including conductors, short-circuit and ground-fault protection, starters, disconnects, and running overload protection. Article 430 also covers adjustable speed drives in addition to motors, motor circuits, and controllers. Specific Code rules are given throughout this article.
2. Article 440, covering “Air-Conditioning and Refrigerating Equipment,” contains provisions for such motor-driven equipment and for branch circuits and controllers for the equipment, taking into account the special considerations involved with sealed (hermetic-type) motor compressors, in which the motor operates under the cooling effect of the refrigerant.

Diagram 430-1 in the **NEC** shows how various parts of Art. 430 cover the particular equipment categories that are involved in motor circuits. That Code diagram can be restructured, as shown in [Fig. 430-1](#) in this handbook, to present the six basic elements that the Code requires the designer to account for in any motor circuit. Although these elements are shown separately here, there are certain cases where the Code will permit a single device to serve more than one function. For instance, in some cases, one switch can serve as both disconnecting means and controller.

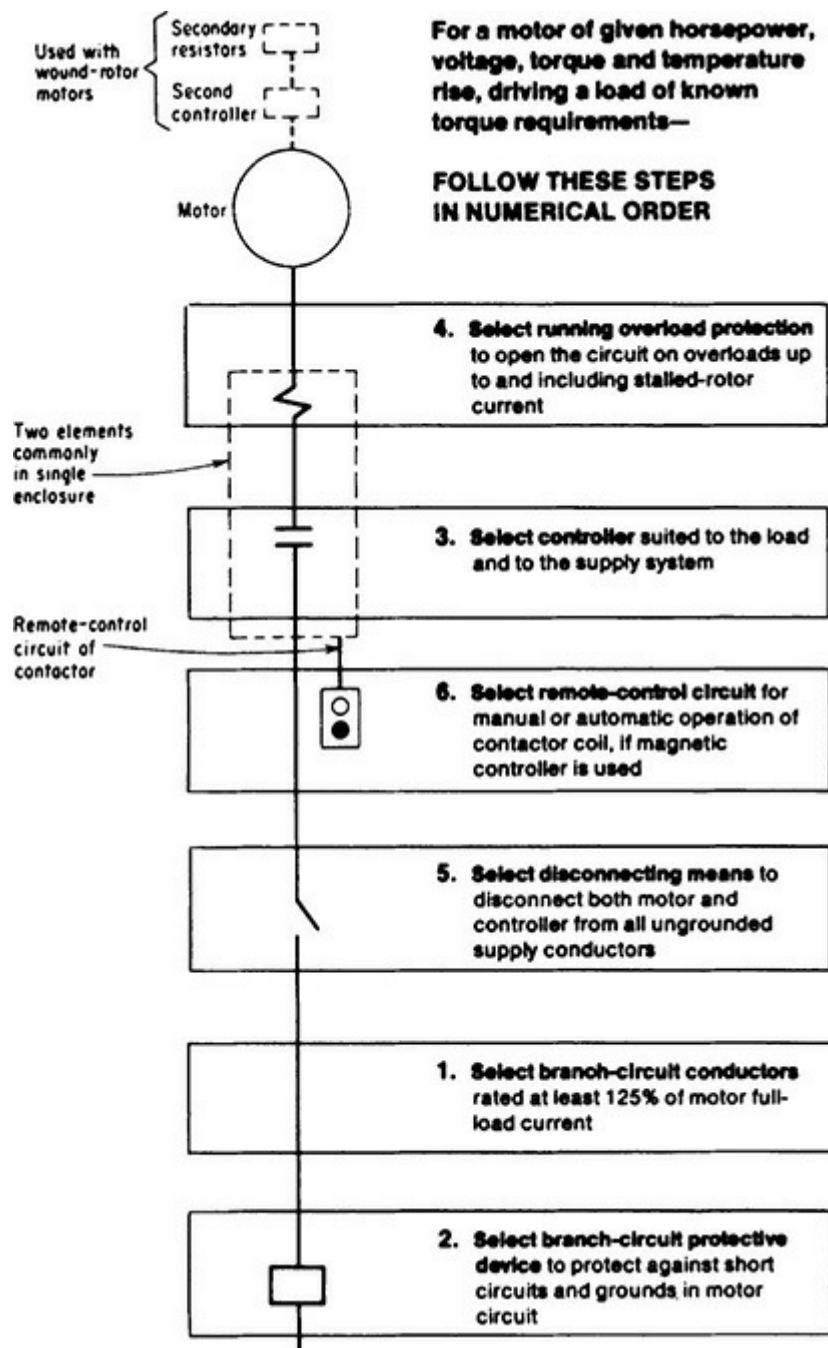

Fig. 430-1. Code rules cover these considerations. (Sec. 430.1.)

In other cases, short-circuit protection and overload protection can be combined in a single CB or set of fuses.

Throughout this article, all references to “running overcurrent devices” or simply “overcurrent devices” have been changed to “overload devices.” And references to motor “running overcurrent protection” have been changed to “overload protection.” This has been done to correlate with the definition of *overload* given in Art. 100, which refers to “Operation of equipment in excess of normal, full-load rating. . . .” A fault, such as a short circuit or ground fault, is not an overload. *Overload* for motors means current due to overload, up to and including locked-rotor current—or failure to start, which is the same level of current.

430.4. Part-Winding Motors. A part-winding starter is an automatic type of starter for use with squirrel-cage motors which (as defined in 430.2) have two separate, parallel windings on the stator. It can be used with the commonly used 220/400-V (dual-voltage) motors when they are used at the lower voltage, with the two windings operating in parallel. Single-voltage motors and 440- and

550-V motors must be ordered as specials if part-winding starting is to be used. The starter contains two magnetic contactors, each of which is rated for half the motor horsepower and is used to supply one winding.

430.6. Ampacity and Motor Rating Determination. For general motor applications (excluding applications of torque motors and sealed hermetic-type refrigeration compressor motors), whenever the current rating of a motor is used to determine the current-carrying capacity of conductors, switches, fuses, or CBs, the values given in Tables 430.247, 430.248, 430.249, and 430.250 must be used instead of the actual motor nameplate current rating. However, selection of separate motor-running overload protection *must* be based on the actual motor nameplate current rating.

There is a very common situation where a horsepower rating needs to be ignored, however, and that is when it is merely advertising hyperbole. As it turns out, when UL looks at nameplate information on appliances, including motor-operated appliances, it only polices the full-load current information. Manufacturers are free to tout bogus horsepower numbers such as “maximum peak horsepower,” etc., that have no relationship to the horsepower/current tables at the end of the article whatsoever. This can make a very significant difference in wiring design. For example, suppose you were intending to put a 6-A garage door opener on the lighting circuit for the garage. This easily falls under the 210.23(A) limit of 50 percent of fixed load on such circuits and is very commonly done. However, if the unit were marked “maximum horsepower output 1 hp” or something equivalent, and you ended up in Table 430.248, all of a sudden the mandatory current number for that appliance would be 16 A and you would need a dedicated 20-A circuit for a 6-A load. Exception No. 3 to 430.6(A)(1) is what allows the use of the current rating from the nameplate in these cases.

As noted in part (B), for any torque motor, the rated nameplate current is the locked-rotor current of the motor, and that value must be used in calculating the motor branch-circuit short-circuit and ground-fault protection in accordance with 430.52(B). The branch circuit for a torque motor must have its conductors and equipment protected at the motor nameplate rating (locked-rotor current) by selecting a fuse or CB in accordance with 240.4(G). The rule also requires that conductor ampacity and the setting or rating of the overload protective device be based on this value.

For shaded-pole motors, permanent-split-capacitor motors, and ac adjustable-voltage motors, the other rules apply. Part (D) covers valve-actuator motor assemblies, which use nameplate ratings, and are actually a special case of the motors referred to in the last sentence of 430.6(A)(1). Refer to the discussion at 430.102(A) Exception No. 3 for more information about this equipment.

430.7. Marking on Motors and Multimotor Equipment. This section covers markings that manufacturers are required to put on the equipment. There are two categories by which the **NEC** organizes this information. The first is general information, covered in (A), that lists information about the motor in 15 different respects as applicable, from the name of the manufacturer to the horsepower, and so forth, all the way down to the rating of condensation prevention heaters. The second involves item (8) in the above list, which addresses locked-rotor current. A manufacturer is free to specify an actual current value, but most use the Code letter instead, which has been standardized since the 1940 **NEC**. Code Table 430.7(B) lists the values associated with the various letters, and the five numbered paragraphs give specialized rules for implementing the Code letter designations. There are a number of applications where it is necessary to calculate the locked-rotor current of a motor, where that value of current is related to selection of overload protection or short-circuit protection. A typical example would be selection of an appropriately rated disconnecting

means for a group motor installation, where 430.110(C)(1) requires as part of the evaluation, a summation of all currents being disconnected under locked rotor conditions, and then the summation is used to figuratively create one single larger motor that has a horsepower that corresponds to the larger locked rotor condition under similar voltage connections.

430.8. Marking on Controllers. Controllers now need to be marked with a short-circuit current rating, unless they are incorporated into larger equipment with that rating, or in limited instances of very small applications. This information may be required to establish the rating of an industrial control panel built in the field. See the discussion at 409.110 for more information on this concept.

430.9. Terminals. As required by part (B), unless marked otherwise, copper conductors must be used with motor controllers, and screw-type terminals of control-circuit devices must be torqued. Part (B) is intended to ensure that only copper wires are used for wiring of motor starters, other controllers, and control-circuit devices because such equipment is designed, tested, and listed for use with copper only. If, however, equipment is tested and listed for aluminum wires, that must be indicated on the equipment, and use of aluminum wires is acceptable.

Part (C) requires that a torque screwdriver be used to tighten screw terminals of control-circuit devices used with No. 14 or smaller copper wires. Such terminals must be tightened to a value of 0.8 N-m (7 lb-in.)—unless marked for a different torque value. It should be noted that, although the rule literally mandates a “minimum” torque value, torque values are exact values. That is, equipment terminals should be torqued to the designated value and should *not* be overtorqued. (See top of [Fig. 430-2](#).) In fact, the larger problem in the industry today is not under tightening, but over tightening that causes terminations to fail through metal fatigue and damaged conductor stranding.

FOR CONTROL CIRCUIT: All screw-type terminals must be torqued to 7 lb-in., unless identified for another torque value.

Copper wire must be used for hookup, unless marked otherwise.

Fig. 430-2. For this size 5 motor starter, use of No. 1/0 THW for the line and load conductors would require a minimum gutter height of 5 in. (125 mm) from Table 430.10(B), to provide Code-acceptable wire bending space. (Sec. 430.10.)

430.10. Wiring Space in Enclosures. As noted in part (A), standard types of enclosures for motor controllers provide space that is sufficient only for the branch-circuit conductors entering and leaving the enclosure and any control-circuit conductors that may be required. No additional conductors should be brought into the enclosure. 430.12 provides a comprehensive set of rules and tables for motor terminal housings to solve the complaint by installers that motor terminal housings are too small to make satisfactory connections.

Part (B) on “Wire Bending Space in Enclosures” is based on Table 430.10(B), which shows the minimum distance from the end of the lug or connector to the wall of the enclosure or to the barrier opposite the lug, for each size of conductor and for one or two wires per terminal lug (Fig. 430-2). The distances are greater than Table 312.6(A) for angle terminations, but run slightly smaller than Table 312.6(B) distances for straight-in terminations. If more than two conductors will be terminated per phase in a parallel makeup, then the distances revert to the requirements in 312.6 without modification.

A further rule applies to use of terminal lugs other than those supplied in the controller by its manufacturer. Such substitute terminal lugs or connectors must be of a type identified by the manufacturer for use with the controller, and use of such devices must *not* reduce the minimum wire bending space. That rule would apply, say, where mechanical set-screw lugs are replaced with crimp-on lugs (as for better connection of aluminum conductors). As with switches, CBs, and other equipment, the controller should be marked on its label to indicate acceptability of field changing of the lugs and to specify what type and catalog number of replacement terminal may be used, along with designation of the correct crimping tool and compression die.

430.11. Protection Against Liquids. Excessive moisture, steam, dripping oil, and the like on the exposed current-carrying parts of a motor may cause an insulation breakdown, which in turn may be the cause of a fire. To prevent such an occurrence, here the Code calls for “protection”—presumably in the form of a fabricated structure above the motor, where the motor is exposed to dripping liquid—or the motor may be listed as suitable for the environment to which it is exposed.

430.12. Motor Terminal Housings. The sizes of these enclosures are standardized as provided in the associated tables, which had their sizes significantly increased by about 40 percent in the 1996 NEC. In part (E) the Code rule requires some provision for connecting an equipment grounding conductor at the terminal box where the branch circuit supplies a motor. The grounding connection may be either a “wire-to-wire” connection or a “fixed terminal” connection, and the ground terminal provision may be either inside the junction box—for connection of an equipment grounding conductor run with the circuit wires within the supply raceway—or outside the junction box—for connection of an “equipment bonding jumper” on the outside of a length of flexible metallic conduit or liquidtight flex, either of which is so commonly used. As required by 348.60 and 350.60, a bonding jumper is required for even short lengths of flex (up to 6 ft [1.8 m]) when the wires within the flex are protected at their origin by fuses or CBs rated over 20 A; and liquidtight flex over metric designator 35 (trade size 1¼ in.) and overcurrent protection over 60 A (see 250.118 for details) must have a bonding jumper for the typical length (up to 6 ft [1.8 m]) used with motor connections. See also 430.245 and Fig. 430-70.

This rule permits either an inside or an outside connection of the bonding jumper to correlate with 250.102(E), which permits the bonding jumper (up to 6 ft [1.8 m] long) to be run either inside or outside the flex.

The exception to this rule eliminates the need for providing “a separate means for motor grounding” at the junction box where a motor is part of “factory-wired equipment” in which the grounding of the motor is already provided by some other conductive connection that is an element of the overall assembly.

430.13. Bushing. Refer also to 300.4(G).

430.16. Exposure to Dust Accumulations. The conditions described in this section could make the location a Class II, Division 2 location: the types of motors required are specified in Art. 502.

430.17. Highest Rated or Smallest Rated Motor. Note that the current rating, not the horsepower rating, determines the “highest rated” motor where Code rules refer to such. See 430.62.

430.22. Single Motor. The basic rule says that the conductors supplying a single-speed motor used for continuous duty must have a current-carrying capacity of not less than 125 percent of the motor full-load current rating, so that under full-load conditions the motor must not load the conductors to more than 80 percent of their ampacity. Be aware that this 125 percent factor has absolutely nothing to do with the 125 percent factor involved in calculating conductor sizing for overcurrent device terminations when those wires are subject to continuous loads. The fact that the two numbers are identical is a coincidence. The motor circuit is based on likely overload protective device settings, and addresses the fact that the 125 percent condition, or something close to it, could continue for a substantial amount of time, but probably not 3 h. Do not make the mistake of looking at a continuous duty motor, adding 25 percent as required for this section, and then adding another 25 percent of that (total factor = 156 percent) for the motor circuit conductor size. That amounts to double derating and the **NEC** does not require it to be done.

Part (A) covers dc motors, and requires that the conductors that supply the rectifier ahead of the motor have an ampacity of not less than 125 percent of the rated rectifier input current. This information is new with the 2011 edition of the **NEC**. If the motor is fed from a rectified single-phase supply, the field-wiring output conductors from the rectifier to the motor must be 150 percent of motor FLA for full-wave rectification, and 190 percent for half-wave rectification. This material is not new; it was reformatted from an exception format as of the 2011 edition.

For a multispeed motor, part (B) provides that the selection of branch-circuit conductors on the supply side of the controller must be based on the highest full-load current rating shown on the motor nameplate.

For a wye-start, delta-run motor with all six leads (twelve for dual-voltage motors) brought out, the starting voltage is $1/\sqrt{3}$ of the phase-to-phase voltage, and the starting current is $(1/\sqrt{3})^2$ or one-third of the full-load current. Because all the leads are brought out, during the normal running condition each phase connection has two wires connected to it, one to each of the two adjacent positions of the delta connection. Each of those two wires carries a current that does not add arithmetically in the final connection, because they connect to different phase windings in the motor. The current in each wire, when added together using three-phase procedures (i.e., multiplied by $\sqrt{3}$) will equal the full-load current taken from the line at the disconnect. This means that each of those wires carries $1/\sqrt{3}$ of the full-load current, or 58 percent of FLC. Part (C) formerly required that

these same wires, which connect the controller and the motor, be “based” on this number for this reason. This was only the first step. For a customary continuous duty cycle application, one multiplied this number by 125 percent to get the actual wire size on the load side of the controller, or 72 percent of FLC. The **NEC** has, in effect, done this calculation out, specifying 72 percent, and adding an informative note explaining where the percentage comes from. If the duty cycle is other than continuous, one would expect to use the multiplier from Table 430.22(E) to get the final factor, but since 125 percent has now been applied, it will be necessary to use the underlying percentage (58%) to begin the calculation. In effect, by oversimplifying the requirement an implicit conflict has been created with (E).

Part (D) requires the comparable conductors that connect a part-winding connected motor to its controller be based on 50 percent of full-load current because each phase winding operates in parallel with its sister. The 2011 **NEC** restated this ampacity rule by doing out the 125 percent calculation to the base 50 percent (to equal 62.5%) and added a corresponding informational note to explain where the number came from. Just as in the case of the wye-delta motor, the result is a conflict with (E) if duty cycles are in play.

Figure 430-3 shows the sizing of branch-circuit conductors to four different motors fed from a panel. (Sizing is also shown for branch-circuit protection and running overload protection, as discussed in 430.34 and 430.52. Refer to Table 430.250 for motor full-load currents and Table 430.52 for maximum ratings of fuses.) [Figure 430-3](#) is based on the following:

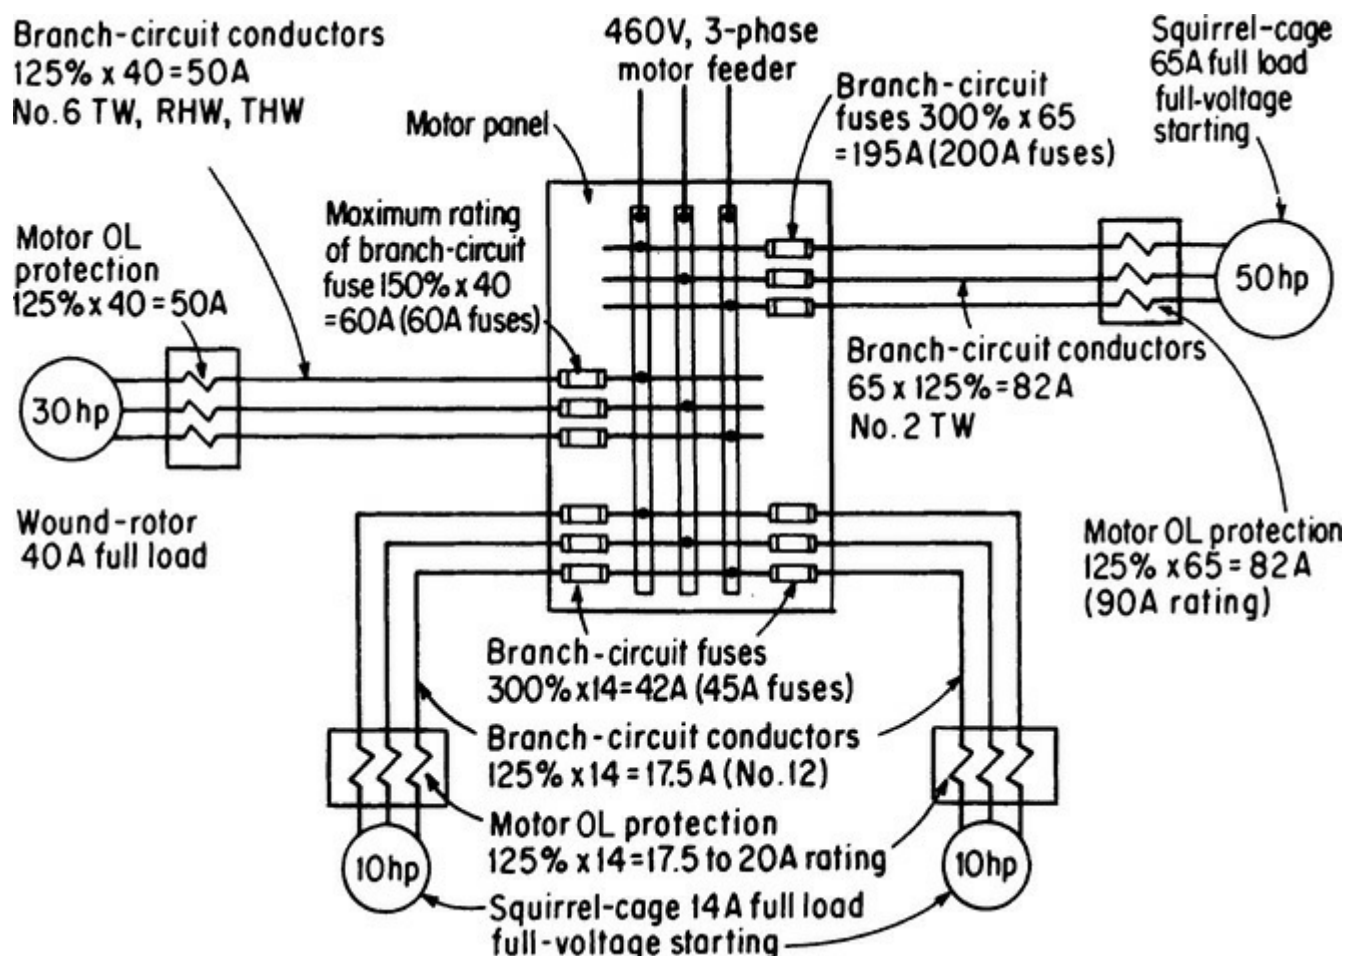

Fig. 430-3. Circuit conductors are sized at 1.25 times motor current. (Sec. 430.22.) The fuses are assumed to be nontime delay.

1. Full-load current for each motor is taken from Table 430.250.
2. Running overload protection is sized on the basis that nameplate values of motor full-load currents are the same as values from Table 430.250. If nameplate and table values are not the same, OL (overload) protection is sized according to nameplate.
3. Conductor sizes shown are for copper. Use the amp values given and Table 310.15(B)(16) to select correct size of aluminum conductors.

It is important to note that this rule establishes minimum conductor ratings based on temperature rise only and does not take into account voltage drop or power loss in the conductors. Such considerations frequently require increasing the size of branch-circuit conductors.

Part **(E)** includes requirements for sizing individual branch-circuit wires serving motors used for short-time, intermittent, periodic, or other varying duty. In such cases, frequency of starting and duration of operating cycles impose varying heat loads on conductors. Conductor sizing, therefore, varies with the application. But it should be noted that the note at the bottom of Table 430.22(E) says any motor is considered to be for continuous duty unless the nature of the apparatus that it drives is such that the motor cannot operate continuously with load under any condition of use.

When a motor is used for one of the classes of service listed in Table 430.22(E), the necessary ampacity of the branch-circuit conductors depends on the class of service and on the rating of the motor. A motor having a 5-min rating is designed to deliver its rated horsepower during periods of approximately 5 min each, with cooling intervals between the operating periods. The branch-circuit conductors have the advantage of the same cooling intervals and hence can safely be smaller than for a motor of the same horsepower but having a 60-min rating.

In the case of elevator motors, the many considerations involved in determining the smallest permissible size of the branch-circuit conductors make this a complex problem, and it is always the safest plan to be guided by the recommendations of the manufacturer of the equipment. This applies also to feeders supplying two or more elevator motors and to circuits supplying noncontinuous-duty motors used for driving some other machines. The duty cycle will essentially be intermittent because buildings are not of infinite height. Part **(G)** covers small motors capable of running on branch-circuit wiring smaller than 14 AWG. The motors must be physically protected by being located in a cabinet or other enclosure to use these allowances. The rule for short-circuit and ground-fault protection is complex, because in these cases, the type of protective device must be one of the three options given in 240.4(D)(1)(2) or (2)(2), but the size of those devices follows 430.52, and now this gets even more complicated. The type limitations in 240.4(D) call for certain specified classes of fast-acting fuses or other fuses or circuit breakers listed to protect the wire sizes being installed.

In order to use Table 430.52, however, you have to know which column to use in selecting a protective device. For a circuit breaker listed for protecting small wires, use the “inverse-time breaker” column, for “Class CC” fuses use the “nontime delay fuse” column [because of Note 1 to the table; also see 430.53(C)(1) Exception No. 2(a) if that condition applies], for a “Class T” fuse use the “nontime delay fuse” column, and for a “Class J” fuse use the applicable fuse column based on the specific fuse at hand because that classification fuse is available in either construction. At the present time no fuses other than those specified in 240.4(D) have been listed for use with these smaller conductors.

The limits on motor sizing are then based on the “full-load current rating” of the motor. Remember that by Table 400.5(A)(1) the 18 and 16 AWG three-phase cord ampacities are 7 and 10 A, which also line up with the limits in 240.4(D).

Moving forward on this basis, the current ranges will be based on the class of overload relay; if unfamiliar the reader should review this topic at 430.32(C). This in turn means that the term “overcurrent” is used incorrectly, instead of short-circuit and ground-fault protection. However, in order to make sense out of this we can assume that is what was intended. We are left with four possibilities for an upper limit on full-load current loading.

For Class 10 (fast) overload protection, 18 AWG wiring will support a full-load motor draw of 5 A and 16 AWG will support 8 A. For Class 20 (normal) overload protection 18 AWG wiring will support a full-load motor draw of 3.5 A and 16 AWG will support 5.5 A.

These provisions match up with the **NFPA** Standard for Industrial Machinery (**NFPA 79**) and are designed to facilitate competition with European enterprises using IEC conductor sizing that is smaller than 14 AWG. The smaller conductors are recognized as single conductors within enclosures, and the 2017 **NEC** extended this recognition to runs outside an enclosure, provided they are part of a jacketed cable assembly or in flexible cord.

430.23. Wound-Rotor Secondary. The full-load secondary current of a wound-rotor or slip-ring motor must be obtained from the motor nameplate or from the manufacturer. The starting, or starting and speed-regulating, portion of the controller for a wound-rotor motor usually consists of two parts—a dial-type or drum controller and a resistor bank. These two parts must, in many cases, be assembled and connected by the installer, as in Fig. 430-4.

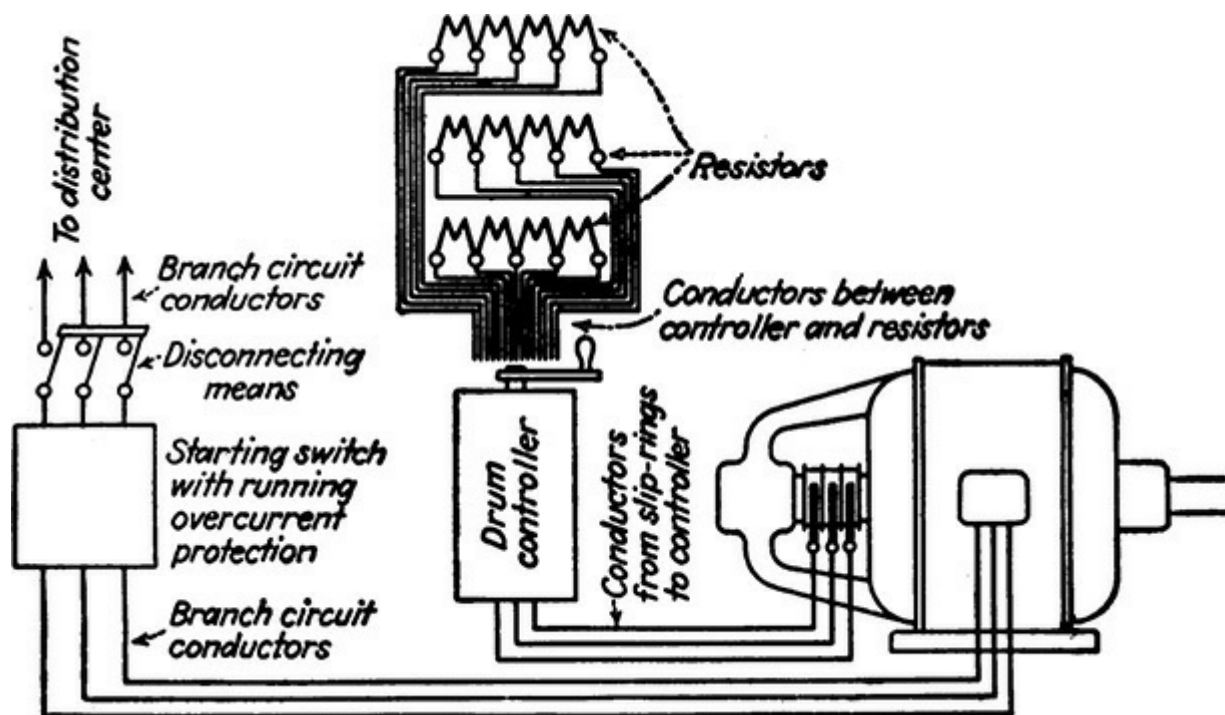

Fig. 430-4. Wound-rotor motor may be used with rotary drum switch for speed control. (Sec. 430.23.)

The conductors from the slip rings on the motor to the controller are in circuit continuously while the motor is running and hence, for a continuous-duty motor, must be large enough to carry the secondary current of the motor continuously.

If the controller is used for starting only and is not used for regulating the speed of the motor, the conductors between the dial or drum and the resistors are in use only during the starting period and are cut out of the circuit as soon as the motor has come up to full speed. These conductors may

therefore be of a smaller size than would be needed for continuous duty.

If the controller is to be used for speed regulation of the motor, some part of the resistance may be left in circuit continuously and the conductors between the dial or drum and the resistors must be large enough to carry the continuous load without overheating. In Table 430.23(C) the term *continuous duty* applies to this condition.

Conductors connecting the secondary of a wound-rotor induction motor to the controller must have a carrying capacity at least equal to 125 percent of the motor's full-load secondary current if the motor is used for continuous duty. If the motor is used for less than continuous duty, the conductors must have capacity not less than the percentage of full-load secondary nameplate current given in Table 430.22(E). Conductors from the controller of a wound-rotor induction motor to its starting resistors must have an ampacity in accordance with Table 430.23(C), as shown in Fig. 430-5 for a magnetic starter used for reduced inrush on starting but not for speed control.

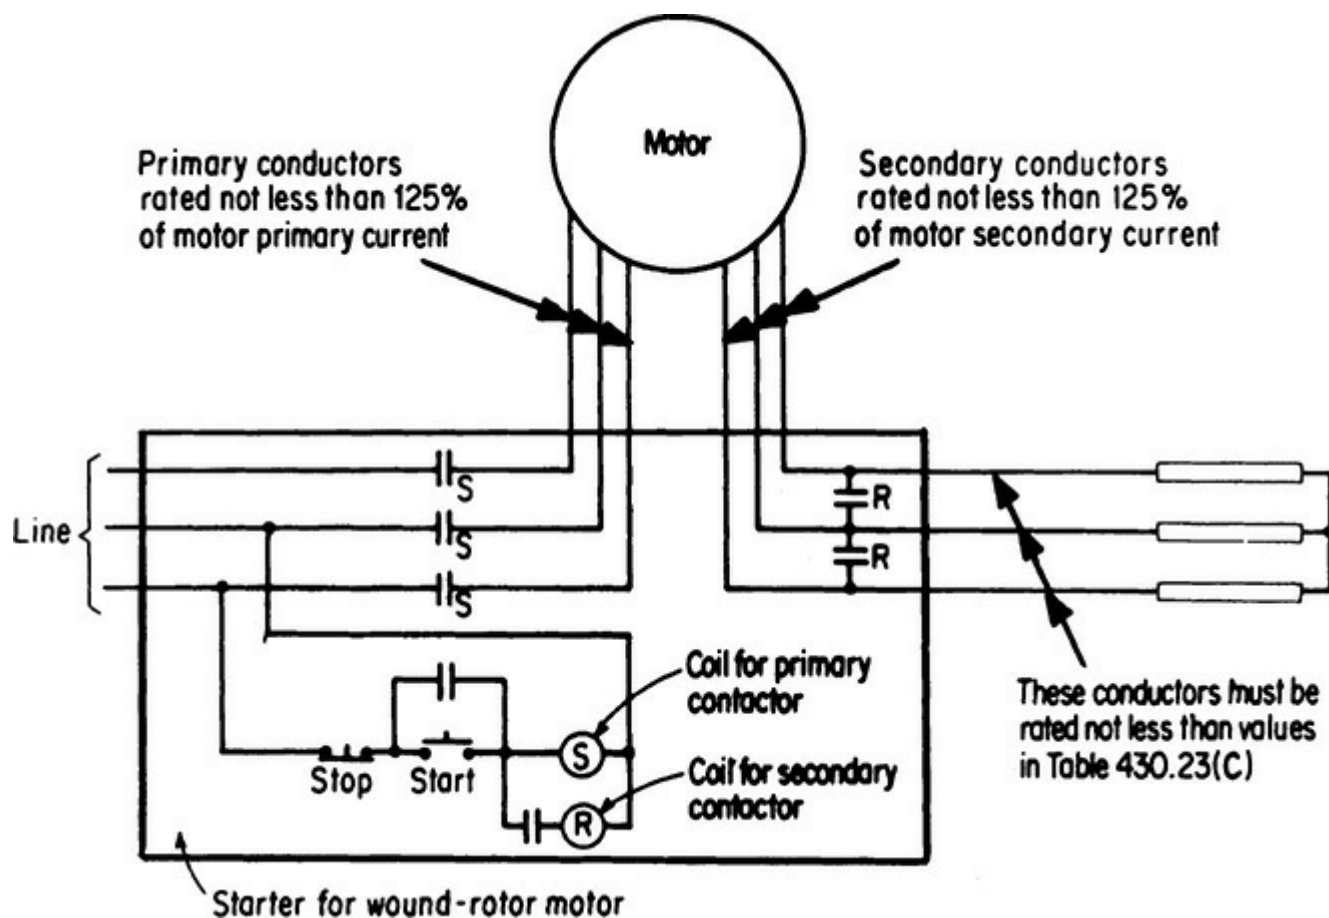

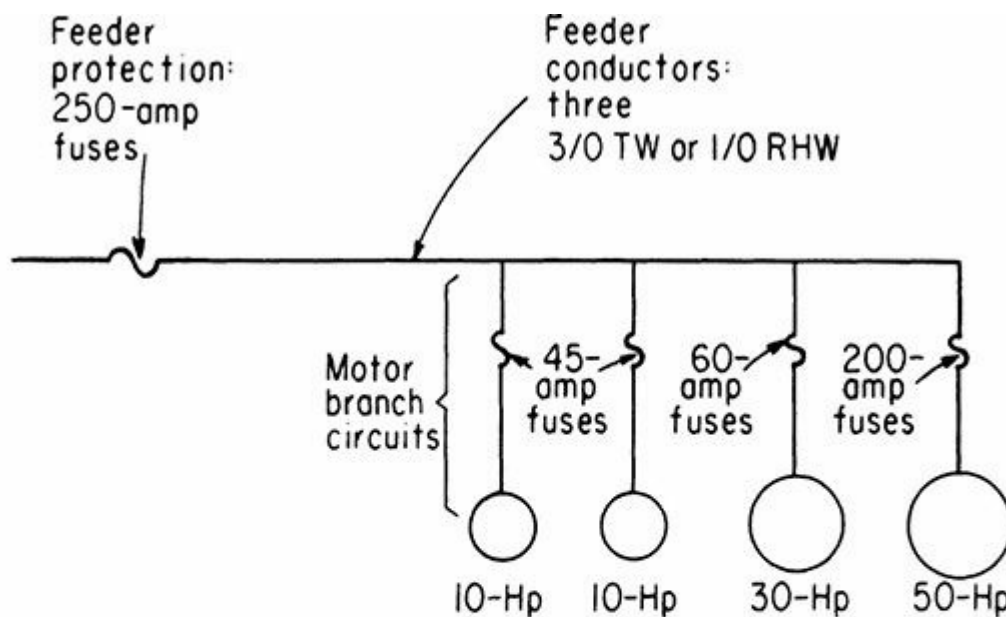

Fig. 430-5. Rules cover conductor sizing for wound-rotor motors without speed control. (Sec. 430.23.)

430.24. Several Motors or a Motor(s) and Other Load(s). Conductors supplying two or more motors (such as feeder conductors to a motor control center, to a panel supplying a number of motors, or to a gutter with several branch circuits tapped off) must have a current rating not less than 125 percent of the full-load current rating of the largest motor supplied, plus the sum of the full-load current ratings of the other motors supplied, plus capacity for the nonmotor loads taken at 100 percent for the noncontinuous and 125 percent of the continuous portion(s) of such other load.

Figure 430-6 shows an example of sizing feeder conductors for a load of four motors, selecting the conductors on the basis of ampacities given in Table 310.15(B)(16) and using conductors with a

60°C or 75°C insulating rating—or using 90°C-rated conductors at the ampacities of 75°C. UL rules generally prohibit use of 90°C conductors at the 90°C ampacities shown in Code Table 310.15(B)(16). [Refer to 110.14(C)(1)(a)(4).]

The four motors supplied by the 3-phase, 440-volt, 60-cycle feeder, which are not marked with a Code letter (see Table 430.52), are as follows:

- 1 50-hp squirrel-cage induction motor (full-voltage starting)
- 1 30-hp wound-rotor induction motor
- 2 10-hp squirrel-cage induction motors (full-voltage starting).

Step 1. Branch-circuit loads

From Table 430-250, the motors have full-load current ratings as follows:

- 50-hp motor—65 amps
- 30-hp motor—40 amps
- 10-hp motor—14 amps

Step 2. Conductors

The feeder conductors must have a carrying capacity as follows (see Section 430-24):

$$1.25 \times 65 = 81 \text{ amps}$$

$$81 + 40 + (2 \times 14) = 149 \text{ amps}$$

The feeder conductors must be at least No. 3/0 TW, 1/0 THW or 1/0 RHH or THHN (copper).

Fig. 430-6. Feeder conductors are sized for the total motor load. (Sec. 430.24.)

For the overcurrent protection of feeder conductors of the minimum size permitted by this section,

the highest permissible rating or setting of the protective device is specified in 430.62. Where a feeder protective device of higher rating or setting is used because two or more motors must be started simultaneously, the size of the feeder conductors shall be increased correspondingly. Note that, as covered in Exception No. 1, if one or more motors is not classified as continuous duty, there is a two-step process involved in determining the highest motor rating. First determine the adjusted current requirements for all such motors by using 430.22(E). Then compare those results with the continuous duty motors taken at the customary 125 percent. The largest result is the number that goes forward as the largest motor for the feeder calculations.

These requirements and those of 430.62 for the overcurrent protection of power feeders are based on the principle that a power feeder should be of such size that it will have an ampacity equal to that required for the starting current of the largest motor supplied by the feeder, plus the full-load running currents of all other motors supplied by the feeder. Except under the unusual condition where two or more motors may be started simultaneously, the heaviest load that a power feeder will ever be required to carry is the load under the condition where the largest motor is started at a time when all the other motors supplied by the feeder are running and delivering their full-rated horsepower.

Where other loads are also supplied, conductor sizing is determined as follows:

1. The current-carrying capacity of feeder conductors supplying a single motor plus other loads must include capacity at least equal to 125 percent of the full-load current of the motor.
2. The current-carrying capacity of feeder conductors supplying a motor load and a lighting and/or appliance load must be sufficient to handle the lighting and/or appliance load as determined from the procedure for calculating size of lighting feeders, plus the motor load as determined from the previous paragraphs.

The Code permits inspectors to authorize use of demand factors for motor feeders—based on reduced heating of conductors supplying motors operating intermittently or on duty-cycle or motors not operating together. Where necessary this should be checked to make sure that the authority enforcing the Code deems the conditions and operating characteristics suitable for reduced-capacity feeders, as noted in 430.26.

For computing the minimum allowable conductor size for a combination lighting and power feeder, the required ampacity for the lighting load is to be determined according to the rules for feeders carrying lighting (or lighting and appliance) loads only. Where the motor load consists of one motor only, the required ampacity for this load is the capacity for the motor branch circuit, or 125 percent of the full-load motor current, as specified in 430.22. Where the motor load consists of two or more motors, or a motor(s) and other loads, the required ampacity for the motor load is the capacity computed according to 430.24.

Figure 430-7 shows a typical installation for which calculation of required feeder ampacity is as follows:

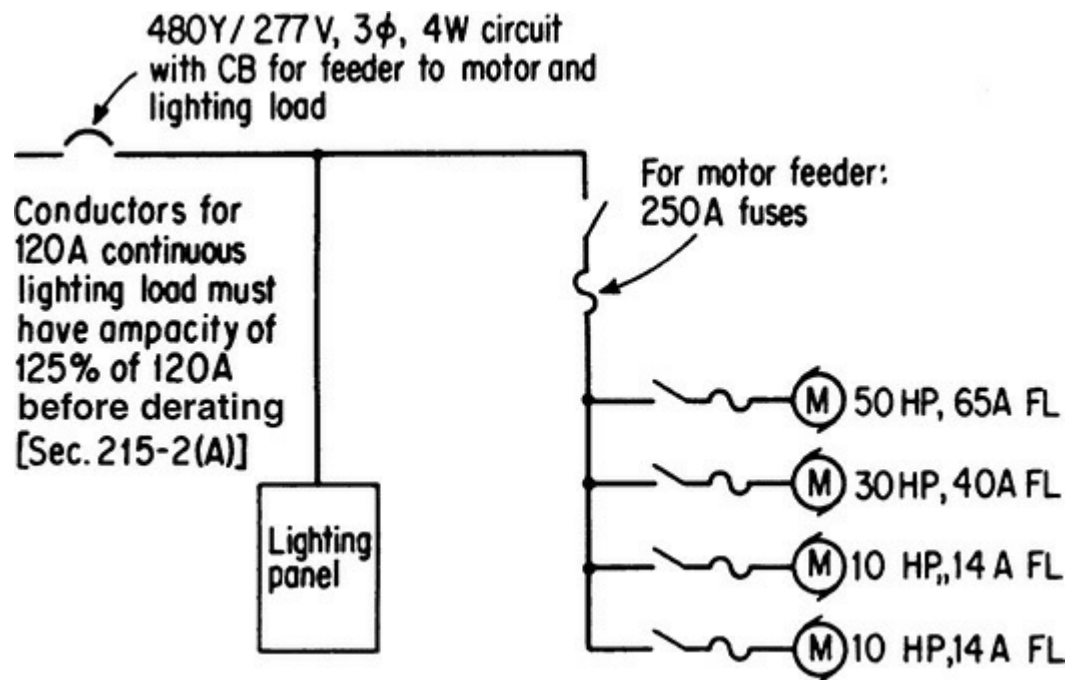

Fig. 430-7. Other load must be properly combined with motor load. (Sec. 430.24.)

Step 1. Total Load

430.24 says that conductors supplying a lighting load and a motor load must have capacity for both loads, as follows:

$$\begin{aligned} \text{Motor load} &= 65 \text{ A} + 40 \text{ A} + 14 \text{ A} + 14 \text{ A} + (0.25 \times 65 \text{ A}) = 149 \text{ A per phase} \\ \text{Lighting load} &= 120 \text{ A per phase} \times 1.25 = 150 \text{ A} \\ \text{Total load} &= 149 + 150 = 299 \text{ A per phase leg} \end{aligned}$$

Step 2. Conductors

Table 310.15(B)(16) shows that a load of 299 A can be served by the following copper conductors:

- 500-kcmil TW
- 350-kcmil THW, RHH, XHHW, or THHN

Table 310.15(B)(16) shows that this same load can be served by the following aluminum or copper-clad aluminum conductors:

- 700-kcmil TW
- 500-kcmil THW, RHH, XHHW, or THHN

Note that the 90°C rating for the THHN was not considered because of termination limitations. If there were adverse environmental conditions such as high temperature ambient conditions or mutual conductor heating, any required derating would have started at the 90°C rating.

430.26. Feeder Demand Factor. A demand factor of less than 100 percent may be applied in the case of some industrial plants where the nature of the work is such that there is never a time when all the motors are operating at one time. But the inspector must be satisfied with (and grant

special permission for, including the provision of written notice) any application of a demand factor. Review also the coverage in 220.50 in this book on the topic of motor demand factors.

Sizing of motor feeders (and mains supplying combination power and lighting loads) may be done on the basis of maximum demand current, calculated as follows:

$$\text{Running current} = (1.25 \times I_f) + (DF \times I_t)$$

where I_f = full-load current of largest motor

DF = demand factor as permitted by 430.26

I_t = sum of full-load currents of all motors except largest

But modern design dictates use of the maximum-demand starting current in sizing conductors for improved voltage stability on the feeder. This current is calculated as follows:

$$\text{Starting current} = I_s + (DF \times I_t)$$

where I_s = average starting current of largest motor. (Use the percent of motor full-load current given for fuses in Table 430.52.)

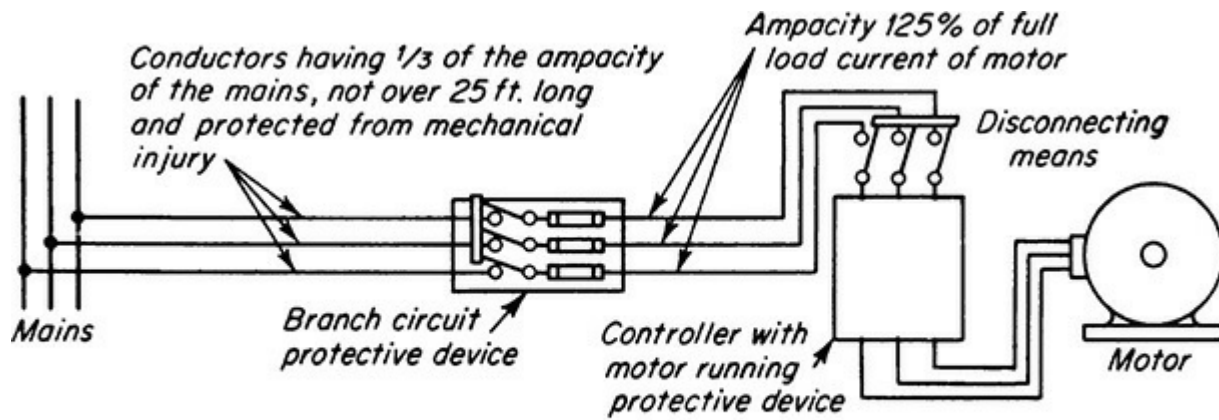

where I_s = average starting current of largest motor. (Use the percent of motor full-load current given for fuses in Table 430.52.)

430.28. Feeder Taps. This Code rule is an adaptation of 240.21(B)(1) and (B)(2), covering use of 10- and 25-ft (3.0- and 7.5-m) feeder taps with no overcurrent protection at the point where the smaller conductors connect to the higher-ampacity feeder conductors. The adaptation establishes that the tap conductors must have an ampacity as required by 430.22, 430.24, or 430.25.

In applying condition **(1)**, the conductor may have an ampacity less than one-tenth that of the feeder conductors but must be limited to not more than 10 ft (3.05 m) in length and be enclosed within a controller or raceway, and rated not less than 10 percent of the rating of the overcurrent device protecting the feeder.

If conductors equal in size to the conductors of a feeder are connected to the feeder, as in condition **(3)**, no fuses or other overcurrent protection are needed at the point where the tap is made, since the tap conductors will be protected by the fuses or CB protecting the feeder.

The more important circuit arrangement permitted by the preceding rule is shown in [Fig. 430-8](#). Instead of placing the fuses or other branch-circuit protective device at the point where the connections are made to the feeder, conductors having at least one-third the ampacity of the feeder are tapped solidly to the feeder and may be run a distance not exceeding 25 ft (7.5 m) to the branch-circuit protective device. From this point on to the motor-running protective device and thence to the motor, conductors are run having the standard ampacity, that is, 125 percent of the full-load motor current, as specified in 430.22. If the tap conductors shown did not have an ampacity at least equal to one-third of that of the feeder conductors, then the tap conductors must not be over 10 ft (3.0 m) long.

Note: Branch-circuit fuses (or CB) may be rated higher than ampacity of the tap conductors.

Fig. 430-8. Feeder tap protection follows 430.52, not their ampacity. (Sec. 430.28.)

Note that this rule actually modifies the requirements of 240.21 for taps to motor loads. 240.21(B) (1) literally calls for 10-ft (3.0-m) tap conductors to have ampacity at least equal to the rating or setting of the fuses or CB (whichever is used) at the load end of the tap. And such protection may be rated up to 4 times motor full-load current. But condition (1) of this Code section requires sizing of the 10-ft (3.0-m) tap conductors to be at least one-tenth the rating of the overcurrent device, protecting the feeder from which the tap conductors are supplied. And condition (2) does *not* require a 25-ft (7.5-m) tap to terminate in a protective device rated to protect the conductors at their ampacity (Fig. 430-9).

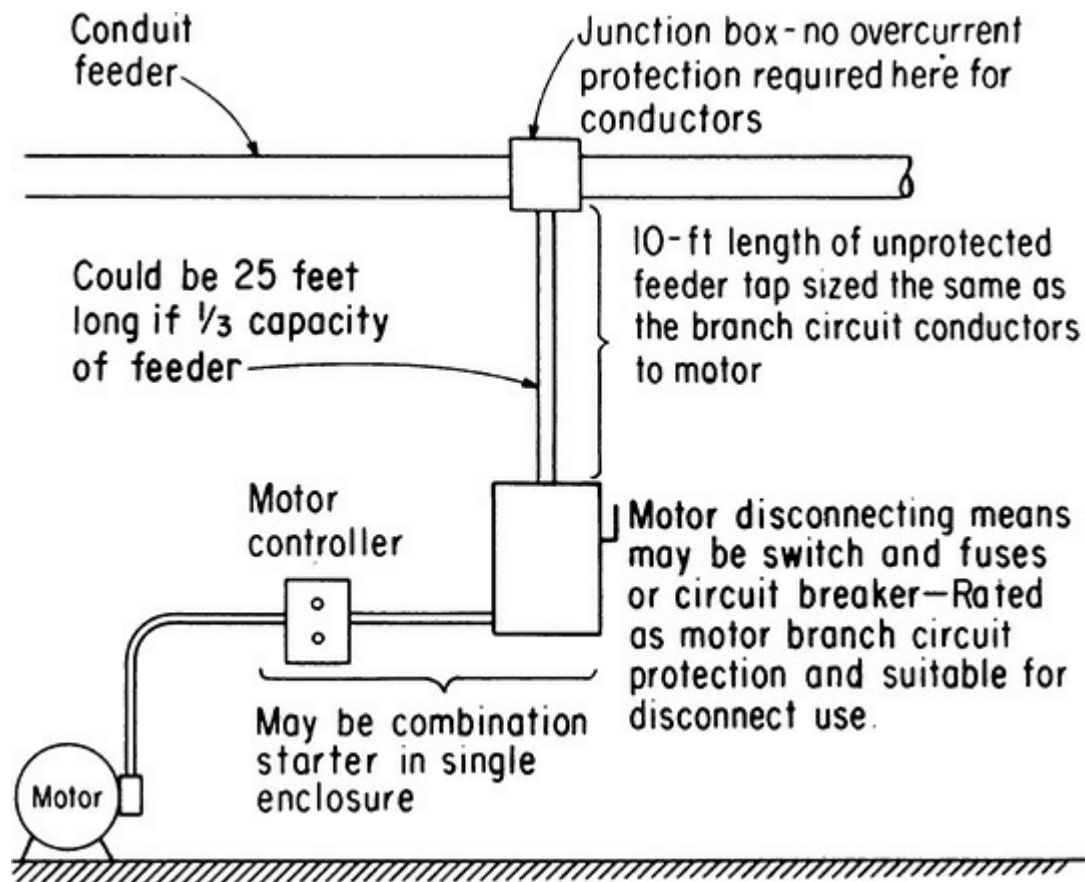

Fig. 430-9. Tap conductors may terminate in protective device rated above their ampacity. (Sec. 430.28.)

example A 15-hp 230-V 3-phase motor with autotransformer starter is to be supplied by a tap made to a 250-kcmil feeder. All conductors are to be Type THW.

The feeder has an ampacity of 255 A; one-third of 255 A equals 85 A. Therefore the tap cannot be smaller than No. 4, which has an ampacity of 85 A for 75°C ratings.

The full-load current of the motor is 40 A and, according to part (IV) of Art. 430, assuming that the motor is not marked with a Code letter, the branch-circuit fuses should be rated at not more than 300 percent of 40 A, or 120 A, which calls for 125-A fuses (430.52) or less. With the motor-running protection set at 50 A (125 percent \times 40 A), the tap conductors are well protected from overload.

The conductors tapped solidly to the feeder must never be smaller than the size of branch-circuit conductors required by 430.22.

The exception in this rule notes that a branch-circuit or subfeeder tap up to 100 ft (30.0 m) long may be made from a feeder to supply motor loads. The specific conditions are given for making a tap that is over 25 ft (7.5 m) long and up to 100 ft (30.0 m) long—where no protection is provided at the point of tap from the feeder conductors. This is a motor-circuit adaptation of the 100-ft (30.0-m) tap permission, which is fully described under 240.21(B)(4).

430.29. Constant-Voltage DC Motors—Power Resistors. These rules cover sizing of conductors from a dc motor controller to separate resistors for power accelerating and dynamic braking. This section, with its table of conductor ampacity percentages, ensures proper application of dc constant-potential motor controls and power resistors.

430.31. General. Detailed requirements for the installation of fire pumps are included in the **National Electrical Code** in Art. 695. Although electrical concerns are now covered in the **NEC**, more in-depth coverage of other concerns is given in **NFPA 20**.

As intended by 430.52, the motor branch-circuit protective device provides short-circuit protection for the circuit conductors. In order to carry the starting current of the motor, this device must commonly have a rating or setting so high that it cannot protect the motor against overload.

For a squirrel-cage induction motor, overload protection must be of the inverse time type with a setting of not over 20 s at 600 percent of the motor full-load current. It is the intent that the fire-pump motor be permitted to run under any condition of loading, even to complete failure, and not be automatically disconnected by an overload protection device. However, should a ground fault or short circuit develop in its conductors, it is also the intent to clear those faults before they result in another task for the fire pump to address. Refer to the extensive coverage of Art. 695 in this book for complete information.

Except where time-delay fuses provide both running overload protection and short-circuit protection as described in 430.55, in practically all cases where motor-running overload protection is provided the motor controller consists of two parts: (1) a switch or contactor to control the circuit to the motor, and (2) the motor-running protective device. Most of the protective devices make use of a heater coil, usually consisting of a few turns of high-resistance metal, though the heater may be of other form.

430.32. Continuous-Duty Motors. The Code makes specific requirements on motor running overload protection intended to protect the elements of the branch circuit—the motor itself, the motor control apparatus, and the branch-circuit conductors—against excessive heating due to motor overloads. Overload protection may be provided by fuses, CBs, or specific overload devices such as OL relays.

Overload is considered to be operating overload up to and including stalled-rotor current. When

overload persists for a sufficient length of time, it will cause damage or dangerous overheating of the apparatus. Overload does not include fault current due to shorts or grounds.

Typical overload devices include:

1. Heaters in series with line conductors acting upon thermal bimetallic overload relays
2. Overload devices using resistance or induction heaters and operating on the solder-ratchet principle ([Fig. 430-10](#))

BIMETALLIC TYPE

SOLDER-RATCHET TYPE

NOTE: For a manual starter, the contacts shown are the main load-current contacts of the switch—connected in series with the heater coil.

Fig. 430-10. Overload relay devices are made in various operating types. (Sec. 430.32.)

3. Magnetic relays with adjustable instantaneous setting or adjustable time-delay setting
4. Microprocessor support in an adjustable speed drive or in other controllers capable of electronic settings

Of course, the provisions for overload protection are integrated in the enclosure of the controller.

Overload protective devices of the straight thermal type are available with varying tripping and time-delay characteristics. In such devices, the heater coils are made in many sizes and are interchangeable to permit use of the required heater sizes to provide running protection for different motor full-load current ratings. In some units, the heater coil can be adjusted to exact current values. Individual covers are used on the heating elements in some starters to isolate the relay from possible effects on its operation because of the temperature of surrounding air.

In general, it is required that every motor shall be provided with a running protective device that will open the circuit on any current exceeding prescribed percentages of the full-load motor current, the percentage depending on the type of motor. The running protective device is intended primarily to protect the windings of the motor; but by providing that the circuit conductors shall have an ampacity not less than 125 percent of the full-load motor current, it is obvious that these conductors are reasonably protected by the running protective device against any overcurrent caused by an overload on the motor.

Part (A) covers application for motors of more than 1 hp. If such a motor is used for continuous duty, running overload protection must be provided. This may be an external overcurrent device actuated by the motor running current and set to open at not more than 125 percent of the motor full-load current for motors marked with a service factor of not less than 1.15 and for motors with a temperature rise not over 40°C. See examples in Fig. 430-3. Sealed (hermetic-type) refrigeration compressor motors must be protected against overload and failure to start, as specified in 440.52. The overload device must be rated or set to trip at not more than 115 percent of the motor full-load current for all other motors, such as motors with a 1.0 service factor or a 55°C rise (Fig. 430-11).

Fig. 430-11. Specific rules apply to continuous-duty motors rated over 1 hp. (Sec. 430.32.)

Be careful when looking at overload element tables provided with controllers. As a general rule, those tables are intended to be directly read out. That is, the 125 percent has already been factored into the selection table. Look up the nameplate FLA, and read out the relay element. If you take the nameplate FLA, multiply by 125 percent, and then go to the table you will be selecting an overload based on 156 percent of the motor nameplate FLA (125 percent of 125 percent). The result will protect neither the motor nor the conductors from sustained overload should the motor malfunction.

The term *rating*, or *setting*, as used here means the current at which the device will open the circuit if this current continues for a considerable length of time.

Note: Refer to 460.9, which discusses the need to correct the sizing of running overload protection when power-factor capacitors are installed on the load side of the controller.

A motor having a temperature rise of 40°C when operated continuously at full load can carry a 25 percent overload for some time without injury to the motor. Other types of motors, such as enclosed types, do not have so high an overload capacity, and the running protective device should therefore open the circuit on a prolonged overload, which causes the motor to draw 115 percent of its rated full-load current.

Basic Code requirements are concerned with the rating or setting of overcurrent devices separate from motors. However, the Code permits the use of integral protection. Paragraph (2) of part (A) covers use of running overload protective devices within the motor assembly rather than in the motor starter. A protective device integral with the motor as used for the protection of motors is shown in Fig. 430-12. This device is placed inside the motor frame and is connected in series with the motor winding. It contains a bimetallic disk carrying two contacts, through which the circuit is normally closed. If the motor is overloaded and its temperature is raised to a certain limiting value, the disk snaps to the open position and opens the circuit. The device also includes a heating coil in series with the motor windings, which causes the disk to become heated more rapidly in case of a sudden heavy overload. For large motors, these devices may have a pair of wires brought out, allowing the sensor to operate within the control circuit and make the contactor or other controller stop the motor.

Fig. 430-12. Running overload protection may be built into the motor. (Sec. 430.32.)

Where the circuit-interrupting device is separate from the motor and is actuated by a device integral with the motor, the two devices must be so designed and connected that any accidental opening of the control circuit will stop the motor; otherwise, the motor would be left operating without any overcurrent protection.

There is special need for running protection on an automatically started motor because, if the motor is stalled when the starter operates, the motor will probably burn out if it has no running protection.

Part **(B)** of this section applies to smaller motors (1 hp or less) that are automatically started. Automatically started motors of 1 hp or less must be protected against running overload in the same way as motors rated over 1 hp—as noted in part **(B)**. That is, a separate or integral overload device must be used.

There are alternatives to the specific overload protection rules of parts **(A)** and **(B)**. Under certain conditions, no specific running overload protection need be used: The motor is considered to be properly protected if it is part of an approved assembly, which does not normally subject the motor to overloads and which has controls to protect against a stalled rotor. Or if the impedance of the motor windings is sufficient to prevent overheating due to failure to start, the branch-circuit protection is considered adequate.

In part **(C)**, the Code covers the procedure for “Selection of Overload Device.” This rule sets the absolute maximum permitted rating of an overload relay where values are higher than the 125 or 115 percent trip ratings of 430.32(A)(1) and (B). Motors with a marked service factor not less than 1.15 and 40°C-rise motors may, if necessary to enable the motor to start or carry its load, be protected by overload relays with trip settings up to 140 percent of motor full-load current. Motors with a 1.0 service factor and motors with a temperature rise over 40°C (such as 55°C-rise motors) must have their relay trip setting at not over 130 percent of motor full-load current.

BUT WATCH OUT! The maximum settings of 140 or 130 percent apply only to OL relays, such as used in motor starters. Use of this option is discouraged, and an informational note advises that instead of raising the trip setting, a better option might be to change the class of the overload relay element. The usual element, a Class 20, will carry 6 times its rated current for 20 s before opening. Class 10 elements will carry the same current for 10 s, and Class 30 elements for 30 s. Changing from a Class 20 to a Class 30 increases the hold-in time by 50 percent without varying the basic trip current, and this should be enough to solve legitimate problems of failure to start. The 2014 **NEC** has added Class 10A relays to the informational note. These relays clear locked rotor current in the same 10 s, and are therefore grouped with Class 10 devices, but undergo additional testing. They must open the circuit in less than 2 h at the rated overload conditions of 430.32, and after having reached thermal equilibrium they must open in less than 2 minutes when subjected to current equal to 150 percent of their setting.

Fuses or CBs may be used for running overload protection but may not be rated or set up to the 140 or 130 percent values. Fuses and breakers must have a maximum rating as shown in 430.32(A) and (B). If the value determined as indicated there does not correspond to a standard rating of fuse or CB, the next smaller size must be used. A rating of 125 percent of full-load current is the absolute maximum for fuses or breakers.

Part **(D)** covers motors of 1 hp or less that are manually started. They are considered to be protected against overload by the branch-circuit protection if the motor is within sight from the starter and the motor is not permanently installed ([Fig. 430-13](#)). Running overload devices are not required

in such cases. A distance of over 50 ft (15.0 m) is considered out of sight. If the motor is out of sight of its controller, or is permanently installed, then the usual rules in 430.32(B) will apply.

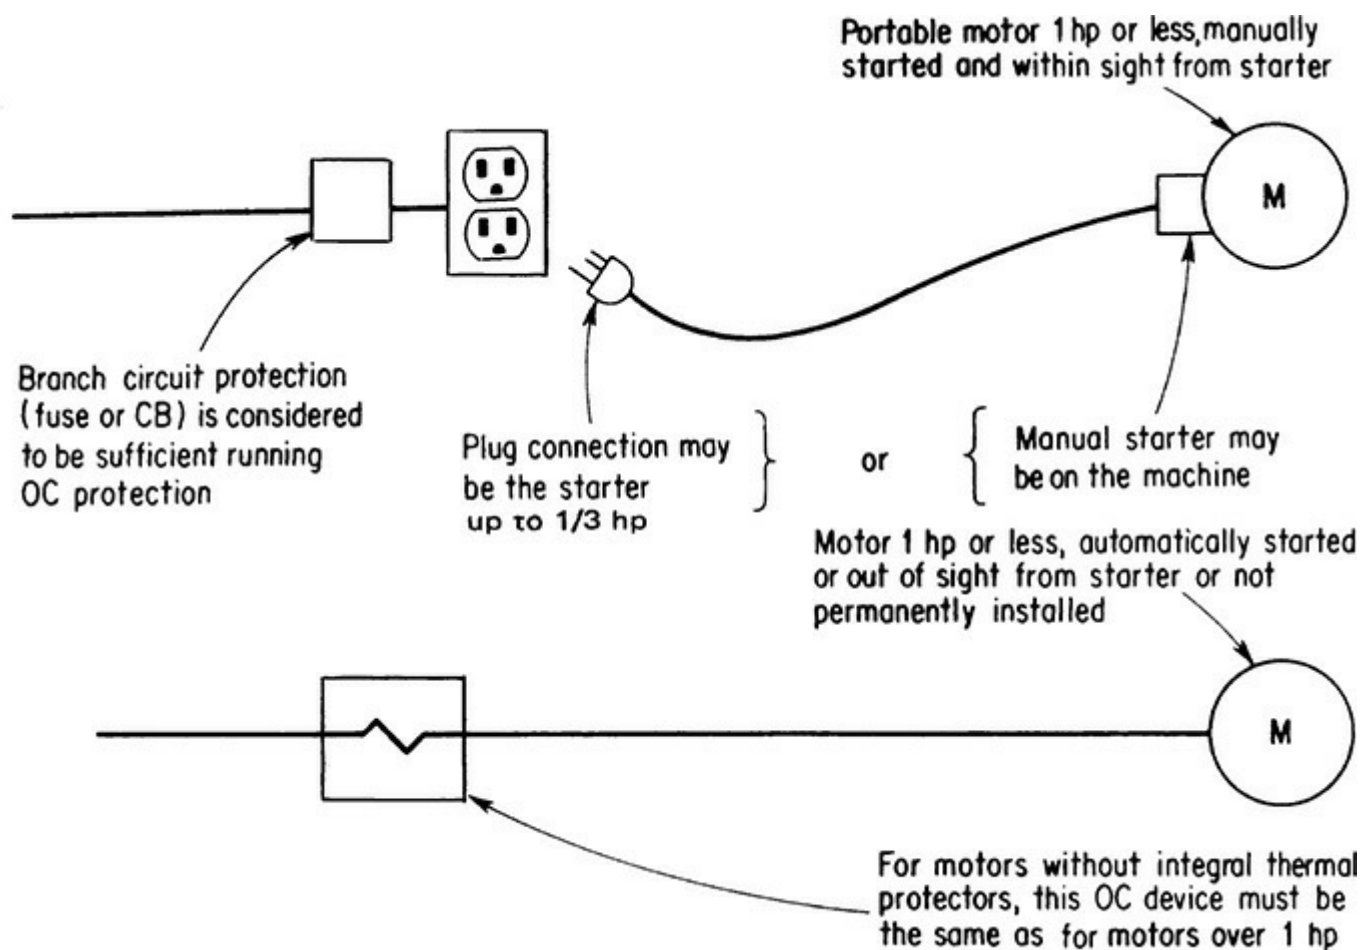

Fig. 430-13. The rules for automatic-start motors are different. (Sec. 430.32.)

430.33. Intermittent and Similar Duty. A motor used for a condition of service which is inherently short-time, intermittent, periodic, or varying duty does not require protection by overload relays, fuses, or other devices required by Sec. 430.32, but, instead, is considered as protected against overcurrent by the branch-circuit overcurrent device (CB or fuses rated in accordance with 430.52). Motors are considered to be for continuous duty unless the motor is completely incapable of operating continuously with load under any condition of use. One classic example is an elevator motor in a building of finite height.

430.35. Shunting During Starting Period. As covered in part (A) for motors that are *not* automatically started, where fuses are used as the motor-running protection, they may be cut out of the circuit during the starting period. This leaves the motor protected only by the branch-circuit fuses, but the rating of these fuses will always be well within the 400 percent limit specified in the rule. If the branch-circuit fuses are omitted, as allowed by the rule in 430.53(D), it is not permitted to use a starter that cuts out the motor fuses during the starting period unless the protection of the feeder is within the limits set by this rule. As shown in Fig. 430-14, a double-throw switch is arranged for across-the-line starting. The switch is thrown to the right to start the motor, thus cutting the running fuses out of the circuit. The switch must be so made that it cannot be left in the starting position.

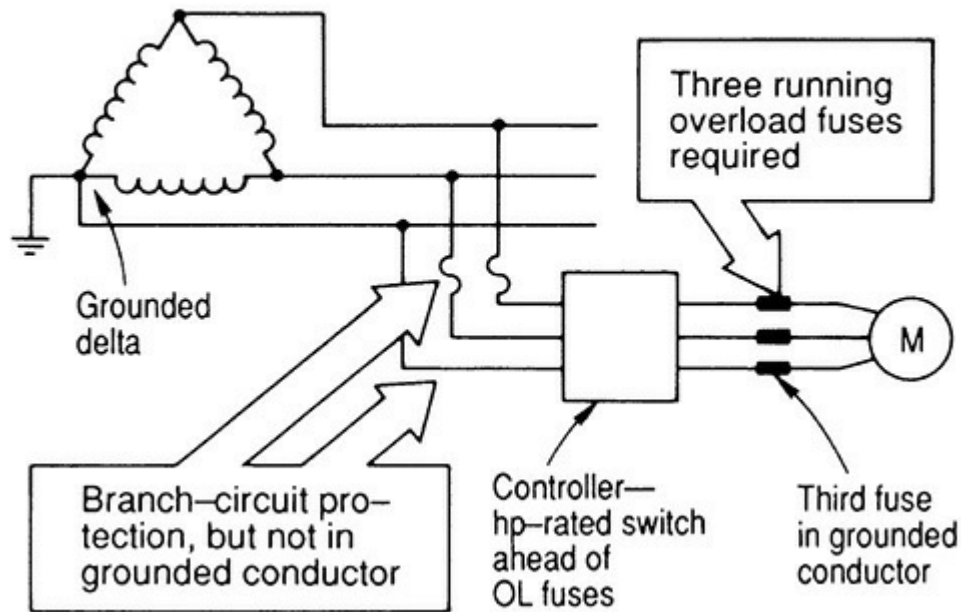

Fig. 430-14. Motor OL fuses may be shunted out for starting. (Sec. 430.35.)

In the exception to part **(B)**, conditions are given for shunting out overload protection of a motor that is automatically started. In previous Code editions, any motor that was automatically started was not permitted to have its overload protection shunted or cut out during the starting period. This exception now accommodates those motor-and-load applications that have a long accelerating time and would otherwise require an overload device with such a long trip time that the motor would not be protected if it stalled while running.

430.36. Fuses—In Which Conductor. This rule is listed in 240.22 as subpart **(2)** to the rule that prohibits use of an overcurrent device in an intentionally grounded conductor. When fuses are used for protection of service, feeder, or branch-circuit conductors, a fuse must never be used in a grounded conductor, such as the grounded leg of a 3-phase, 3-wire corner-grounded delta system. But, if fuses are used for OL protection for a 3-phase motor connected on such a system, a fuse must be used in all three phase legs—EVEN THE GROUNDED LEG. [Figure 430-15](#) shows two conditions of such fuse application for OL protection for a motor.

Fuses for OL protection only

Fuses for branch-circuit and OL protection

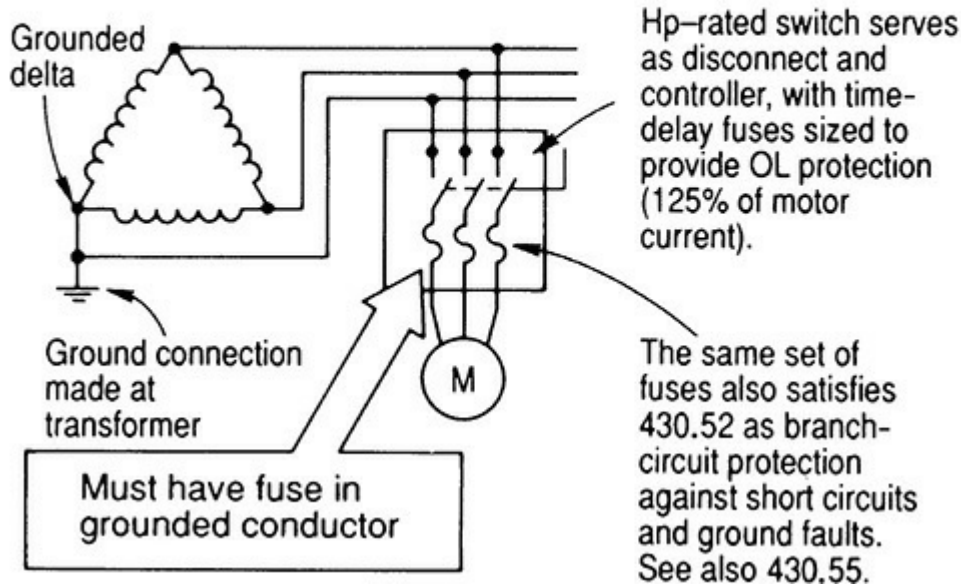

Fig. 430-15. A fuse for OL protection must be used in each phase leg of circuit. (Sec. 430.36.)

430.37. Devices Other than Fuses—In Which Conductor. Complete data on the number and location of overcurrent devices are given in Code Table 430.37.

Table 430.37 requires three running overload devices (trip coils, relays, thermal cutouts, etc.) for all 3-phase motors unless protected by other approved means, such as specifically designed embedded detectors with or without supplementary external protective devices.

Figure 430-16 points out this requirement.

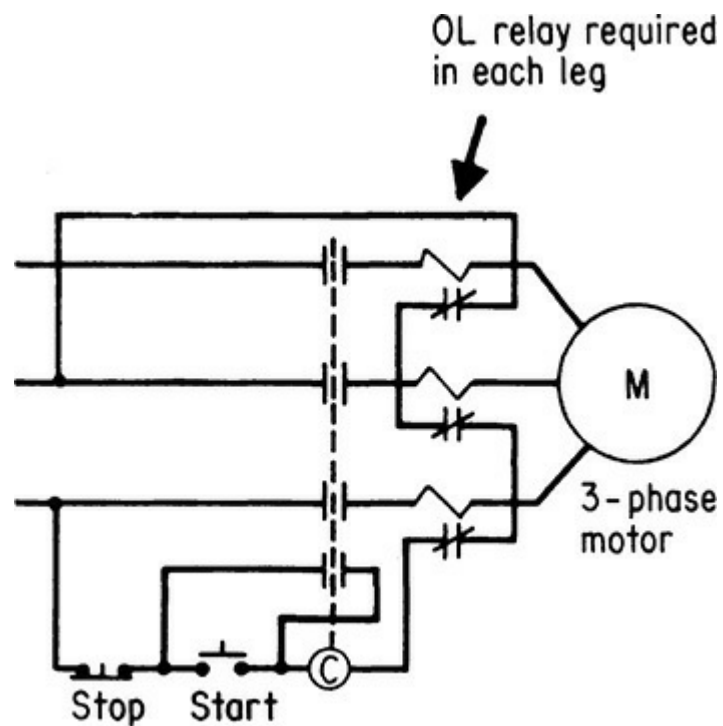

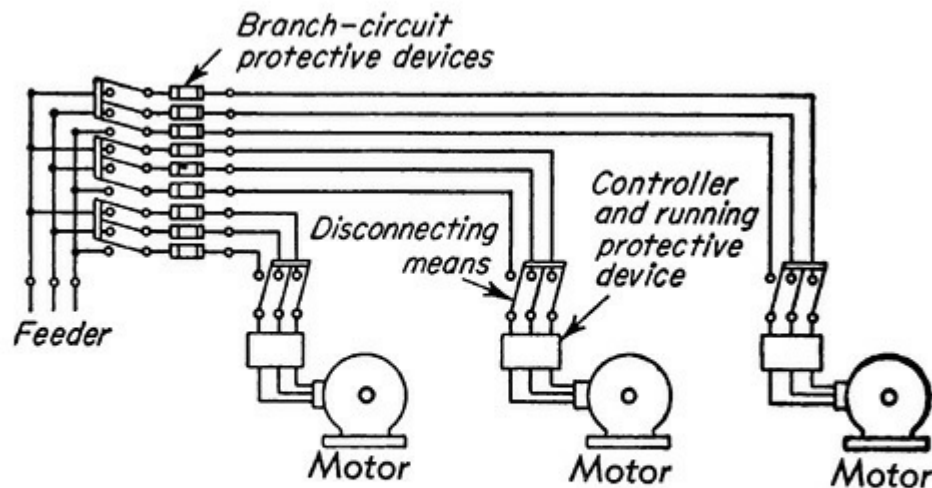

Fig. 430-16. Three OL units are required for 3-phase motors. (Sec. 430.37.)

If fuses are used as the running protective device, 430.36 requires a fuse in each ungrounded conductor. If the protective device consists of an automatically operated contactor or CB, the device must open a sufficient number of conductors to stop the current flow to the motor and must be equipped with the number of overload units specified in Table 430.37.

430.42. Motors on General-Purpose Branch Circuits. Refer to [Fig. 430-17](#), Type 3.

Type 1

Type 2

Type 3

Fig. 430-17. Motor branch-circuit protection is used in various types of layouts. (Sec. 430.51.)

Branch circuits supplying lamps are usually 120-V single-phase circuits, and on such circuits the effect of subparagraphs (A) and (B) is that any motor larger than 6 A must be provided with a starter that is approved for group operation.

It is provided in 210.24 that receptacles on a 20-A branch circuit may have a rating of 20 A, and in such case subparagraph (C) requires that any motor or motor-driven appliance connected through a plug and receptacle must have running overcurrent protection. If the motor rating exceeds 1 hp or 6 A, the protective device must be permanently attached to the motor and subparagraph (B) must be

complied with.

The requirements of 430.32 for the running overcurrent protection of motors must be complied with in all cases, regardless of the type of branch circuit by which the motor is supplied and regardless of the number of motors connected to the circuit.

430.43. Automatic Restarting. As noted in the comments to 430.32, an integral motor-running protective device may be of the type that will automatically restart, or it may be so constructed that after tripping out it must be closed by means of a reset button. However, an automatic restart type of protective device must not be used if an automatic restart could injure someone.

430.44. Orderly Shutdown. Although the NEC has all those requirements on use of running overload protection of motors, this section recognizes that there are cases when automatic opening of a motor circuit due to overload may be objectionable from a safety standpoint. In recognition of the needs of many industrial applications the rule here permits alternatives to automatic opening of a circuit in the event of overload. This permission for elimination of overload protection is similar to the permission given in 240.4(A) to eliminate overload protection when automatic opening of the circuit on an overload would constitute a more serious hazard than the overload itself. However, it is necessary that the circuit be provided with a motor overload sensing device conforming to the Code requirement on overload protection to indicate by means of a supervised alarm the presence of the overload (Fig. 430-18). Overload indication instead of automatic opening will alert personnel to the objectionable condition and will permit corrective action, either immediately or at some more convenient time, for an orderly shutdown to resolve the difficulty. But, as is required in 240.4(A), short-circuit protection on the motor branch circuit must be provided to take care of those high-level ground faults and short circuits that would be more serious in their hazardous implications than simple overload.

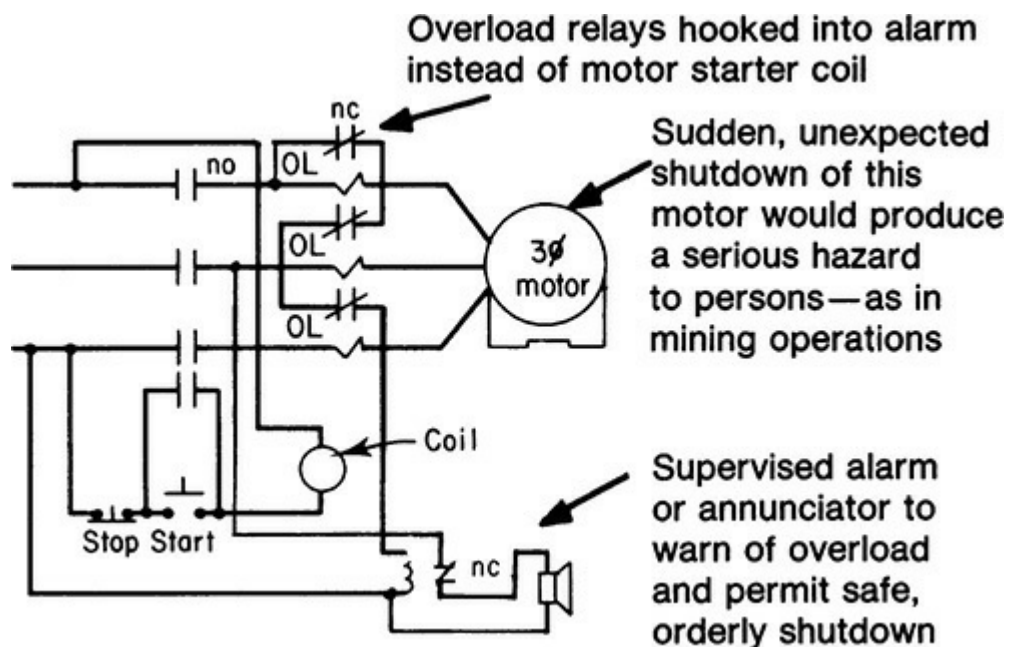

Fig. 430-18. This type of hookup may be used to warn of, but not open, an overload. (Sec. 430.44.)

Note: 445.12 also has an exception that permits this same use of an alarm instead of overcurrent protection where it is better to have a generator fail than stop operating.

430.51. General. This section indicates the coverage of Part IV, which requires “Motor Branch-

Circuit Short-Circuit and Ground-Fault Protection.” Although the phrase “ground-fault protection” is used in several of the sections of Part IV, it should be noted that it refers to the protection against ground fault that is provided by the set of fuses or CB that is used to provide short-circuit protection. The single CB or set of fuses is referred to as a “short-circuit and ground-fault protective device.” The rule is *not* intended to require the type of ground-fault protective hookup required by 230.95 on service disconnects (such as a zero-sequence transformer and relay hookup).

Motor branch circuits are commonly laid out in a number of ways. With respect to branch-circuit protection location and type, the layouts shown in [Fig. 430-17](#) are as follows:

Type 1

An individual branch circuit leads to each motor from a distribution center. This type of layout can be used under any conditions and is the one most commonly used.

Type 2

A feeder or subfeeder supports branch circuits tapped on at convenient points. This is the same as Type 1 except that the branch-circuit overcurrent protective devices are mounted individually at the points where taps are made to the subfeeder, instead of being assembled at one location in the form of a branch-circuit distribution center. Under certain conditions, the branch-circuit protective devices may be located at any point not more than 25 ft (7.5 m) distant from the point where the branch circuit is tapped to the feeder.

Type 3

Small motors, lamps, and appliances may be supplied by a 15- or 20-A circuit as described in Art. 210. Motors connected to these circuits must be provided with running overcurrent protective devices in most cases. See 430.42.

Figure 430-19 shows the typical elements of a motor branch circuit in their relation to branch-circuit protection, so that the protection is effective for the circuit conductors, the control and disconnect means, and the motor. Motor controllers provide protection for the motors they control against all ordinary overloads but are not intended to open short circuits. Fuses, CBs, or motor short-circuit protectors used as the branch-circuit protective device will open short circuits and therefore provide short-circuit protection for both the motor and the running protective device. Where a motor is supplied by an individual branch circuit having branch-circuit protection, the circuit protective devices may be either fuses or a CB, and the rating or setting of these devices must not exceed the values specified in 430.52. In [Fig. 430-19](#), the fuses or CB at the panelboard must carry the starting current of the motor, and in order to carry this current the fuse rating or CB setting may be rated up to 300 or 400 percent of the running current of the motor, depending on the size and type of motor. It is evident that to install motor circuit conductors having an ampacity up to that percent of the motor full-load current would be unnecessary.

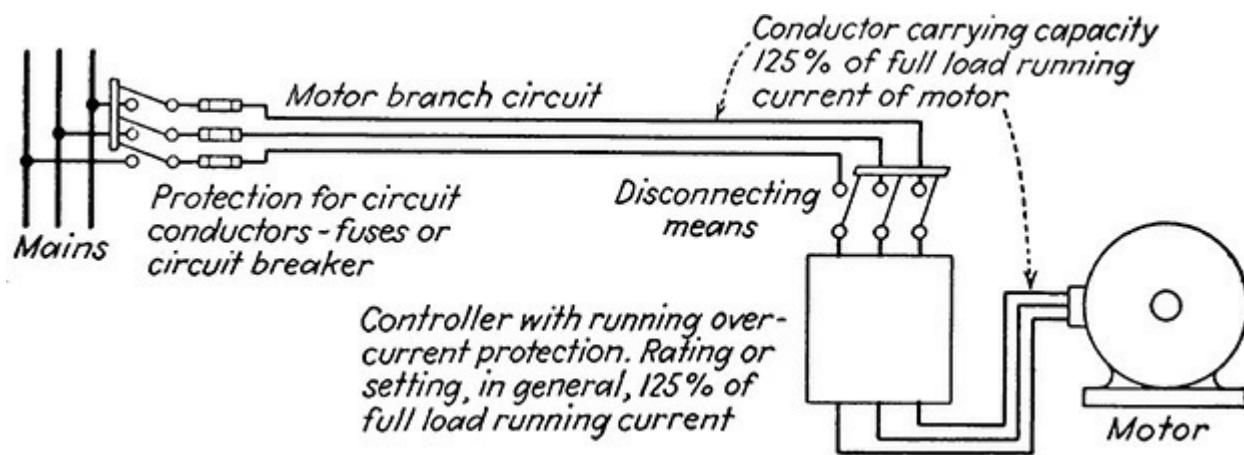

Fig. 430-19. Branch-circuit protection is on the line side of other components. (Sec. 430.51.)

There are three possible causes of excess current in the conductors between the panelboard and the motor controller—a short circuit between two of these conductors, a ground fault on one conductor that forms a short circuit, and an overload on the motor. A short circuit would draw so heavy a current that the fuses or breaker at the panelboard would immediately open the circuit, even though the rating or setting is in excess of the conductor ampacity. Any excess current due to an overload on the motor must pass through the protective device at the motor controller, causing this device to open the circuit. Therefore, with circuit conductors having an ampacity equal to 125 percent of the motor-running current and with the motor-protective device set to operate at near the same current, the conductors are reasonably protected.

430.52. Rating or Setting for Individual Motor Circuit. The Code requires that branch-circuit protection for motor circuits must protect the circuit conductors, the control apparatus, and the motor itself against overcurrent due to short circuits or ground (430.51 through 430.58).

The first, and obviously necessary, rule is that the branch-circuit protective device for an individual branch circuit to a motor must be capable of carrying the starting current of the motor without opening the circuit. Then the Code proceeds to place maximum values on the ratings or settings of such overcurrent devices. It says that such devices must not be rated in excess of the values given in Table 430.52.

In case the values for branch-circuit protective devices determined by Table 430.52 do not correspond to the standard sizes or ratings of fuses, nonadjustable CBs, or thermal devices, or possible settings of adjustable CBs adequate to carry the load, the next higher size, rating, or setting may be used.

Under exceptionally severe starting conditions where the nature of the load is such that an unusually long time is required for the motor to accelerate to full speed, the fuse or CB rating or setting recommended in Table 430.52 may not be high enough to allow the motor to start. It is desirable to keep the branch-circuit protection at as low a rating as possible, but in unusual cases, it is permissible to use a higher rating or setting. Where absolutely necessary in order to permit motor starting, the device may be rated at other maximum values, as follows:

1. The rating of a fuse that is *not* a dual-element time-delay fuse (or a time-delay Class CC fuse) and is rated not over 600 A may be increased above the Code table value but must never exceed 400 percent of the full-load current.
2. The rating of a time-delay (dual-element) fuse may be increased but must never exceed 225 percent of full-load current.

3. The setting of an instantaneous trip CB (also known as a “motor circuit protector”) that is part of a *listed* combination starter (which contains a magnetic short-circuit trip element, without time delay, and independent overload device) may be increased but never over 1300 percent of the motor full-load current, unless supplying a Design B energy-efficient motor, in which the setting may be increased to not more than 1700 percent of motor full-load current. In this category, it is not necessary to actually experiment with a lower-rated breaker; the need can be established by engineering evaluation. And it is never necessary to decrease the protection below 15 A. Motor short-circuit protectors (also where part of a listed combination controller) and listed self-protected combination controllers are permitted to use the same parameters for protection.
4. The rating of an inverse time CB (a typical thermal-magnetic CB with a time-delay and instantaneous trip characteristic) may be increased but must not exceed 400 percent for full-load currents of 100 A or less and must not exceed 300 percent for currents over 100 A.
5. A fuse rated 601 to 6000 A may be increased but must not exceed 300 percent of full-load current.
6. Torque motors must be protected at the motor nameplate current rating, and if a standard overcurrent device is not made in that rating, the next higher standard rating of protective device may be used.
7. Multispeed motors may have a single short-circuit and ground-fault protective device if it meets the multipliers established in Table 430.52. As an alternative, the protection can be set based on the needs of the highest current winding, provided there is running overload protection for both speed windings, and both the controllers and the circuit conductors for every speed winding are sized in accordance with the comparable components of the highest current winding.
8. There are two global provisions to be considered before leaving this topic. The first is the issue of “Power Electronic Devices” that are special “semiconductor” fuses that can be substituted for any of the short-circuit and ground-fault protective devices considered so far. Their use is limited to solid-state motor controller systems, along with some associated electromechanical devices such as bypass and isolation contactors, and there must be a marking for replacement fuses provided adjacent to the fuseholders.
9. The second is 430.52(C)(2), which is a very important and widely overlooked item. This provision says that if the manufacturer of the overload relay components chooses to specify a maximum setting of short-circuit and ground-fault protective devices that can be used ahead of its equipment, and posts it as part of its relay table (or otherwise on the equipment), that number absolutely trumps any calculations made in accordance with multipliers in Table 430.52. That requirement is also specified in UL regulations that regulate the exposure of motor controllers to short-circuit currents to protect internal components, such as overload relays and contacts, from damage or destruction. Those rules state:

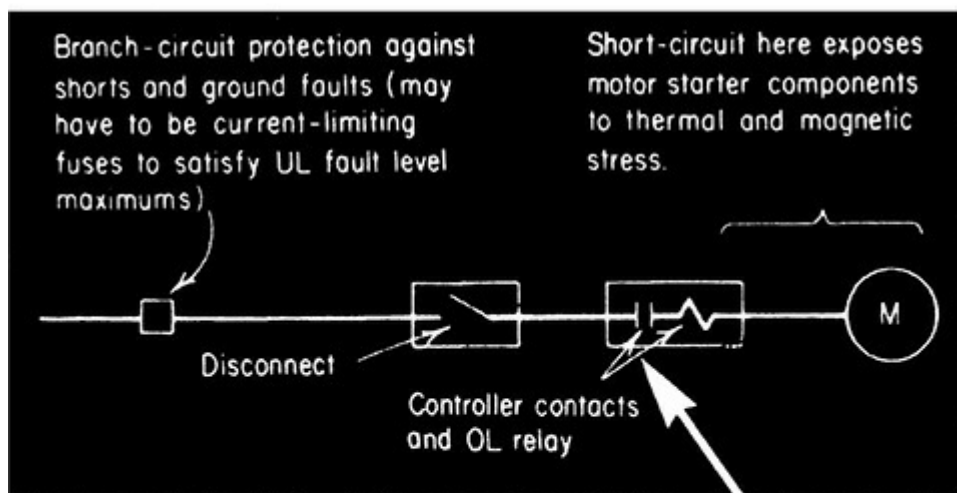

Motor controllers incorporating thermal cutouts, thermal overload relays, or other devices for motor-running overcurrent protection are considered to be suitably protected against overcurrent due to short circuits or grounds by motor branch circuit, short circuit, and ground-fault protective devices selected in accordance with the **National Electrical Code** and any additional information marked on the product. Motor controllers may specify that protection is to be provided by fuses or by an inverse time circuit breaker. If there is no marking of protective device type, controllers are considered suitably protected by either type of device. Motor controllers may specify a maximum rating of protective device. If not marked with a rating, the controllers are considered suitably protected by a protective device of the maximum rating permitted by the **National Electrical Code**.

The rules of this section establish maximum values for branch-circuit protection, setting the limit of safe applications. However, use of smaller sizes of branch-circuit protective devices is obviously permitted by the Code and does offer opportunities for substantial economies in selection of CBs, fuses and the switches used with them, panelboards, and so forth. In any application, it is only necessary that the branch-circuit device which is smaller than the maximum permitted rating must have sufficient time delay in its operation to permit the motor starting current to flow without opening the circuit.

But a CB for branch-circuit protection must have a continuous current rating of not less than 115 percent of the motor full-load current, as required by 430.58.

Unless otherwise marked, motor controllers incorporating thermal cutouts or overload relays are considered suitable for use on circuits having available fault currents not greater than (refer to Fig. 430-20):

Horsepower rating	RMS symmetrical amperes
1 or less	1,000
1½ to 50	5,000
51 to 200	10,000
201 to 400	18,000
401 to 600	30,000
601 to 900	42,000
901 to 1600	85,000

**AVAILABLE SHORT-CIRCUIT CURRENT HERE
MUST NOT EXCEED VALUES GIVEN BY UL
OR MUST BE LIMITED TO THOSE VALUES**

Fig. 430-20. UL specifies maximum short-circuit withstand ratings for controllers. (Sec. 430.52.)

Typical application of the basic rule of 430.52 on short-circuit protection for motor circuits is shown in Fig. 430-3. Overcurrent (branch-circuit) protection (from Table 430.52 and 430.52) using nontime-delay fuses is calculated as follows:

1. The 50-hp squirrel-cage motor must be protected at not more than 200 A (65 A × 300 percent,

next higher standard size device allowed).

2. The 30-hp wound-rotor motor must be protected at not more than 60 A ($40 \text{ A} \times 150$ percent).
3. Each 10-hp motor must be protected at not more than 45 A ($14 \text{ A} \times 300$ percent, next higher standard size device allowed).

As shown in Code Table 430.52, if thermal-magnetic CBs were used, instead of the fuses, for branch-circuit protection, the maximum ratings that are permitted by the basic rule are:

1. For the 50-hp motor— $65 \text{ A} \times 250$ percent, or 162.5 A, with the next higher standard CB rating of 175 A permitted.
2. For the 30-hp wound-rotor motor— $40 \text{ A} \times 150$ percent, or 60 A, calling for a 60-A CB.
3. For each 10-hp motor— $14 \text{ A} \times 250$ percent, or 35 A, calling for a 35-A CB.

Instantaneous Trip CBs

The **NEC** recognizes the use of an instantaneous trip CB (without time delay) for short-circuit protection of motor circuits. Such breakers—also called *magnetic-only* breakers—may be used only if they are adjustable and if combined with motor starters in combination assemblies. An instantaneous-trip CB or a motor short-circuit protector (MSCP) may be used *only* as part of a *listed* (such as by UL) combination motor controller. A combination motor starter using an instantaneous trip breaker must have running overload protection in each conductor (Fig. 430-21). Such a combination starter offers use of a smaller CB than would be possible if a standard thermal-magnetic CB were used. And the smaller CB offers faster operation for greater protection against grounds and short circuits—in addition to offering greater economy. Note that because these devices are only permitted as components in listed combination controllers, they are recognized components of listed equipment, but *they are not and can never be listed*. They will have a mark similar to the one shown in Fig. 100-29. Refer to the discussion of the new concept in receptacles as explained in Art. 100 for more information on the component recognition principle.

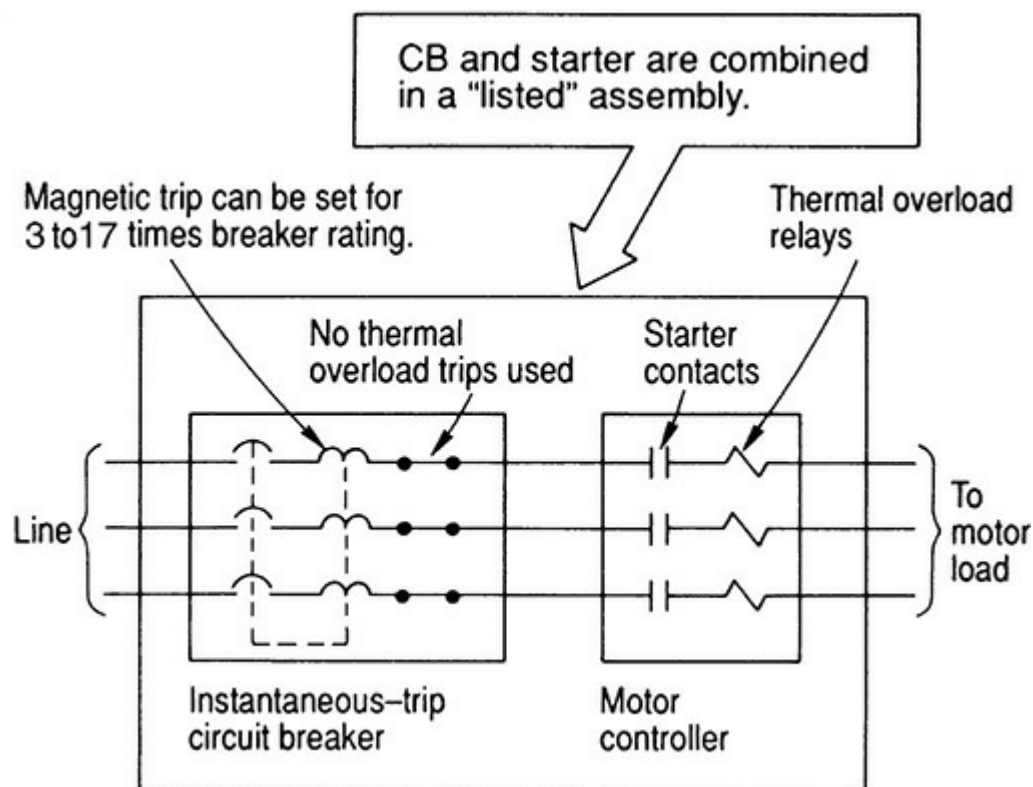

Fig. 430-21. Section 430.52 accepts use of a magnetic-only circuit breaker if it is part of a “listed” assembly of a combination starter. (Sec. 430.52.)

A combination motor starter, as shown in Fig. 430-21, is based on the characteristics of the instantaneous-trip CB, which is covered by the third percent column from the left in Code Table 430.52. Molded-case CBs with only magnetic instantaneous-trip elements in them are available in almost all sizes. Use of such a device requires careful accounting for the absence of overload protection in the CB, up to the short-circuit trip setting. Such a CB is designed for use as shown in Fig. 430-21. The circuit conductors are sized for at least 125 percent of motor current. The thermal overload relays in the starter protect the entire circuit and all equipment against operating overloads up to and including stalled rotor current. They are commonly set at 125 percent of motor current. In such a circuit, a CB with an adjustable magnetic trip element can be set to take over the interrupting task at currents above stalled rotor and up to the short-circuit duty of the supply system at that point of installation. The magnetic trip in a typical unit might be adjustable from 3 to 17 times the breaker current rating; that is, a 100-A trip can be adjusted to trip anywhere between 300 and 1700 A. Thus the CB serves as motor circuit disconnect and short-circuit protection.

Selection of such a listed assembly with an instantaneous-only CB is based on choosing a nominal CB size with a current rating at least equal to 115 percent of the motor full-load current to carry the motor current and to qualify under 430.58 and 430.110(A) as a disconnect means. Then the adjustable magnetic trip is set to provide the short-circuit protection—the value of current at which instantaneous circuit opening takes place, which should be just above the starting current of the motor involved—using a multiplier of something like 1.5 on locked-rotor current to account for asymmetry in starting current. Asymmetry can occur when the circuit to the motor is closed at that point on the alternating voltage wave where the inrush starting current is going through the negative maximum value of its alternating wave. That is the same concept as asymmetry in the initiation of a short-circuit current. Where supplying Design B energy-efficient motors, a greater inrush can be anticipated on start-up. As a result, higher initial and maximum settings are recognized.

Listed equipment using an instantaneous CB type is available with very simple instructions by the manufacturer to make proper selection and adjustment of the instantaneous-trip CB combination starter a quick, easy matter. The following describes the concept behind the application of listed combination starters with instantaneous-only CBs.

Given: A 30-hp, 230-V, 3-phase, squirrel-cage motor marked with the code letter M, indicating that the motor has a locked-rotor current of 10 to 11.19 kVA per horsepower, from Code Table 430.7(B). A full-voltage controller is combined with the CB, with running overload protection in the controller to protect the motor within its heating damage curve on overload in a listed unit.

Required: Select the maximum setting and minimum rating for the CB which will provide short-circuit protection and will qualify as the motor circuit disconnect means.

Solution: The motor has a full-load current of 80 A (Code Table 430.250). A CB suitable for use as disconnect must have a current rating at least 115 percent of 80 A. As covered in 430.52(C)(3), for instantaneous-trip CBs, the initial setting from Table 430.52 would be limited to 800 percent of the 80-A full-load current. The maximum setting—for other than the high-efficiency Design B energy-efficient motors—is 1300 percent. For Design B energy-efficient motors, the initial setting may be 1100 percent of motor full-load current with a maximum setting of 1700 percent of the motor full-load current.

It should be noted that settings above 800 or 1100 percent of the motor's full-load current are permitted only if nuisance tripping occurs on starting *or* if evaluation of the motor's starting characteristics and the time-current trip curve of the breaker indicates that a greater setting is needed. Although not completely clear, the trip value established through the engineering evaluation should be considered as the maximum setting.

Because the use of a magnetic-only CB does not protect against low-level grounds and shorts in the circuit conductors on the line side of the starter running overload relays, the **NEC** rule permits such application only where the CB and starter are part of a *listed* combination starter in a single enclosure.

MSCPs

A motor short-circuit protector (MSCP), as referred to in part (7) of 430.52, is a fuselike device designed for use only in its own type of fusible-switch combination motor starter. As clarified in an informational note, it is not an instantaneous-trip circuit breaker. The combination offers short-circuit protection, running overload protection, disconnect means, and motor control—all with assured coordination between the short-circuit interrupter (the motor short-circuit protector) and the running OL devices. It involves the simplest method of selection of the correct MSCP for a given motor circuit. This packaged assembly is a third type of combination motor starter—added to the conventional fusible-switch and CB types.

The **NEC** recognizes motor short-circuit protectors in 430.40 and 430.52, provided the combination is a *listed* assembly. This means a combination starter equipped with motor short-circuit protectors and listed by Underwriters Laboratories, Inc., or another nationally recognized testing lab, as a package called an *MSCP starter*. And here again, the motor short-circuit protector is a *recognized component* of the listed assembly, but it is ineligible for a listing because it cannot be used as a standalone device.

430.53. Several Motors or Loads on One Branch Circuit. A single branch circuit, which must be protected by fuses or inverse-time circuit breakers because instantaneous devices cannot be adequately coordinated, may be used to supply two or more motors as follows:

Part (A): Two or more motors, each rated not more than 1 hp and each drawing not over 6 A full-load current, may be used on a branch circuit protected at not more than 20 A at 125 V or less, or 15 A at 600 V or less. And the rating of the branch-circuit protective device marked on any of the controllers must not be exceeded. That is also a UL requirement.

Individual running overload protection is necessary in such circuits, unless: The motor is not permanently installed, is manually started, and is within sight from the controller location; or the motor has sufficient winding impedance to prevent overheating due to stalled rotor current; or the motor is part of an approved assembly that does not subject the motor to overloads and that incorporates protection for the motor against stalled rotor; or the motor cannot operate continuously under load.

Part (B): Two or more motors of any rating, each having individual running overload protection, may be connected to a branch circuit that is protected by a short-circuit protective device selected in accordance with the maximum rating or setting of a device that could protect an individual circuit to the motor of the smallest rating. This may be done only where it can be determined that the branch-circuit device so selected will not open under the most severe normal conditions of service that might

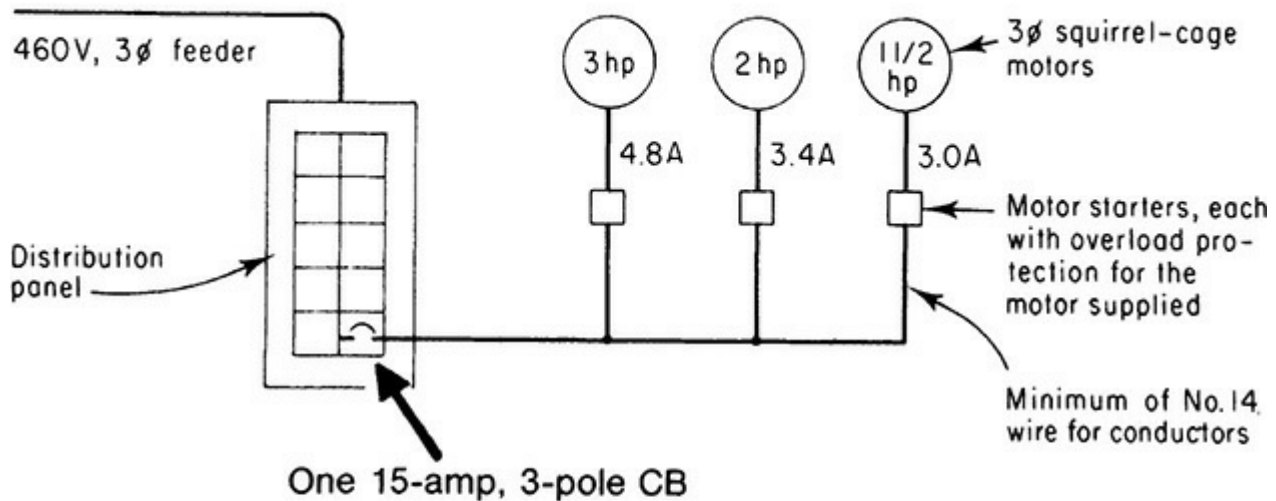

be encountered.

This permission of part (B) offers wide application of more than one motor on a single circuit, particularly in the use of small integral-horsepower motors installed on 460-V, 3-phase systems. This application primarily concerns use of small integral-horsepower 3-phase motors as used in 208-, 220-, 460-, and 575-V industrial and commercial systems. Only such 3-phase motors have full-load operating currents low enough to permit more than one motor on circuits fed from 15-A protective devices.

There are a number of ways of connecting several motors on a single branch circuit, as follows:

In case I, Fig. 430-22, using a three-pole CB for branch-circuit protective device, application is made in accordance with part (B) as follows:

CASE I—USING A CIRCUIT BREAKER FOR PROTECTION

HERE IS THE KEY: A 15-amp, 3-pole CB is used, based on 430.52 and Table 430.250. This is the “next higher size” of standard protective device above $250\% \times 3.0$ amps (the required rating for the smallest motor of the group). The 15-amp CB makes this application possible, because the 15-amp CB is the smallest standard rating of CB and is suitable as the branch-circuit protective device for the 1 1/2-hp motor.

Fig. 430-22. Three integral-horsepower motors may be supplied by this circuit makeup. (Sec. 430.53.)

1. The full-load current for each motor is taken from **NEC** Table 430.250 [as required by 430.6(A)].
2. Choosing to use a CB instead of fuses for branch-circuit protection, the rating of the branch-circuit protective device, 15 A, does not exceed the maximum value of short-circuit protection required by 430.52 and Table 430.52 for the smallest motor of the group—which is the 1 1/2-hp motor. Although 15 A is greater than the maximum value of 250 percent times motor full-load current ($2.5 \times 3.0 \text{ A} = 7.5 \text{ A}$) set by Table 430.52 (under the column “Inverse Time Breaker” opposite “polyphase squirrel-cage” motors), the 15-A breaker is the “next higher size, rating, or setting” for a standard CB—as permitted in 430.52. A 15-A CB is the smallest standard rating recognized by 240.6.

3. The total load of motor currents is:

$$4.8 \text{ A} + 3.4 \text{ A} + 3.0 \text{ A} = 11.2 \text{ A}$$

This is well within the 15-A CB rating, which has sufficient time delay in its operation to permit starting of any one of these motors with the other two already operating. Torque characteristics of the loads on starting are not high. It was therefore determined that the CB will not open under the most severe normal service.

4. Each motor has individual running overload protection in its starter.

5. The branch-circuit conductors are sized in accordance with 430.24:

$$4.8 \text{ A} + 3.4 \text{ A} + 2.6 \text{ A} + (25 \text{ percent of } 4.8 \text{ A}) = 12.4 \text{ A}$$

Conductors must have an ampacity at least equal to 12 A. No. 14 THW, TW, RHW, RHH, THHN, or XHHW conductors will fully satisfy this application.

In case II, Fig. 430-23, a similar hookup is used to supply three motors—also with a CB for branch-circuit protection.

CASE II—USING A CIRCUIT BREAKER FOR PROTECTION

Fig. 430-23. Fractional-horsepower and integral-horsepower motors may be supplied by the same circuit. (Sec. 430.53.)

1. Section 430.53(B) requires branch-circuit protection to be not higher than the maximum amps set by 430.52 for the lowest rated of the motors.

2. From 430.52 and Table 430.52, that maximum protection rating for a CB is $250 \text{ percent} \times 1.1 \text{ A}$ (the lowest rated motor), or 2.5 A. But, 2.8 A is not a “standard rating” of CB from 240.6; and the first exception to 430.52(C)(1) permits use of the “next higher size, rating, or setting” of standard protective device.
3. Because 15 A is the lowest standard rating of CB, it is the “next higher” device rating above 2.5 A and satisfies Code rules on the rating of the branch-circuit protection.

The applications shown in cases I and II permit use of several motors up to circuit capacity, based on 430.24 and 430.53(B) and on starting torque characteristics, operating duty cycles of the motors and their loads, and the time delay of the CB. Such applications greatly reduce the number of CB poles, the number of panels, and the amount of wire used in the total system. One limitation, however, is placed on this practice in 430.52(C)(2), as noted previously. Where more than one fractional- or small-integral-horsepower motor is used on a single branch circuit of 15-A rating in accordance with NEC 430.53(A) or (B), care must be taken to observe all markings on controllers that indicate a maximum rating of short-circuit protection ahead of the controller (Fig. 430-24).

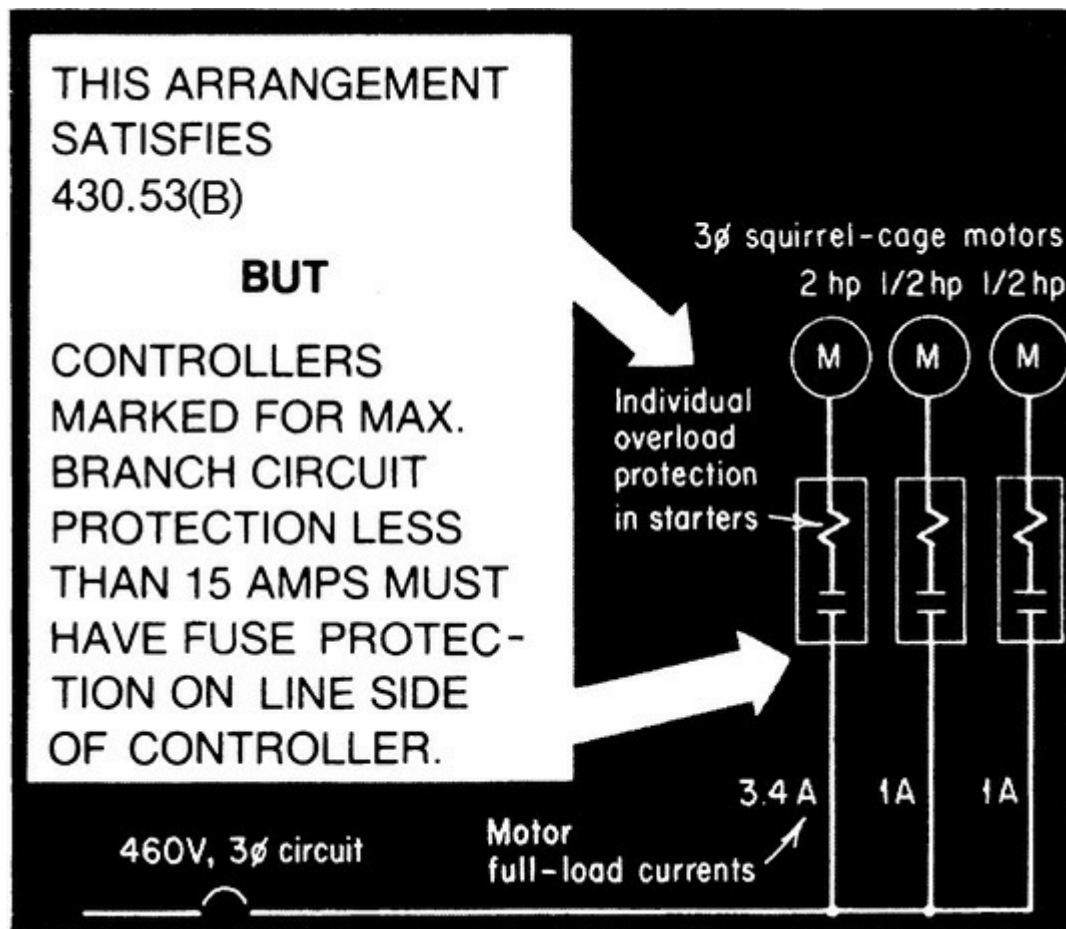

Fig. 430-24. Branch-circuit protection must not exceed marked maximum value. (Sec. 430.53.)

In case III, Fig. 430-25, the same three motors shown in case II would be subject to different hookup to comply with the rules of 430.53(B) when fuses, instead of a CB, are used for branch-circuit protection, as follows:

Fig. 430-25. Fuse protection may require different circuiting for several motors. (Sec. 430.53.)

1. To comply with 430.53(B), fuses used as branch-circuit protection must have a rating not in excess of the value permitted by 430.52 and Table 430.52 for the smallest motor of the group—one of the 1/2-hp motors.
2. Table 430.52 shows that the maximum permitted rating of nontime-delay type fuses is 300 percent of full-load current for 3-phase squirrel-cage motors. Applying that to one of the 1/2-hp motors gives a maximum fuse rating of

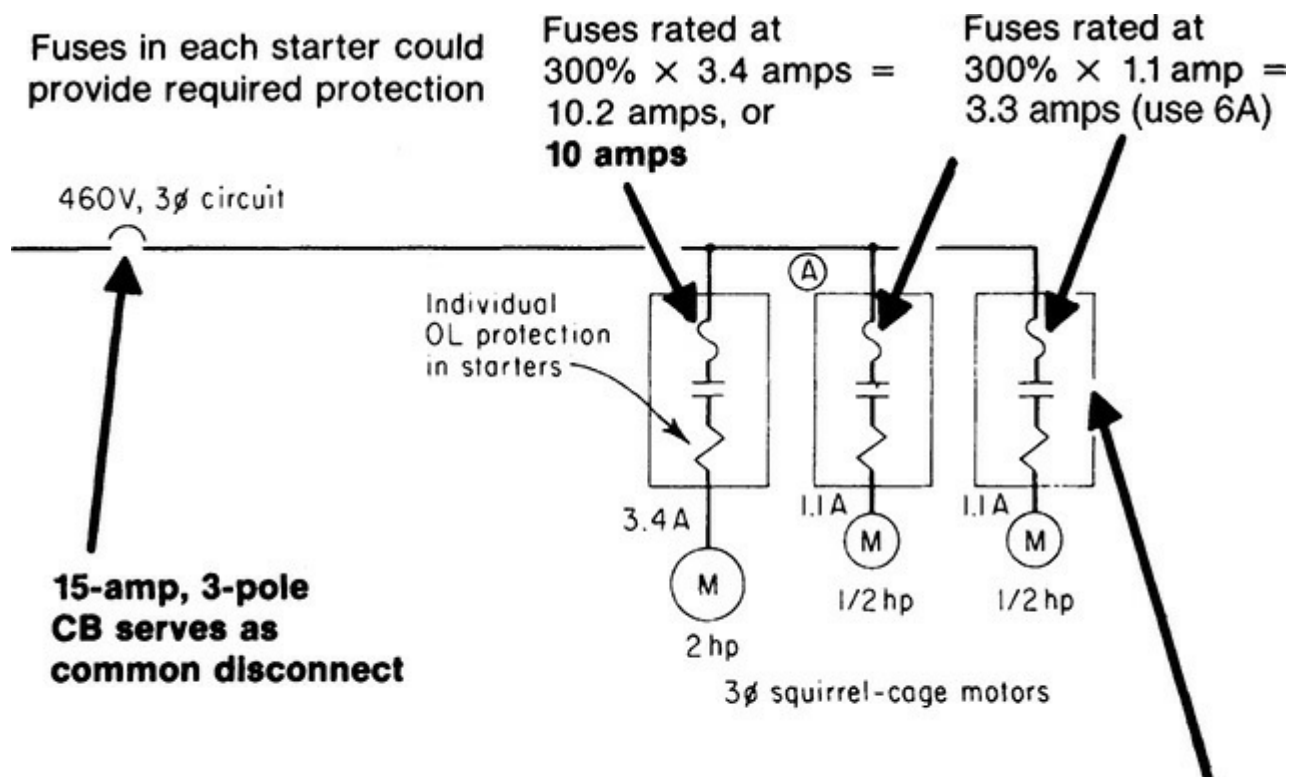

$$300 \text{ percent} \times 1.1 \text{ A} = 3.3 \text{ A}$$

3. The fuse protection will need to be set at 6 A—BECAUSE 6 A IS A “STANDARD” RATING OF FUSE (but not a standard rating of CB). 240.6 considers fuses rated at 1, 3, 6, and 10 A to be “standard” ratings.
4. The maximum branch-circuit fuse permitted by 430.53(B) for a 1/2-hp motor is 6 A (next higher standard size).
5. The two 1/2-hp motors may be fed from a single branch circuit with three 6-A fuses in a three-pole switch.
6. Following the same Code rules, the 2-hp motor would require fuse protection rated not over 10 A (300 percent × 3.4 A = 10.2 A).

Note: Because the standard fuse ratings below 15 A place fuses in a different relationship to the applicable Code rules, it may require interpretation of the Code rules to resolve the question of acceptable application in case II versus case III. Some jurisdictions may attempt to exclude CBs as circuit protection in these cases where use of fuses, in accordance with the precise wording of the Code, provides lower-rated protection than CBs—when applying the rule of the third paragraph of 430.52. However, there is no support in the current Code text for an enforcement position that would compel a change of overcurrent design from CBs to fuses in this case, with one exception that tends to make the general point by virtue of its clearly limited effect. Review the discussion and UL data in 430.52(C)(2) in this book. If the manufacturer elects to specify the type and size of protection for its overloads, then and only then would a design change become enforceable.

Figure 430-26 shows one way of combining cases II and III to satisfy 430.53(B), 430.52, and

240.6; but the 15-A CB would then technically be feeder protection, because the fuses would be serving as the “branch-circuit protective devices” as required by 430.53(B). Those fuses might be acceptable in each starter, without a disconnect switch, in accordance with 240.40—which allows use of cartridge fuses at any voltage without an individual disconnect for each set of fuses, provided only qualified persons have access to the fuses. But 430.112 would have to be satisfied to use the single CB as a disconnect for the group of motors. And part (B) of that exception recognizes one common disconnect in accordance with 430.53(A) but not 430.53(B). Certainly, the use of a fusible-switch-type combination starter for each motor would fully satisfy all rules.

Fuses without individual disconnects might be acceptable under 240.40; or a single disconnect switch, fused at 6 amps, could be installed at point “A,” eliminating the need for fuses in the two starters for the 1/2-hp motors.

Fig. 430-26. Multimotor circuit may be acceptable with fused starters. (Sec. 430.53.)

Figure 430-27 shows another hookup that might be required to supply the three motors of [Fig. 430-22](#).

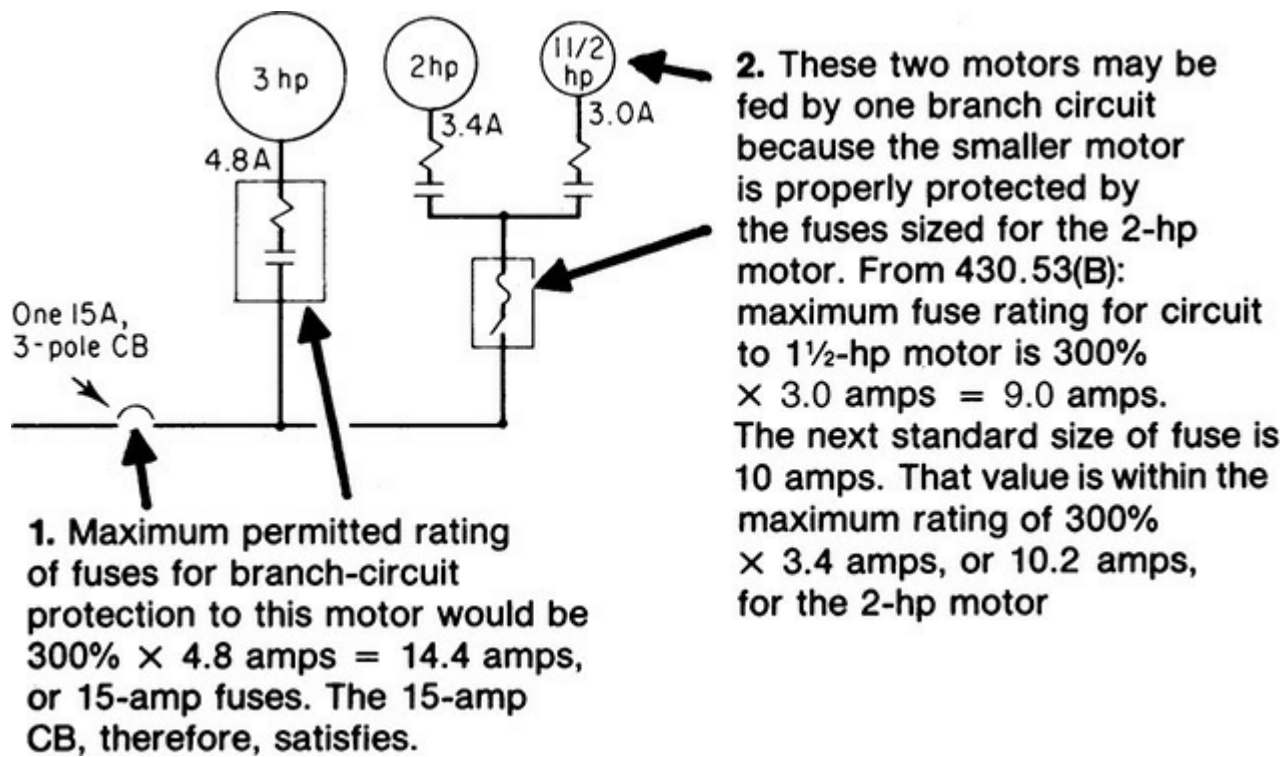

Fig. 430-27. This hookup might be required to satisfy literal Code wording. (Sec. 430.53.)

Figure 430-28 shows another hookup of several motors on one branch circuit—an actual job installation that was based on application of 430.53(B). The installation was studied as follows:

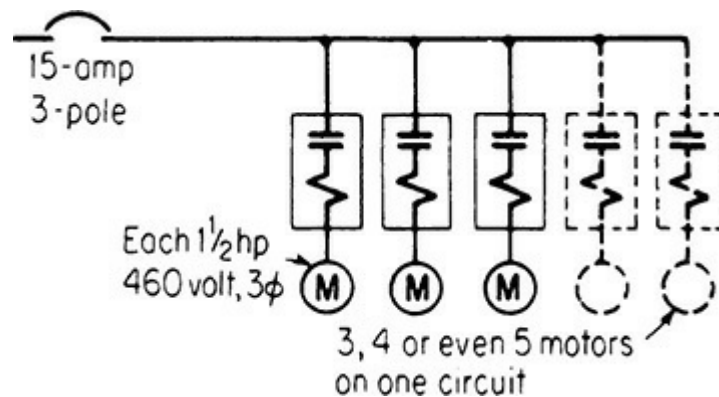

Fig. 430-28. Multimotor circuits offer economical supply to small integral-horsepower motors. (Sec. 430.53.)

Problem: A factory has 100 1 1/2-hp, 3-phase motors, with individual motor starters incorporating overcurrent protection, rated for 460 V. Provide circuits.

Solution: Prior to 1965, the **NEC** would not permit several integral-horsepower motors on one branch circuit fed from a three-pole CB in a panel. Each of the 100 motors would have had to have its own individual 3-phase circuit fed from a 15-A, 3-pole CB in a panel. As a result, a total of 300 CB poles would have been required, calling for seven panels of 42 circuits each plus a smaller panel (or special panels of greater numbers than 42 poles per panel).

Under the present Code, depending on the starting torque characteristics and operating duty of the motors and their loads, with each motor rated for 3.0 A, three or four motors could be connected on each 3-phase, 15-A circuit—greatly reducing the number of panelboards and overcurrent devices and

the amount of wire involved in the total system. Time delay of CB influences number of motors on each circuit.

BUT, an extremely important point that must be strictly observed is the requirement that the rating of branch-circuit protection must not exceed any maximum value that might be marked on the starters used with the motors.

Part (C): In selecting the wording for part (C), it was the intent of the Code-making panel to clarify the intent that several motors should not be connected to one branch circuit unless careful engineering is exercised by qualified persons to determine that all components of the branch circuit are selected and specified to meet the present requirements and to function together. The intent is to allow:

- a. Completely factory-assembled equipment, or
- b. A factory-assembled unit with a separate branch-circuit short-circuit and ground-fault protective device of a type and rating specified, or
- c. Separately mounted components that are listed for use together and are specified for such use together by manufacturer's instructions and/or nameplate markings. Note that the circuit breaker need only be a listed inverse-time breaker, and need not be specifically evaluated for group installations. This was the procedure that generated the "HACR" label; it was established that all circuit breakers of the relevant sizes could be marked in that way because the product standard required the same testing anyway, whether or not the HACR label was applied, and therefore the group installations qualification was withdrawn.

It is not the intent to change requirements for supplemental overcurrent protection such as in 422.11(F) or 424.22(C).

Two or more motors of any rating may be connected to one branch circuit if each motor has running overload protection, if the overload devices and controllers are listed for group installation, and if the branch-circuit fuse or time-delay CB rating is in accordance with 430.52 for the largest motor plus the sum of the full-load current ratings of the other motors (Fig. 430-29). The branch-circuit fuses or CB must not be larger than the rating or setting of short-circuit protection permitted by 430.52 for the smallest motor of the group, unless the thermal device is approved for group installation with a given maximum size of fuse or time-delay CB for short-circuit protective device. (See 430.40.) Effective with the 2011 **NEC**, if the short-circuit and ground-fault protection protects each motor overload device and its associated motor in accordance with the parameters that would apply if the installation were not part of a group, then the overload devices in question need not be listed for group installations. The same permission is now effective for the controllers. In such cases, where in effect the line-up to each motor could be used by right as an individual motor circuit, nothing is added in terms of safety to require the group listing on either the overloads or the controllers.

Fig. 430-29. Motors of any horsepower rating require circuit equipment for group installation. (Sec. 430.53.) This is no longer a requirement for the circuit breaker, which now need only be listed and of the inverse-time type.

Part (D): For installations of groups of motors as covered in part (C), tap conductors run from the branch-circuit conductors to supply individual motors must be sized properly. Such tap conductors would, of course, be acceptable where they are the same size as the branch-circuit conductors themselves. However, tap conductors to a single motor may be smaller than the main branch-circuit conductors provided they have an ampacity of at least one-third of the branch-circuit conductors; their ampacity is not less than 125 percent of the motor full-load current; they are not over 25 ft (7.5 m) long; and they are in a raceway or are otherwise protected from physical damage (Fig. 430-30).

Condition 1

Condition 2

Fig. 430-30. Overcurrent protection not required for taps to single motors of a group. (Sec. 430.53.)

An additional option is to use even smaller tap conductors based on not less than 10 percent of the branch-circuit short-circuit and ground-fault protective device [but still in accordance with 430.22(A)] that run in a raceway or other suitably sheltered location and not over 3 m (10 ft) in length, ending at a listed manual motor controller that is marked “Suitable for Tap Conductor Protection in Group Installations.” Effective with the 2011 **NEC**, the conductors may also land on a “branch-circuit protective device.” If the tap conductors are fully sized to be equal to the branch-circuit conductors, then the length and enhanced protection requirements don’t apply. This takes the principles of 430.28 and translates them here, with the terminating branch circuit device in 430.28 replaced by a special issue manual motor controller that has an instantaneous-trip component in it, according to the original substantiation.

The principle applied here is that, since the conductors are short and protected from physical damage, it is unlikely that trouble will occur in the run between the mains and the motor protection which will cause the conductors to be overloaded, except some accident resulting in an actual short circuit. A short circuit will blow the fuses or trip the CB protecting the mains. An overload on the conductors caused by overloading the motor or trouble in the motor itself will cause the motor protective device to operate and so protect the conductors.

The 2017 **NEC** extended this concept of a tap to a similar manual motor controller to an arrangement that parallels the 25-ft tap rule. As you would expect, these tap conductors are at least one-third of the branch circuit conductors, up from one-tenth, and the permitted distance goes from 10 ft to 25 ft.

430.55. Combined Overcurrent Protection. A CB or set of fuses may provide both short-circuit protection and running overload protection for a motor circuit. For instance, a CB or dual-element time-delay fuse sized at not over 125 percent of motor full-load current (430.32) for a 40°C-rise continuous-duty motor would be acceptable protection for the branch circuit and the motor against shorts, ground faults, and operating overloads on the motor. See the bottom of Fig. 430-15 for a typical fuse application.

Figure 430-31 shows a CB used to fulfill four Code requirements simultaneously. For the continuous-duty, 40°C-rise motor shown, the CB may provide running overload protection if it is rated not over 125 percent of the motor's full-load running current. Therefore, $28 \text{ A} \times 1.25 = 35 \text{ A}$, which satisfies 430.32(A). Because the rating of the thermal-magnetic CB is not over 250 percent times the full-load current (from Table 430.52), the 35-A CB satisfies 430.52 and 430.58 as short-circuit and ground-fault protection. The CB may serve both those functions, as noted in 430.55. The CB may serve as the motor controller, as permitted by 430.83(A)(2). The CB also satisfies as the required disconnect means in accordance with 430.111 and has the rating "of at least 115 percent of the full-load current rating of the motor," as required by 430.110(A). And because it satisfies 430.110(A) on the disconnect minimum rating, it therefore satisfies 430.58, which sets the same minimum rating for a CB used as branch-circuit protection.

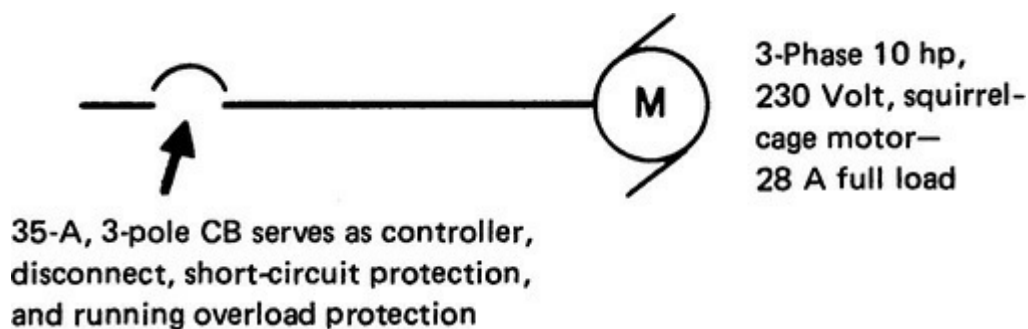

Fig. 430-31. Overcurrent functions may be combined in a single CB or set of fuses. (Sec. 430.55.)

430.56. Branch-Circuit Protective Devices—In Which Conductor. Motor branch circuits are to be protected in the same way as other circuits with regard to the number of fuses and the number of poles and overcurrent units of CBs. If fuses are used, a fuse is required in each ungrounded conductor. If a CB is used, there must be an overcurrent unit in each ungrounded conductor (see 240.15).

430.57. Size of Fuseholder. The basic rule of this section covers sizing of fuse-holders for standard nontime-delay fuses used as motor branch-circuit protection. The exception recognizes that time-delay fuses permit use of smaller switches and lower-rated fuseholders.

A fusible switch can take either standard **NEC** fuses or time-delay fuses—up to the rating of the switch. Because a given size of time-delay fuse can hold on the starting current of a motor larger than that which could be used with a standard fuse of the same rating, fusible switches are given two horsepower ratings—one for use with standard fuses, the other for use with time-delay fuses. For example, a 3-pole, 30-A, 240-V fused switch has a rating of 3 hp for a 3-phase motor if standard fuses without time-delay characteristics are used. If time-delay fuses are used, the rating is raised to 7½ hp.

Consider a 7½-hp, 230-V, 3-phase motor (full-voltage starting, without code letters, or with code

letters F to V), with a full-load current of 22 A. **NEC** Table 430.52 shows that such a motor may be protected by nontime-delay fuses with a maximum rating equal to 300 percent of the full-load current (66 A), or time-delay fuses with a maximum rating equal to 175 percent of the full-load current (38.5 A).

If standard, nontime-delay fuses were used, the maximum size permitted would be 70 A (the next standard size larger than 66 A). From the table, this would require a 100-A, 15-hp switch, which would have fuseholders that could accommodate the fuses, as required by the basic rule. Or, a 60-A, 7½-hp switch might be used with standard fuses rated 60 A maximum. But such a switch would be required by the basic rule to have fuseholders that could accommodate 70-A fuses. Because such a fuse has knife-blade terminals instead of end ferrules and is larger than a 60-A fuse, fuseholders in the 60-A switch could be held in conflict with the Code rule, even though the level of protection would be better with 60-A fuses in the 60-A switch. This is the reason for the exception that now clearly establishes that a switch designed for the smaller time-delay fuses can be used.

430.58. Rating of Circuit Breaker. This rule sets a maximum and minimum rating for a CB as branch-circuit protection. Refer to 430.55.

In the case of a CB having an adjustable trip point, this rule refers to the capacity of the CB to carry current without overheating and has nothing to do with the setting of the breaker. The breaker most commonly used as a motor branch-circuit protective device is the nonadjustable CB (see 240.6), and any breaker of this type having a rating in conformity with the requirements of 430.52 will have an ampacity considerably in excess of 115 percent of the full-load motor current.

430.62. Rating or Setting—Motor Load. Overcurrent protection for a feeder to several motors must have a rating or setting not greater than the largest rating or setting of the branch-circuit protective device for any motor of the group plus the sum of the full-load currents of the other motors supplied by the feeder.

The second paragraph notes that there are cases where two or more motors fed by a feeder will have the same rating as the branch-circuit device. And that can happen where the motors are of the same or different horsepower ratings. It is possible for motors of different horsepower ratings to have the same rating as the branch-circuit protective device, depending on the type of motor and the type of protective device. If two or more motors in the group are of different horsepower rating but the rating or setting of the branch-circuit protective device is the same for both motors, then one of the protective devices should be considered as the largest for the calculation of feeder overcurrent protection.

And because Table 430.52 recognizes many different ratings of branch-circuit protective devices (based on use of fuses or CBs and depending on the particular type of motor), it is possible for two motors of equal horsepower rating to have widely different ratings of branch-circuit protection. If, for instance, a 25-hp motor was protected by nontime-delay fuses, Table 430.52 gives 300 percent of the full-load motor current as the maximum rating or setting of the branch-circuit device. Thus, 250-A fuses would be used for a motor that had a 78-A full-load rating. But another motor of the same horsepower and even of the same type, if protected by time-delay fuses, must use fuses rated at only 175 percent of 78 A, which would be 150-A fuses, as shown in [Fig. 430-32](#). If the two 25-hp motors were of different types, one being a wound-rotor motor, it would still be necessary to base selection of the feeder protection on the largest rating or setting of a branch-circuit protective device, regardless of the horsepower rating of the motor.

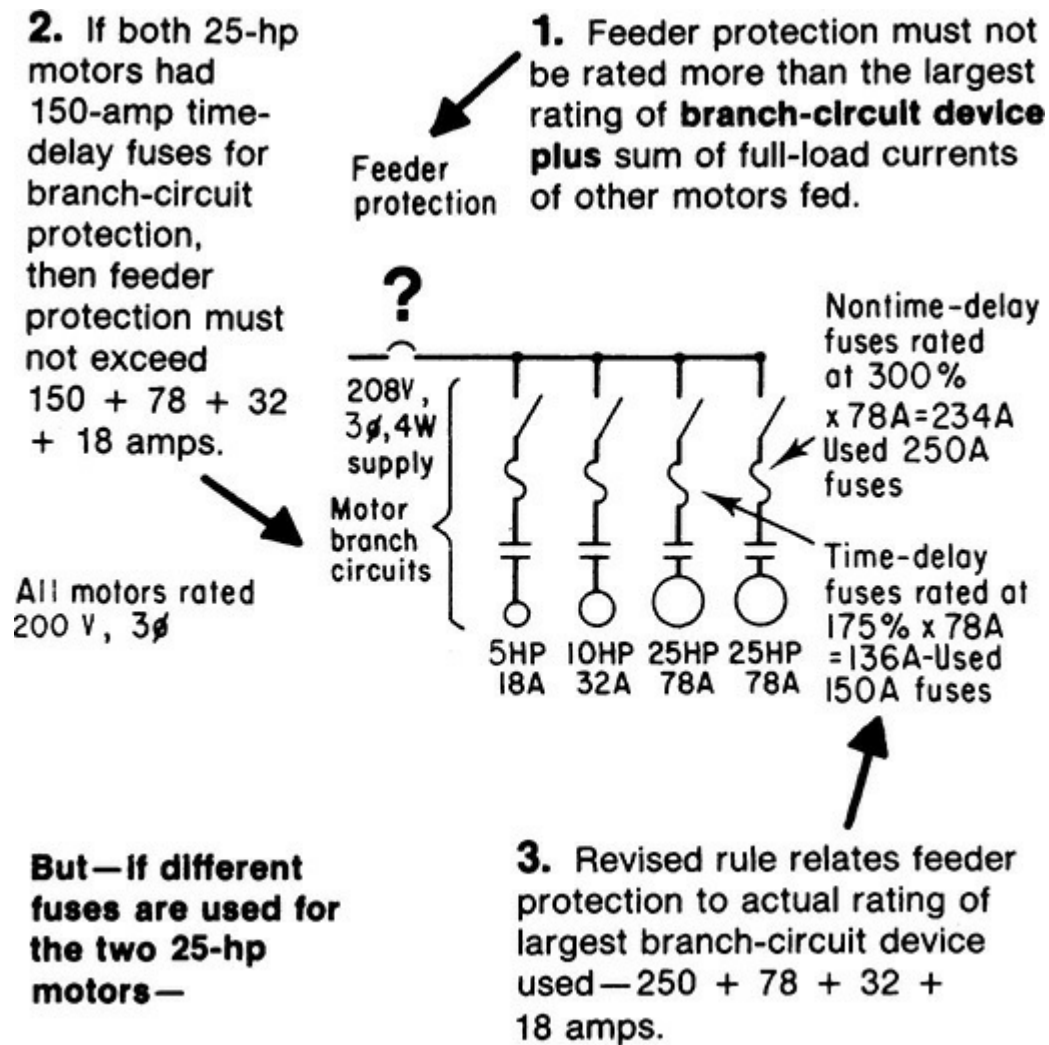

Fig. 430-32. Feeder protection is based on largest branch-circuit protection, not on motor horsepower ratings. (Sec. 430.62.)

Figure 430-33 shows a typical motor feeder calculation, as follows:

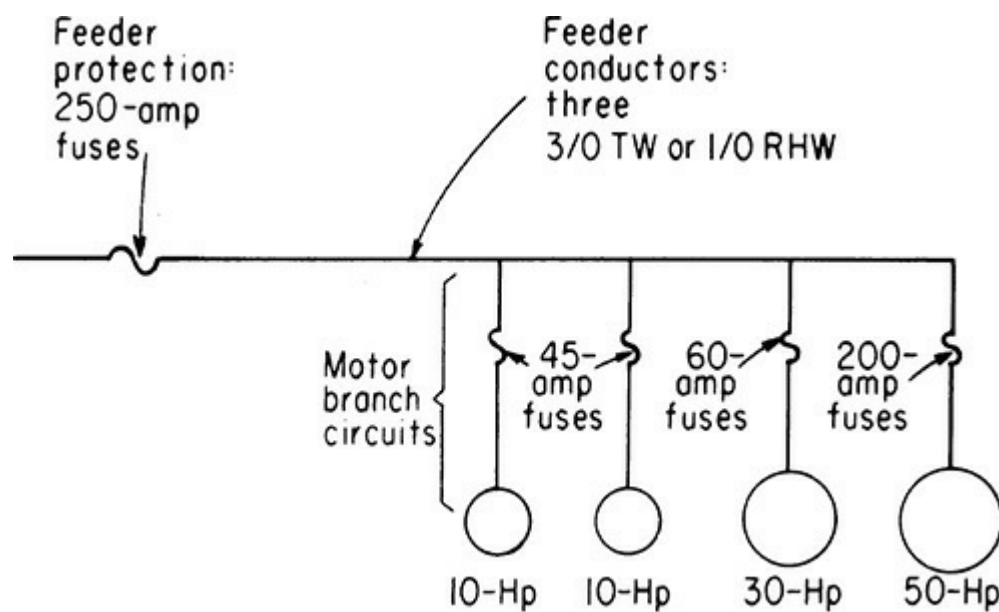

Fig. 430-33. Rating of feeder protection is based on branch protection and motor currents. (Sec. 430.62.)

The four motors supplied by the 3-phase, 460-V, 60-cycle feeder, which are not marked with a code letter (see Table 430.52), are as follows:

- One 50-hp squirrel-cage induction motor (full-voltage starting)
- One 30-hp wound-rotor induction motor
- Two 10-hp squirrel-cage induction motors (full-voltage starting)

Step 1. Branch-Circuit Loads

From Table 430.250, the motors have full-load current ratings as follows:

50-hp motor—65 A

30-hp motor—40 A

10-hp motor—14 A

Step 2. Conductors

The feeder conductors must have a carrying capacity as follows (see 430.24):

$$1.25 \times 65 = 81 \text{ A}$$
$$81 + 40 + (2 \times 14) = 149 \text{ A}$$

The feeder conductors must be at least No. 3/0 TW, 1/0 THW, or 1/0 RHH or THHN (copper).

Step 3. Branch-Circuit Protection

Overcurrent (branch-circuit) protection (from Table 430.52 and 430.52) using nontime-delay fuses is as follows:

1. The 50-hp motor must be protected at not more than 200 A (65 A \times 300 percent).
2. The 30-hp motor must be protected at not more than 60 A (40 A \times 150 percent).
3. Each 10-hp motor must be protected at not more than 45 A (14 A \times 300 percent).

Step 4. Feeder Protection

As covered in 430.62, the maximum rating or setting for the overcurrent device protecting such a feeder must not be greater than the largest rating or setting of branch-circuit protective device for one of the motors of the group plus the sum of the full-load currents of the other motors. From the preceding, then, the maximum allowable size of feeder fuses is $200 + 40 + 14 + 14 = 268$ A.

This calls for a maximum standard rating of 250 A for the motor feeder fuses, which is the nearest standard fuse rating that does not exceed the maximum permitted value of 268 A.

Exception No. 1 to part (A) addresses those installations where instantaneous-trip CBs and/or MSCPs are used as short-circuit and ground-fault protection for the largest motor supplied by the feeder to be protected. Under certain conditions those devices may be set or rated to trip at 13 times or, for Design B energy-efficient motors, even as high as 17 times the motor full-load current. To prevent the feeder conductors from being underprotected, this exception requires that the rating or setting of the feeder protective device be based on the type of device used. That is, if nontime-delay fuses are used for feeder protection, the rating of those fuses must be based on the rating of fuse that would be permitted to protect the motor branch circuit if a fuse were used as branch-circuit

protection instead of an instantaneous-trip CB or MSCP. For example, consider a 460-V, 3-phase, 100-hp motor, which draws approximately 124 A. If an instantaneous-trip breaker were used for branch-circuit short-circuit and ground-fault protection, it could be rated at over 1600 A (13×124 A).

When establishing the rating of protection for the feeder supplying a motor branch-circuit so protected, if nontime-delay fuses are used, the value of current that is summed with the ratings of the other type branch-circuit protective devices must be no more than that which would be permitted if nontime-delay fuses were used as branch-circuit protection instead of an instantaneous-trip CB or MSCP. In this example, Table 430.52 would permit a nontime-delay fuse to be 300 percent of the motor full-load current. If the branch circuit in question is protected by nontime-delay fuses, they would be rated at 350 A (3×125 A; rounded down because the exception gives no allowance to modify the Table 430.52 results). And 350 A, *not* 1300 A, would be used to calculate the maximum rating of nontime-delay fuses that are permitted to protect the feeder conductors.

Note: There is no provision in 430.62 whatsoever that would permit the use of “the next higher size, rating, or setting” of the protective device, for a motor feeder when the calculated maximum rating does not correspond to a standard size of device. The feeder calculations are rounded down, not up.

According to part **(B)** of this section, in large-capacity installations where extra feeder capacity is provided for load growth or future changes, the feeder overcurrent protection may be calculated on the basis of the rated current-carrying capacity of the feeder conductors. In some cases, such as where two or more motors on a feeder may be started simultaneously, feeder conductors may have to be larger than usually required for feeders to several motors.

In selecting the size of a feeder overcurrent protective device, the **NEC** calculation is concerned with establishing a maximum value for the fuse or CB. If a lower value of protection is suitable, it may be used. The motor example in Annex D (Example D8) is extremely informative and helpful, and was significantly improved further in the 2017 **NEC** with respect to the feeder calculations covered here. There are now two separate calculations based first on nontime-delay fuse protection (the traditional one), and a new one based on inverse-time circuit breakers, which produces a differently sized feeder protective device.

430.63. Rating or Setting—Motor Load and Other Load(s). Protection for a feeder to both motor loads and a lighting and/or appliance or other load must be rated on the basis of both of these loads. The rating or setting of the overcurrent device must be sufficient to carry the lighting and/or appliance load plus the rating or setting of the motor branch-circuit protective device if only one motor is supplied, or plus the highest rating or setting of branch-circuit protective device for any one motor plus the sum of the full-load currents of the other motors, if more than one motor is supplied.

Figure 430-34 presents basic **NEC** calculations for arriving at minimum requirements on wire sizes and overcurrent protection for a combination power and lighting load as follows:

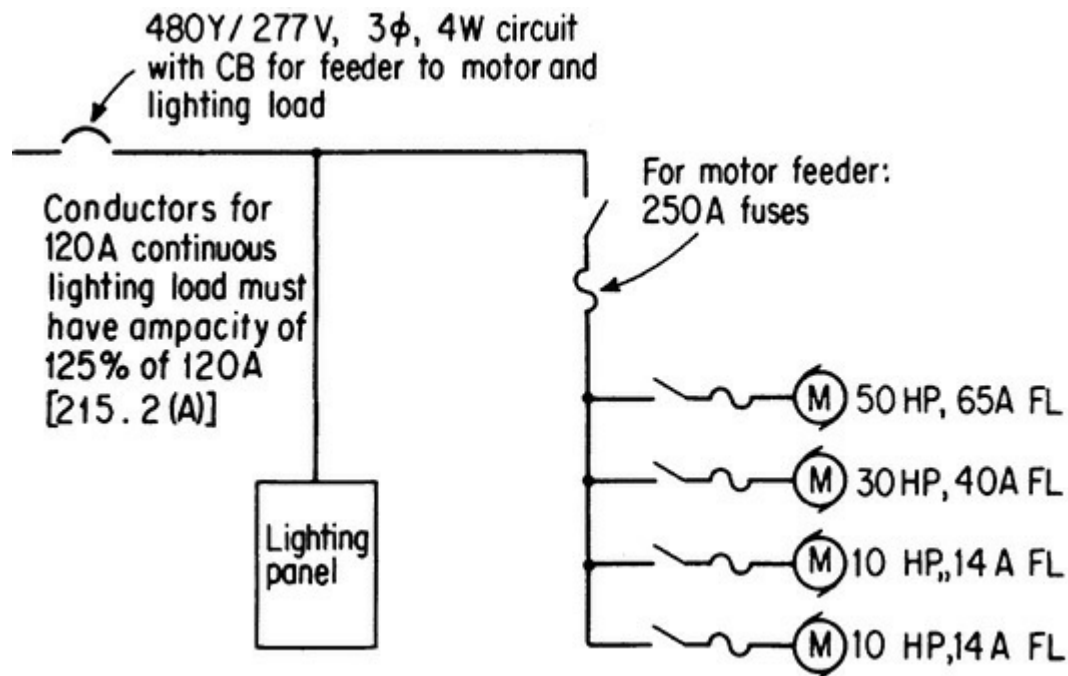

Fig. 430-34. Feeder protection for combination load must properly add both loads. (Sec. 430.63.)

Step 1. Total Load

430.25(A) says that conductors supplying a lighting load and a motor must have capacity for both loads, as follows:

$$\begin{aligned} \text{Motor load} &= 65 \text{ A} + 40 \text{ A} + 14 \text{ A} + 14 \text{ A} + (0.25 \times 65 \text{ A}) = 149 \text{ A per phase} \\ \text{Lighting load} &= 120 \text{ A per phase} \times 1.25 = 150 \text{ A} \\ \text{Total load} &= 149 + 150 = 299 \text{ A per phase leg} \end{aligned}$$

Step 2. Conductors

Table 310.15(B)(16) shows that a load of 299 A can be served by the following copper conductors:

500-kcmil TW
350-kcmil THW

Table 310.15(B)(16) shows that this same load can be served by the following aluminum or copper-clad aluminum conductors:

700-kcmil TW
500-kcmil THW, RHH, or THHN

Step 3. Protective Devices

430.63 says, in effect, that the protective device for a feeder supplying a combined motor load and lighting load may have a rating not greater than the sum of the maximum rating of the motor feeder protective device and the lighting load, as follows:

1. Motor feeder protective device = rating or setting of the largest branch-circuit device for any motor of the group being served plus the sum of the full-load currents of the other motors:

$$200 \text{ A (50-hp motor)} + 40 + 14 + 14 = 268 \text{ A maximum}$$

This calls for a maximum standard rating of 250 A for the motor feeder fuses, which is the nearest standard fuse rating that does not exceed the maximum permitted value of 268 A.

2. Lighting load = $120 \text{ A} \times 1.25 = 150 \text{ A}$

$$\text{Rating of CB for combined load} = 268 + 150 = 418 \text{ A maximum}$$

This calls for a 400-A CB, the nearest standard rating that does not exceed the 418-A maximum.

Again: There is no provision in 430.63 that permits the use of “the next higher size, rating, or setting” of the protective device for a motor feeder when the calculated maximum rating does not correspond to a standard size of device.

Such considerations as voltage drop, I^2R loss, spare capacity, lamp dimming on motor starting, and so forth would have to be made to arrive at actual sizes to use for the job. But, the circuiting as shown would be safe—although maybe not efficient or effective for the particular job requirements.

430.71. General. Figure 430-35 shows the *motor control circuit* part of a motor branch circuit, as defined in the second paragraph of this section. A control circuit, as discussed here, is any circuit that has as its load device the operating coil of a magnetic motor starter, a magnetic contactor, or a relay. Strictly speaking, it is a circuit that exercises control over one or more other circuits. And these other circuits controlled by the control circuit may themselves be control circuits or they may be *load* circuits—carrying utilization current to a lighting, heating, power, or signal device.

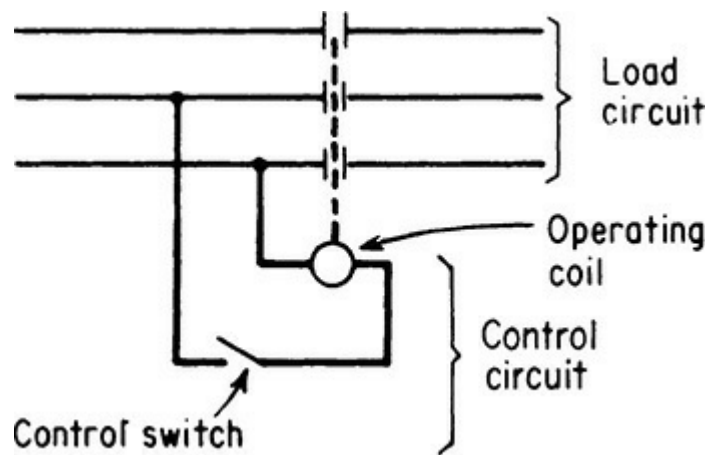

Fig. 430-35. A control circuit governs the operating coil that switches the load circuit. (Sec. 430.71.)

The elements of a control circuit include all the equipment and devices concerned with the function of the circuit: conductors, raceway, contactor operating coil, source of energy supply to the circuit, overcurrent protective devices, and all switching devices that govern energization of the operating coil.

The **NEC** covers application of control circuits in Art. 725 and in 240.4 and 430.71 through 430.74. Design and installation of control circuits are basically divided into three classes (in Art. 725) according to the energy available in the circuit. Class 2 and 3 control circuits have low energy-handling capabilities; and any circuit, to qualify as a class 2 or 3 control circuit, must have its open-

circuit voltage and overcurrent protection limited to conditions given in 725.121.

Most control circuits for magnetic starters and contactors could not qualify as class 2 or 3 circuits because of the relatively high energy required for operating coils. And any control circuit rated over 150 V (such as 230- or 460-V coil circuits) can never qualify, regardless of energy.

Class 1 control circuits include all operating coil circuits for magnetic starters that do not meet the requirements for class 2 or 3 circuits. Class 1 circuits must be wired in accordance with 725.41 to 725.52.

430.72. Overcurrent Protection. Part (A) tells the basic idea behind protection of the operating coil circuit of a magnetic motor starter, as distinguished from a manual (mechanically operated) starter:

1. 430.72 covers motor control circuits that are derived within a motor starter from the power circuit that connects to the line terminals of the starter. The rule here refers to such a control circuit as one “tapped from the load side” of the fuses or circuit breaker that provides branch-circuit protection for the conductors that supply the starter. See the top of [Fig. 430-36](#).

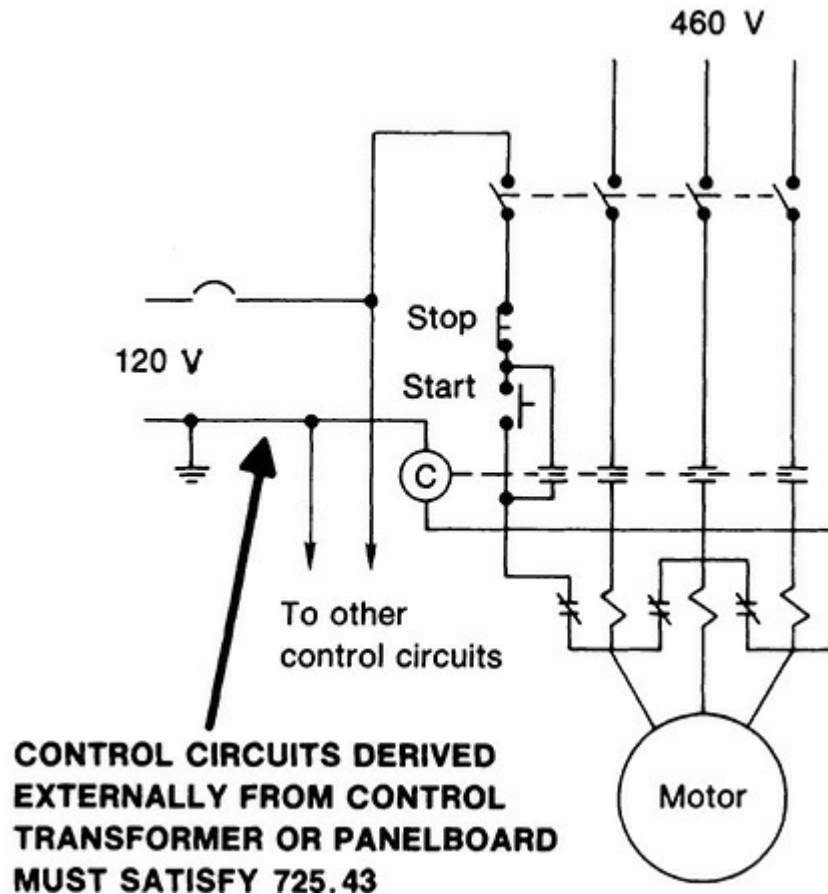

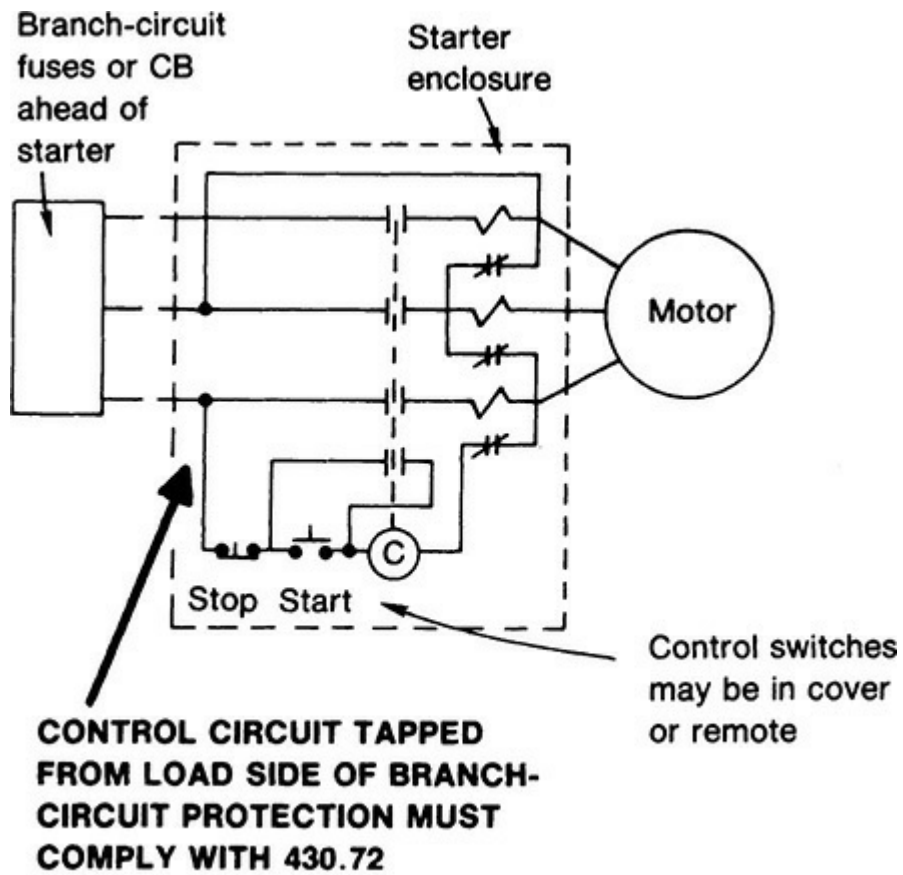

Fig. 430-36. Source of power supply to the control circuit determines which Code section applies to the coil circuit. (Sec. 430.72.)

2. The control circuit that is tapped from the line terminals within a starter is *not* a branch circuit itself.

3. Depending on other conditions set in 430.72, the conductors of the control circuit will be considered as protected by *either* the branch-circuit protective device ahead of the starter or the supplementary protection (usually fuses) installed in the starter enclosure.
4. Any motor control circuit that is not tapped from the line terminals within a starter must be protected against overcurrent in accordance with 725.43. Such control circuits would be those that are derived from a panelboard or a control transformer—as where, say, 120-V circuits are derived external to the starters and are typically run to provide lower-voltage control for 230-, 460-, or 575-V motors. See the bottom of [Fig. 430-36](#).

Part **(B)** applies to overcurrent protection of conductors used to make up the control circuits of magnetic motor starters. Such overcurrent protection must be sized in accordance with the amp values shown in Table 430.72(B). And where that table makes reference to amp values specified in 310.15, as applicable, it does *not* specify that 310.15(B)(3) must be observed by derating conductor ampacity where more than three current-carrying conductors are used in a conduit. Previously, the rule in part **(B)** of this section specifically recognized the use of control-circuit wires in raceway “without derating factors.” 725.51(A), however, does require class 1 remote-control wires to have their ampacity derated in accordance with 310.15(B)(3), based on the number of conductors, when the conductors “carry continuous loads” in excess of 10 percent of each conductor’s ampacity.

That makes the application in [Fig. 430-37](#) compliant (almost, but not completely certain). The reason for the rule in 725.51(A) is that heat given off from a wire is a function of I^2R losses. A wire carrying 10 percent of its ampacity is putting out 1 percent (0.1^2) of the heat generated when fully loaded. That is a negligible amount. Further, the realities of most control circuits are that they seldom carry much in the way of actual current. Most contactor coils and other such devices take a fraction of an ampere over time, and in order to trip over 310.15(B)(2)(a) the 10 percent limit not only has to be exceeded, it must be exceeded on a continuous basis, not just for the fraction of a second that a coil is actually pulling in. So, unless the control circuits are very unusual, the wires are as a practical matter not subject to derating for mutual conductor heating.

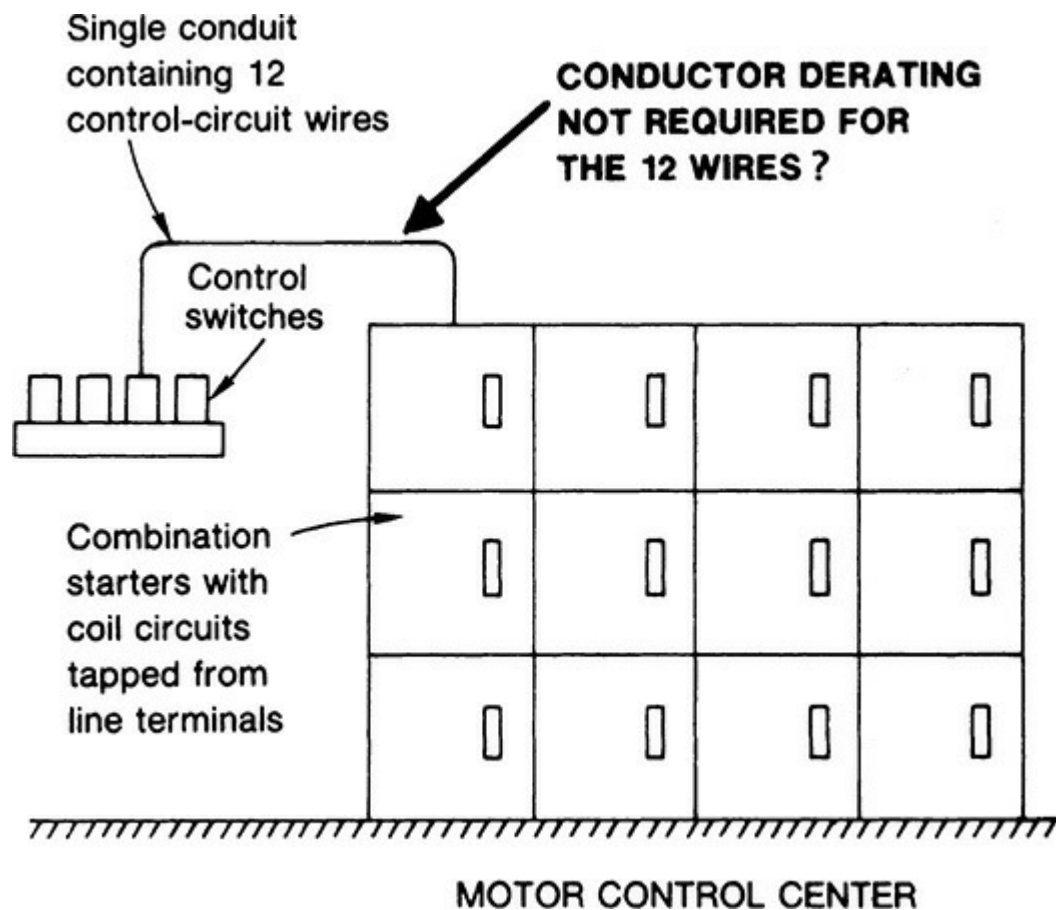

Fig. 430-37. Derating of control-wire ampacity is seldom necessary when more than three conductors are run within the same raceway. (Sec. 430.72.)

The basic rule of part **(B)(1)** requires coil-circuit conductors to have overcurrent protection rated in accordance with the maximum values given in Column A of Table 430.72(B). That table shows 7 A as the maximum rating of protection for 18 AWG copper wire and 10 A for 16 AWG wire and refers to Table 310.15(B)(16) for larger wires—20 A for 14 AWG copper, 25 A for No. 12, and so forth. These values are taken from the 60°C column to be consistent with other calculations in this table, but purposely not using the 240.4(D) special ampacities because the work here is governed by 240.4(G). The basic rules in part **(B)(2)** cover conditions under which other ratings of protection may be used, as follows:

The first sentence in part **(B)(2)** covers protection of control wires for magnetic starters that have their START-STOP buttons in the cover of the starter enclosure.

In part **(B)(2)**, the value of branch-circuit protection must be compared to the ampacity of the control-circuit wires that are factory-installed in the starter and connected to the START-STOP buttons in the cover. If the rating of the branch-circuit fuse or CB does not exceed the value of the current shown in Column B of Table 430.72(B) for the particular size of either copper or aluminum wire used to wire the coil circuit within the starter, then other protection is not required to be installed within the starter (Fig. 430-38). If the rating of branch-circuit protection *does* exceed the value shown in Column B for the size of coil-circuit wire, then separate protection must be provided within the starter, and it must be rated not greater than the value shown for that size of wire in Column A of Table 430.72(B). For instance, if the internal coil circuit of a starter is wired with No. 16 copper wire and the branch-circuit device supplying the starter is rated over the 40-A value shown for 16 AWG copper wire in Column B of Table 430.72(B), then protection must be provided in the

starter for the 16 AWG wire and the protective device(s) must be rated not over the 10-A value shown for 16 AWG copper wire in Column A of Table 430.72(B).

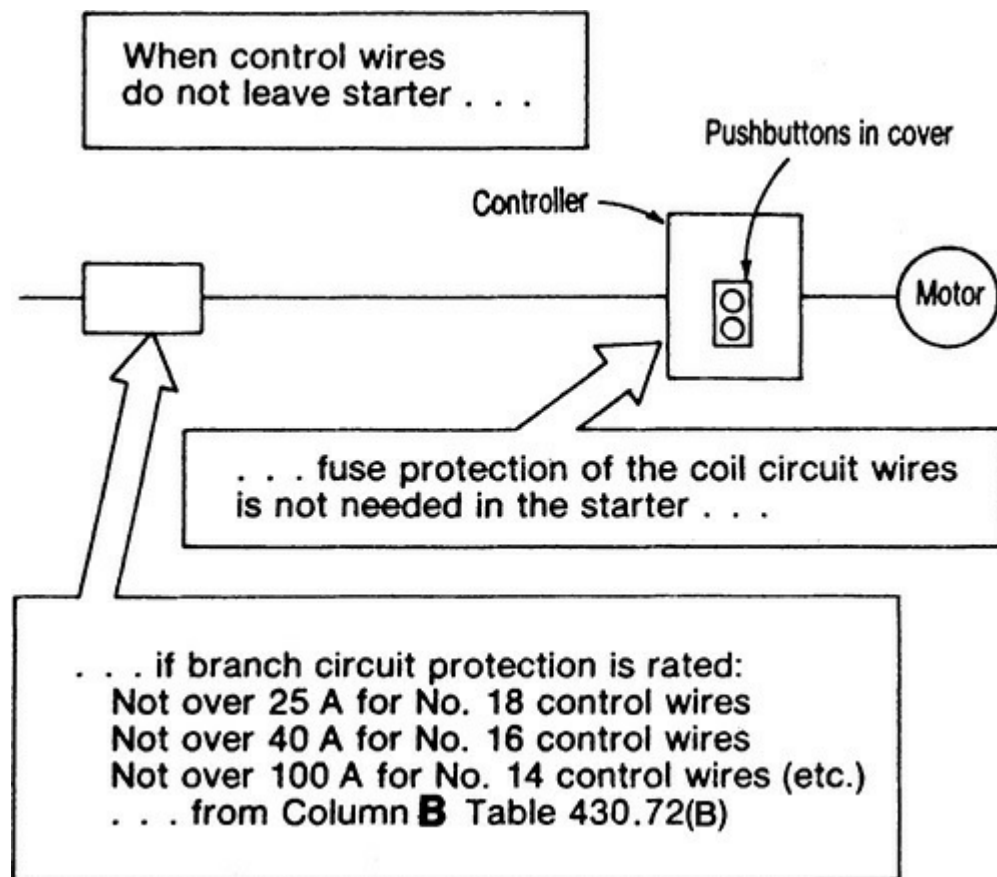

Fig. 430-38. This is the rule of part **(B)(1)** of Sec. 430.72.

Because most starters are the smaller ones using 18 and 16 AWG wires for their coil circuits, part **(B)(2)** and its reference to Column B are particularly applicable to those wire sizes. For 16 AWG control wires, branch-circuit protection rated up to 40 A would eliminate any need for a separate control-circuit fuse in the starter. And for 18 AWG control wires, separate coil-circuit protection is not needed for a starter with branch-circuit protection rated not over 25 A. For 14, 12, and 10 AWG copper control wires, maximum protective-device ratings are given in Column B as 100, 120, and 160 A, respectively. For conductors larger than No. 10, the protection may be rated up to 400 percent of (or 4 times) the free-air ampacity of the size of conductor from Table 310.17.

The third sentence in part **(B)(2)** covers protection of control wires that run from a starter to a remote-control device (pushbutton station, float switch, limit switch, etc.). Such control wires may be protected by the branch-circuit protective device—without need for separate protection within the starter—if the branch-circuit device has a rating not over the value shown for the particular size of copper or aluminum control wire in Column C of Table 430.72(B) (Fig. 430-39). Note that the maximum ratings of 7 A for 18 AWG and 10 A for 16 AWG require that *fuse* protection at those ratings must always be used to protect those sizes of control-circuit wires connected to motor starters supplied by CB branch-circuit protection, because 15 A is the lowest available standard rating of CB. But branch-circuit fuses of 7- or 10-A rating could eliminate the need for protection in the starter where 18 AWG or 16 AWG control wires are used. Figure 430-40 shows an application that was permitted for many years under previous wording of the Code rule but is now contrary to the letter and intent of the rule.

Fig. 430-39. This is covered by part (B)(2) of Sec. 430.72.

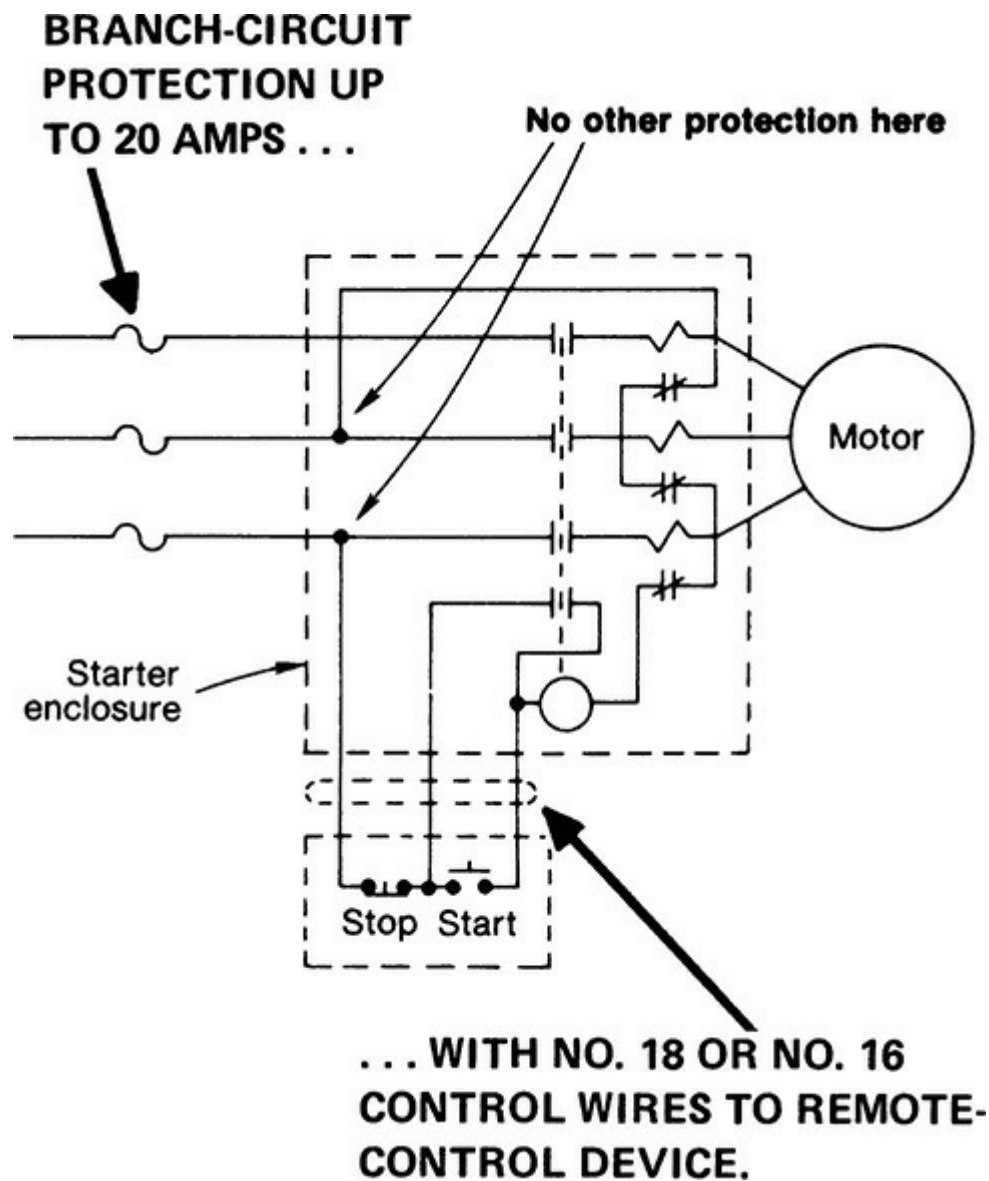

Fig. 430-40. This was permitted by previous **NEC** editions but is now a violation of part **(B)(2)**. (Sec. 430.72.)

For any size of control wire, if the branch-circuit protection ahead of the starter has a rating greater than the value shown in Column C of Table 430.72(B), then the control wire must be protected by a device(s) rated not over the amp value shown for that size of wire in Column A of Table 430.72(B). For instance, if 14 AWG copper wire is used for the control circuit from a starter to a remote pushbutton station and the branch-circuit protection ahead of the starter is rated at 40 A, then the branch-circuit device is not over the value of 45 A shown in Column C, and separate control protection is not required within the starter. But if the branch-circuit protection were, say, 100 A, then 14 AWG control wire would have to be protected at 15 A because Column A shows that 14 AWG must have maximum protection rating from Note 1—which refers to Table 310.15(B)(16) where 14 AWG wire in conduit is shown as 20 A. As noted previously, values are taken from the 60°C column to be consistent with other calculations in this table, but purposely not using the 240.4(D) special ampacities because the work here is governed by 240.4(G).

It should be noted that Column A gives the values to be used for overcurrent protection placed within the starter to protect control-circuit wires in any case where the rating of branch-circuit protection exceeds the value shown in either Column B (for starters with no external control wires)

or Column C (for control wires run from a starter to a remote pilot control device).

Part (C) permits protection on the primary side of a control transformer to protect the transformer in accordance with 450.3 and the secondary conductors in accordance with the amp value shown in Table 430.72(B) for the particular size of the control wires fed by the secondary. This use is limited to transformers with 2-wire secondaries (Fig. 430-41). Because 430.72(A) notes that the rules of 430.72 apply to control circuits tapped from the motor branch circuit, the rule of part (C) must be taken as applying to a control transformer installed within the starter enclosure—although the general application may be used for any transformer because it conforms to 240.4(F), and to 450.3.

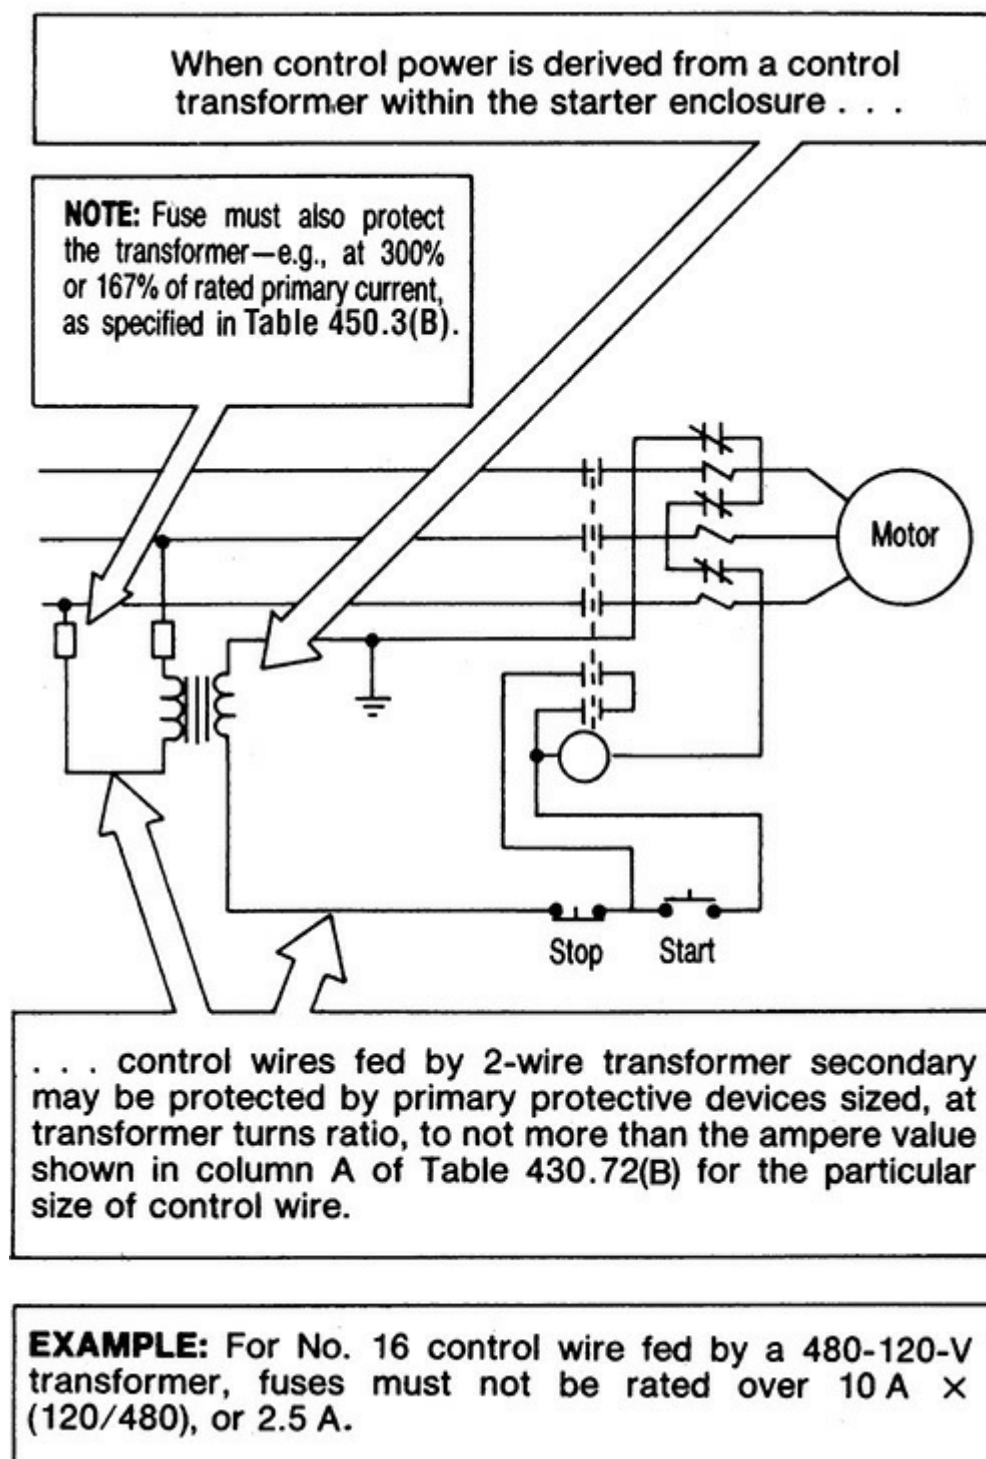

Fig. 430-41. Exception No. 2 to part (B) of 430.72 permits the secondary wires of the coil circuit to be protected by primary-side overcurrent protection. (Sec. 430.72.)

The exception eliminates any need for control-circuit protection where opening of the circuit would be objectionable, as for a fire-pump motor or other essential or safety-related operation.

Part (C) covers the use of control transformers and requires protection on the primary side. And, again, it must be taken to apply specifically to such transformers used in motor control equipment enclosures. The basic rule in part (C)(2) calls for each control transformer to be protected in accordance with 450.3 (usually by a primary-side protective device rated not over 125 or 167 percent of primary current), as shown in Fig. 430-41. But other options are given.

Part (C)(3) eliminates any need for protection of any control transformer rated less than 50 VA, provided it is part of the starter and within its enclosure.

Part (C)(4) permits a control transformer with a rated primary current of *less* than 2 A to be protected at up to 500 percent of rated primary current by a protective device in each ungrounded conductor of the supply circuit to the transformer primary, as shown in Fig. 430-42.

Fig. 430-42. A control circuit fed by a transformer within the starter enclosure may have overcurrent protection in the primary rated up to 500 percent of the rated primary current of a small transformer. (Sec. 430.72.)

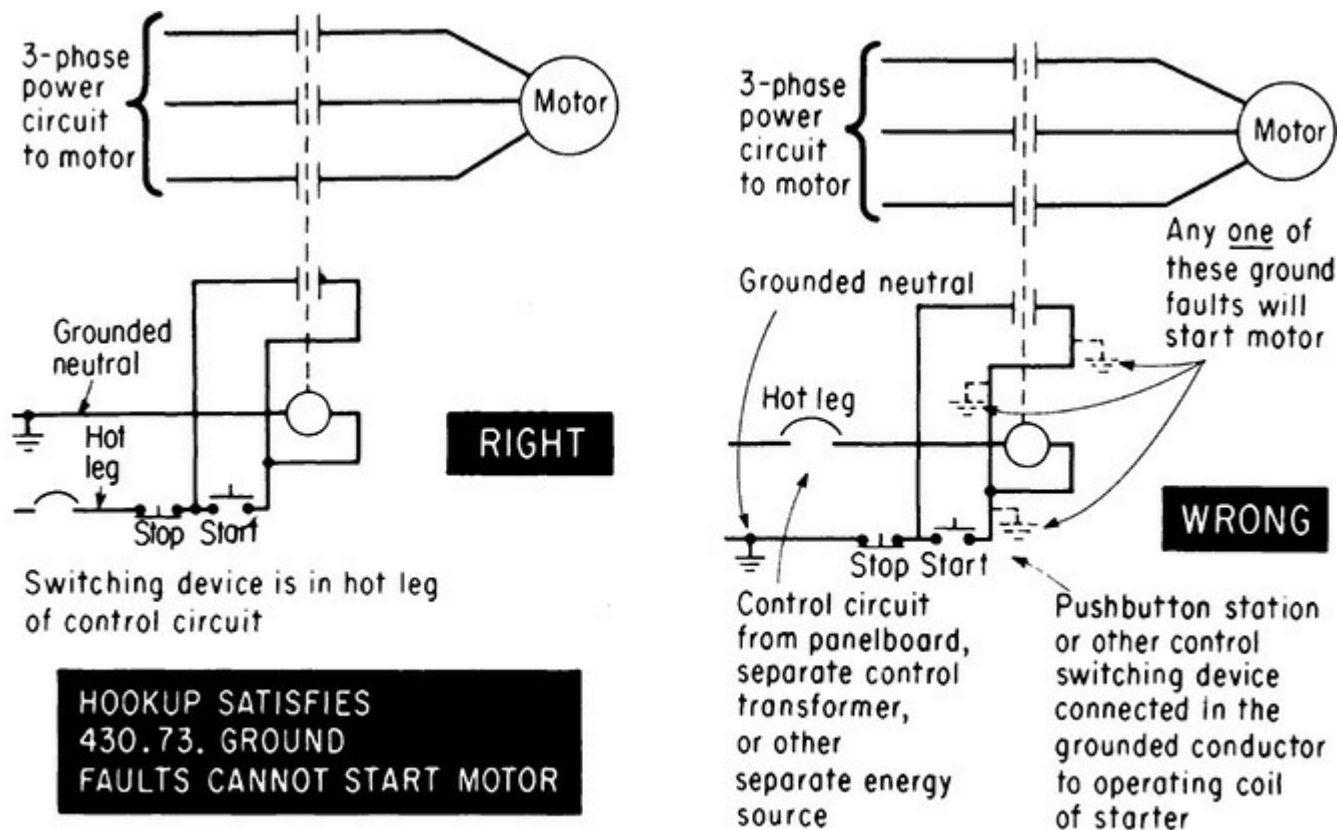

In the majority of magnetic motor controllers and contactors, the voltage of the operating coil is the voltage provided between two of the conductors supplying the load, or one conductor and the neutral. Conventional starters are factory wired with coils of the same voltage rating as the phase voltage to the motor. However, there are many cases in which it is desirable or necessary to use control circuits and devices of lower voltage rating than the motor. Such could be the case with high-voltage (over 600 V) controllers, for instance, in which it is necessary to provide a source of low voltage for practical operation of magnetic coils. And even in many cases of motor controllers and contactors for

use under 600 V, safety requirements dictate the use of control circuits of lower voltage than the load circuit.

Although contactor coils and pilot devices are available and effectively used for motor controllers with up to 600-V control circuits, such practice has been prohibited in applications where atmospheric and other working conditions make it dangerous for operating personnel to use control circuits of such voltage. And certain OSHA regulations require 120- or 240-V coil circuits for the 460-V motors. In such cases, control transformers are used to step the voltage down to permit the use of lower-voltage coil circuits.

430.73. Protection of Conductors from Physical Damage. The condition under which physical protection of the control circuit conductor becomes necessary is where damage to the conductors would constitute either a fire or an accident hazard. Damage to the control circuit conductors resulting in short-circuiting two or more of the conductors or breaking one of the conductors would either cause the device to operate or render it inoperative, and in some cases either condition would constitute a hazard either to persons or to property; hence, in such cases the conductors should be installed in rigid or other metal conduit. On the other hand, damage to the conductors of the low-voltage control circuit of a domestic oil burner or automatic stoker does not constitute a hazard, because the boiler or furnace is equipped with an automatic safety control.

430.74. Electrical Arrangement of Control Circuits. This section focuses on the hazard of accidental starting of a motor. [Figure 430-43](#) shows an example of a control circuit installation that should be carefully designed and is required to be observed for any control circuit that has one leg grounded. Whenever the coil is fed from a circuit made up of a hot conductor and a grounded conductor (as when the coil is fed from a panelboard or separate control transformer, instead of from the supply conductors to the motor), care must be taken to place the pushbutton station or other switching control device in the hot leg to the coil and not in the grounded leg to the coil. By switching in the hot leg, the starting of the motor by accidental ground fault can be effectively eliminated.

Note: OL relays are not shown in diagrams.

Fig. 430-43. Control hookup must prevent accidental starting. (Sec. 430.73.)

Note the words “remote from the motor controller.” This means the rule does not require that the running overload relay contacts be wired on the ungrounded side of the control circuit. Very few are done this way and not much can go wrong to short leads that never leave their enclosure, but it is certainly permissible, if seldom done, to place them on the ungrounded side.

Combinations of ground faults can develop to short the pilot starting device—pushbutton, limit switch, pressure switch, and so forth—accidentally starting the motor even though the pilot device is in the OFF position. And because many remote-control circuits are long, possible faults have many points at which they might occur. Insulation breakdowns, contact shorts due to accumulation of foreign matter or moisture, and grounds to conduit are common fault conditions responsible for accidental operation of motor controllers.

Although not specifically covered by Code rules, there are many types of ground-fault conditions that affect motor starting and should be avoided.

As shown in Fig. 430-44, any magnetic motor controller used on a 3-phase, 3-wire ungrounded system always presents the possibility of accidental starting of the motor. If, for instance, an undetected ground fault exists on one phase of the 3-phase system—even if this system ground fault is a long distance from the controller—a second ground fault in the remote-control circuit for the operating coil of the starter can start the motor.

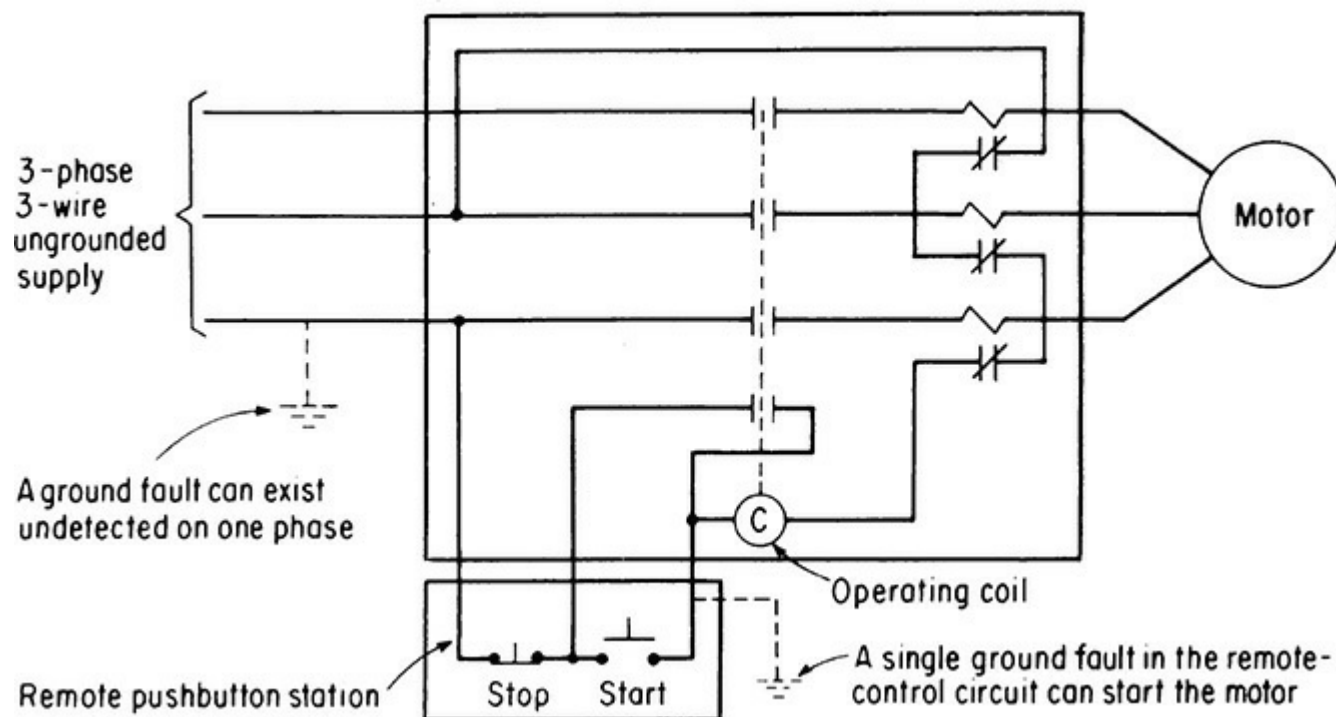

Fig. 430-44. Accidental motor starting can be hazardous and contrary to Code rule. (Sec. 430.73.)

Figure 430-45 shows the use of a control transformer to isolate the control circuit from responding to the combination of ground faults shown in Fig. 430-46. This transformer may be a one-to-one isolating transformer, with the same primary and secondary voltage, or the transformer can step the motor circuit voltage down to a lower level for the control circuit.

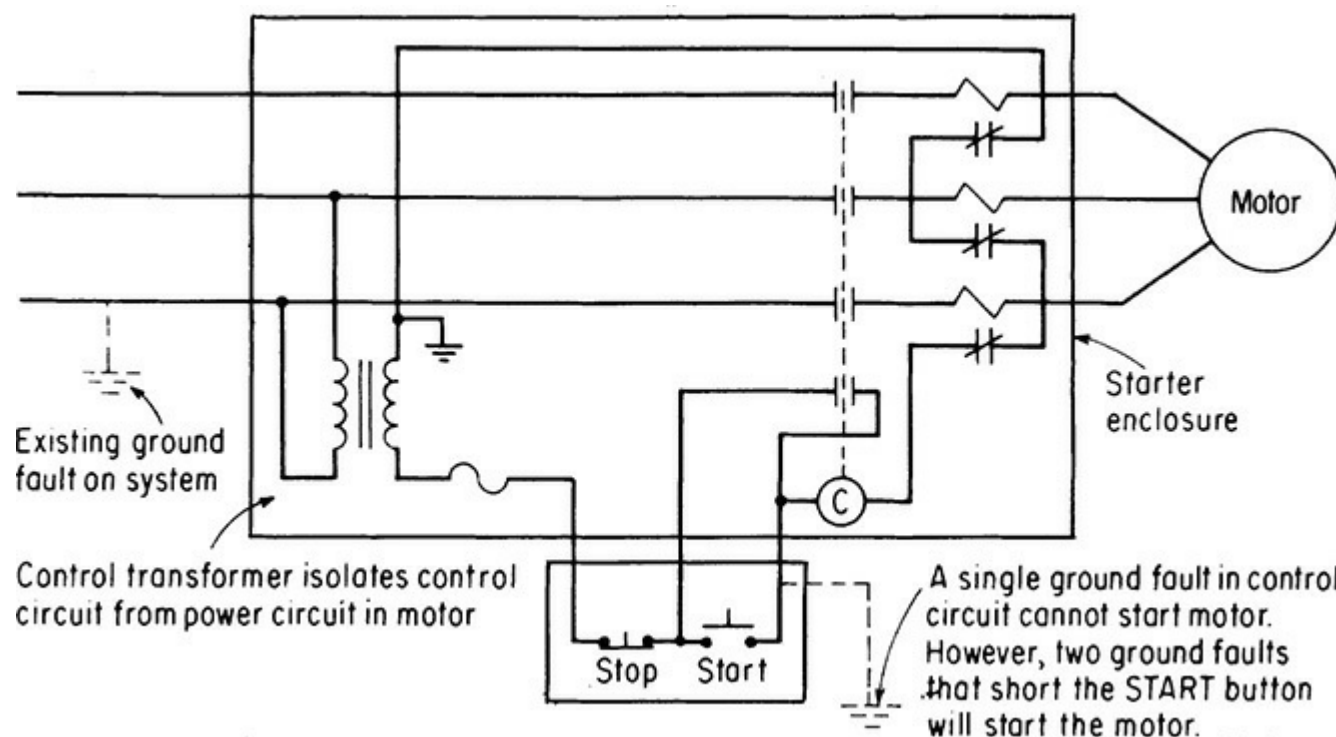

Fig. 430-45. Control transformer can isolate control circuit from accidental starting. (Sec. 430.73.)

In the hookup shown in Fig. 430-46, a 2-pole START button is used in conjunction with two sets of holding contacts in the motor starter. This hookup protects against accidental starting of the motor under the fault conditions shown in Fig. 430-44. The hookup also protects against accidental starting

due to two ground faults in the control circuit simply shorting out the START button and energizing the operating coil. This could happen in the circuit of Fig. 430-44 or the circuit of Fig. 430-45.

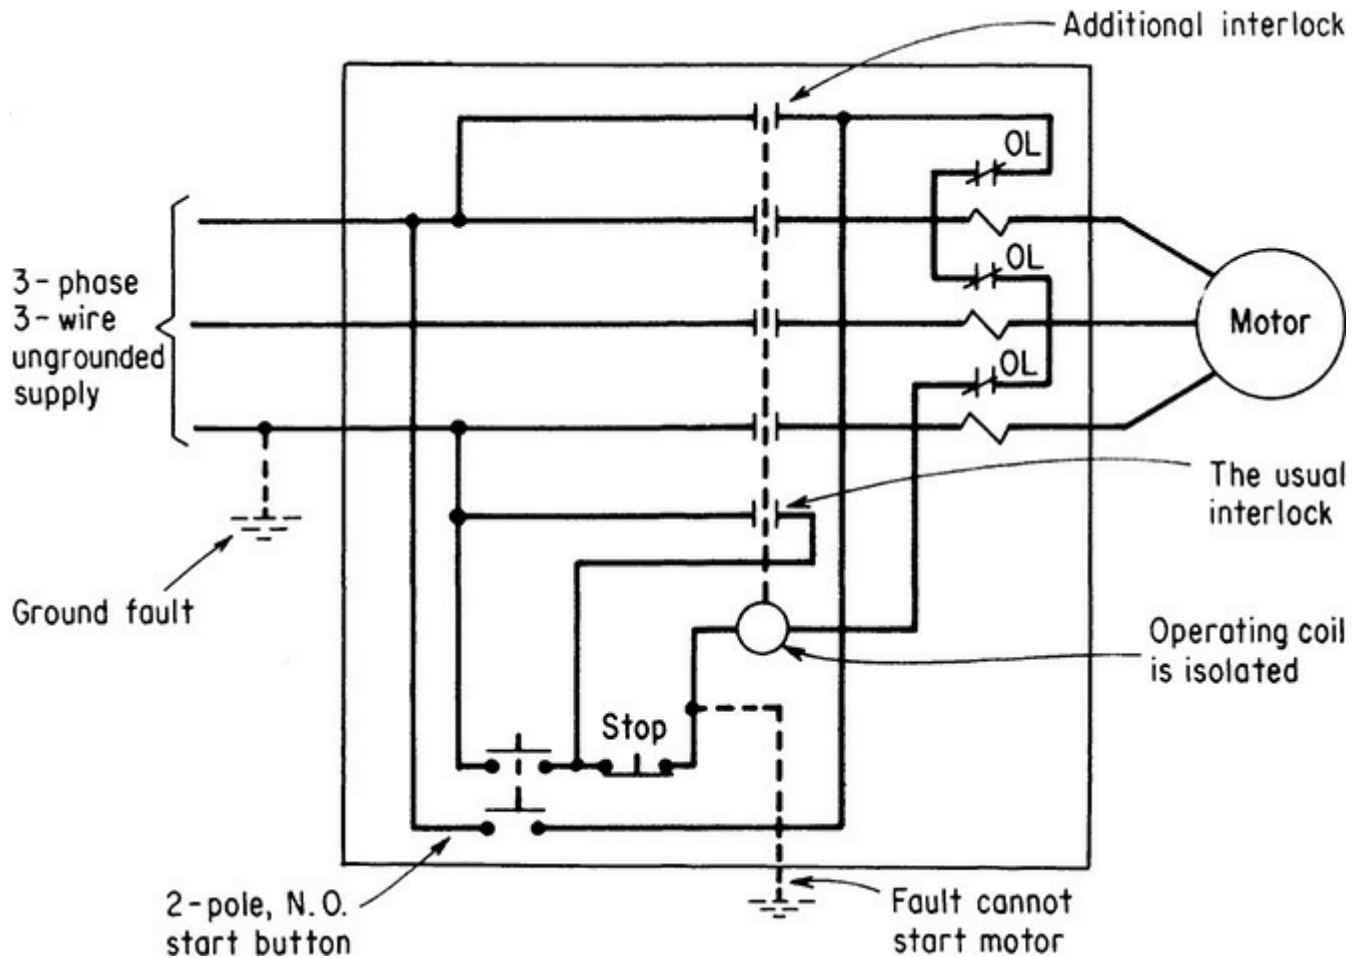

Fig. 430-46. Use of 2-pole start button can prevent accidental starting. (Sec. 430.73.)

Another type of motor control circuit fault can produce a current path through the coil of a closed contactor to hold it closed regardless of the operation of the pilot device for opening the coil circuit. Again this can be done by a combination of ground faults that short the STOP device. Failure to open can do serious damage to motors in some applications and can be a hazard to personnel. The operating characteristics of contactor coils contribute to the possible failure of a controller to respond to the opening of the STOP contacts. It takes about 85 percent of rated coil voltage to operate the armature associated with the coil; but it takes only about 50 percent of the rated value to enable the coil to hold the contactor closed once it is closed. Under such conditions, even partial grounds and shorts on control contact assemblies can produce paths for sufficient current flow to cause shorting of the STOP position of pilot devices. And faults can short out running overload relays, eliminating overcurrent protection of the motor, its associated control equipment, and conductors.

Figure 430-47 is a modification of the circuit of Fig. 430-46, using a 2-pole START button and a 2-pole STOP button—protecting against both accidental starting and accidental failure to stop when the STOP button is pressed. Both effects of ground faults are eliminated.

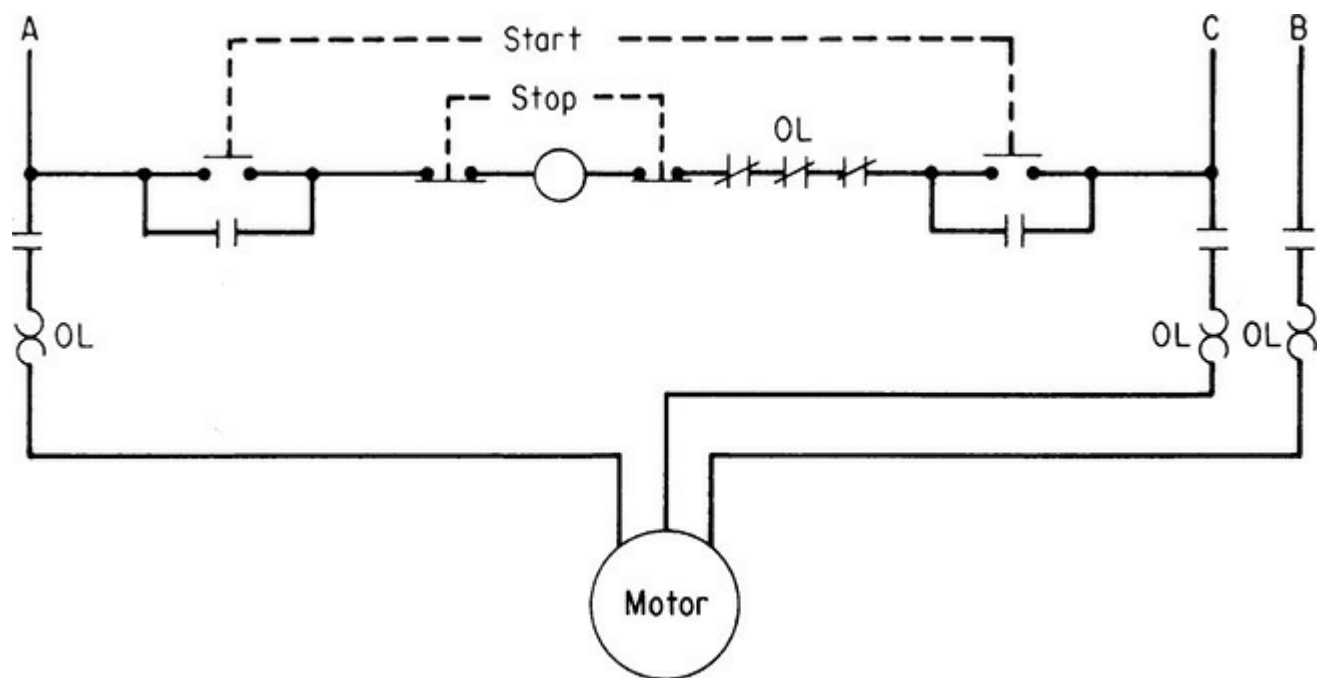

Fig. 430-47. This circuit prevents accidental starting and assures stopping. (Sec. 430.73.)

430.75. Disconnection. The control circuit of a remote-control motor controller shall always be so connected that it will be cut off when the disconnecting means is opened, unless a separate disconnecting means is provided for the control circuit.

When the control circuit of a motor starter is tapped from the line terminals of the starter—in which case it is fed at line-to-line voltage of the circuit to the motor itself—opening of the required disconnect means ahead of the starter de-energizes the control circuit from its source of supply, as shown in Fig. 430-48. But, where voltage supply to the coil circuit is derived from outside the starter enclosure (as from a panelboard or from a separate control transformer), provision must be made to ensure that the control circuit is capable of being de-energized to permit safe maintenance of the starter. In such cases, the required power-circuit disconnect ahead of the starter can open the power circuit to the starter's line terminals; but, unless some provision is made to open the externally derived control circuit voltage supply, a maintenance worker could be exposed to the unexpected shock hazard of the energized control circuit within the starter.

Fig. 430-48. Disconnect ahead of starter opens supply to line-voltage coil circuit. (Sec. 430.74.)

The disconnect for control voltage supply could be an extra pole or auxiliary contact in the switch or CB used as the main power disconnect ahead of the starter, as shown in [Fig. 430-49](#). Or the control disconnect could be a separate switch (like a toggle switch), provided this separate switch is installed “immediately adjacent” to the power disconnect—so it is clear to maintenance people that *both* disconnects must be opened to kill *all* energized circuits within the starter. Control circuits operating contactor coils, and so forth, within controllers present a shock hazard if they are allowed to remain energized when the disconnect is in the OFF position. Therefore, the control circuit either must be designed in such a way that it is disconnected from the source of supply by the controller disconnecting means or must be equipped with a separate disconnect immediately adjacent to the controller disconnect for opening of both disconnects. [For grounding of the control transformer secondary in [Fig. 430-49](#), refer to 250.20(B).]

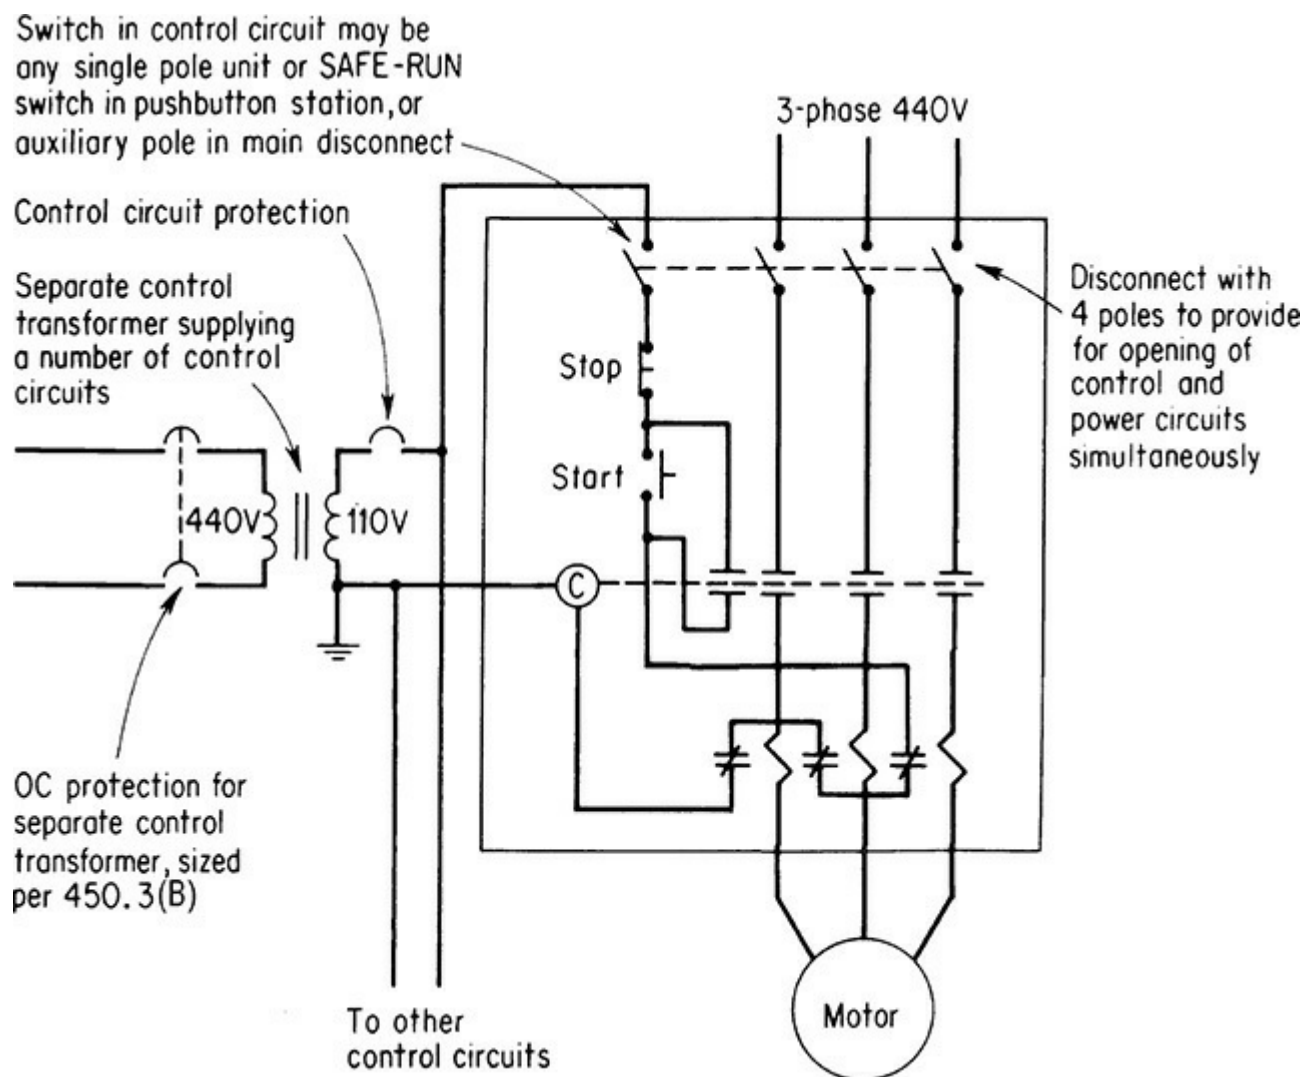

Fig. 430-49. Control disconnect means must supplement power-circuit disconnect. (Sec. 430.74.)

Exception No. 1 of part (A) is aimed at industrial-type motor control hookups, which involve extensive interlocking of control circuits for multimotor process operations or machine sequences. In recognition of the unusual and complex control conditions that exist in many industrial applications—particularly process industries and manufacturing facilities—Exception No. 1 alters the basic rule that disconnecting means for control circuits must be located “immediately adjacent one to each other” (Fig. 430-50). When a piece of motor control equipment has more than 12 motor control conductors associated with it, remote locating of the disconnect means is permitted under the conditions given in Exception No. 1. As shown in Fig. 430-51, this permission is applicable only where qualified persons have access to the live parts and sufficient warning signs are used on the equipment to locate and identify the various disconnects associated with the control circuit conductors.

Fig. 430-50. Industrial control layouts with more than 12 control circuit conductors for interlocking of controllers and operating stations (arrow) do not require control disconnects to be “immediately adjacent” to power disconnects. (Sec. 430.74.)

Where an assembly of motor control equipment or a machine or process layout has **more than 12** control conductors coming into it and requiring disconnect means . . .

. . . the disconnect devices required by 430.74(A) for the control conductors may be remote from, instead of adjacent to, the disconnects for the power circuits to the motor controllers.

Fig. 430-51. For extensively interlocked control circuits, control disconnects do not have to be adjacent to power disconnects. (Sec. 430.74.)

Exception No. 2 presents another instance in which control circuit disconnects may be mounted other than immediately adjacent to each other. It notes that where the opening of one or more motor control circuit disconnects might result in hazard to personnel or property, remote mounting may be used where the conditions specified in Exception No. 1 exist, that is, that access is limited to qualified persons and that a warning sign is located on the outside of the equipment to indicate the location and the identification of each remote control circuit disconnect.

The requirement of part **(B)** of this section is shown in [Fig. 430-52](#). When a control transformer is in the starter enclosure, the power disconnect means is on the line side and can de-energize the transformer control circuit. Grounding of the control circuit is not always necessary, as noted in 250.21(C), although there must be a showing of a need for power continuity and ground detectors must be installed when this option is used. Overcurrent protection must be provided for the control circuit when a control circuit transformer is used, as covered in 430.72(B). Such protection may be on the primary or secondary side of the transformer, as described. In 450.1, Exception No. 2 notes that the rules of Art. 450 do not apply to “dry-type transformers that constitute a component part of other apparatus. . . .” A control transformer supplied as a factory-installed component in a starter would therefore be exempt from the rules of 450.3(B), covering overcurrent protection for transformers, but would have to comply with 430.72(C).

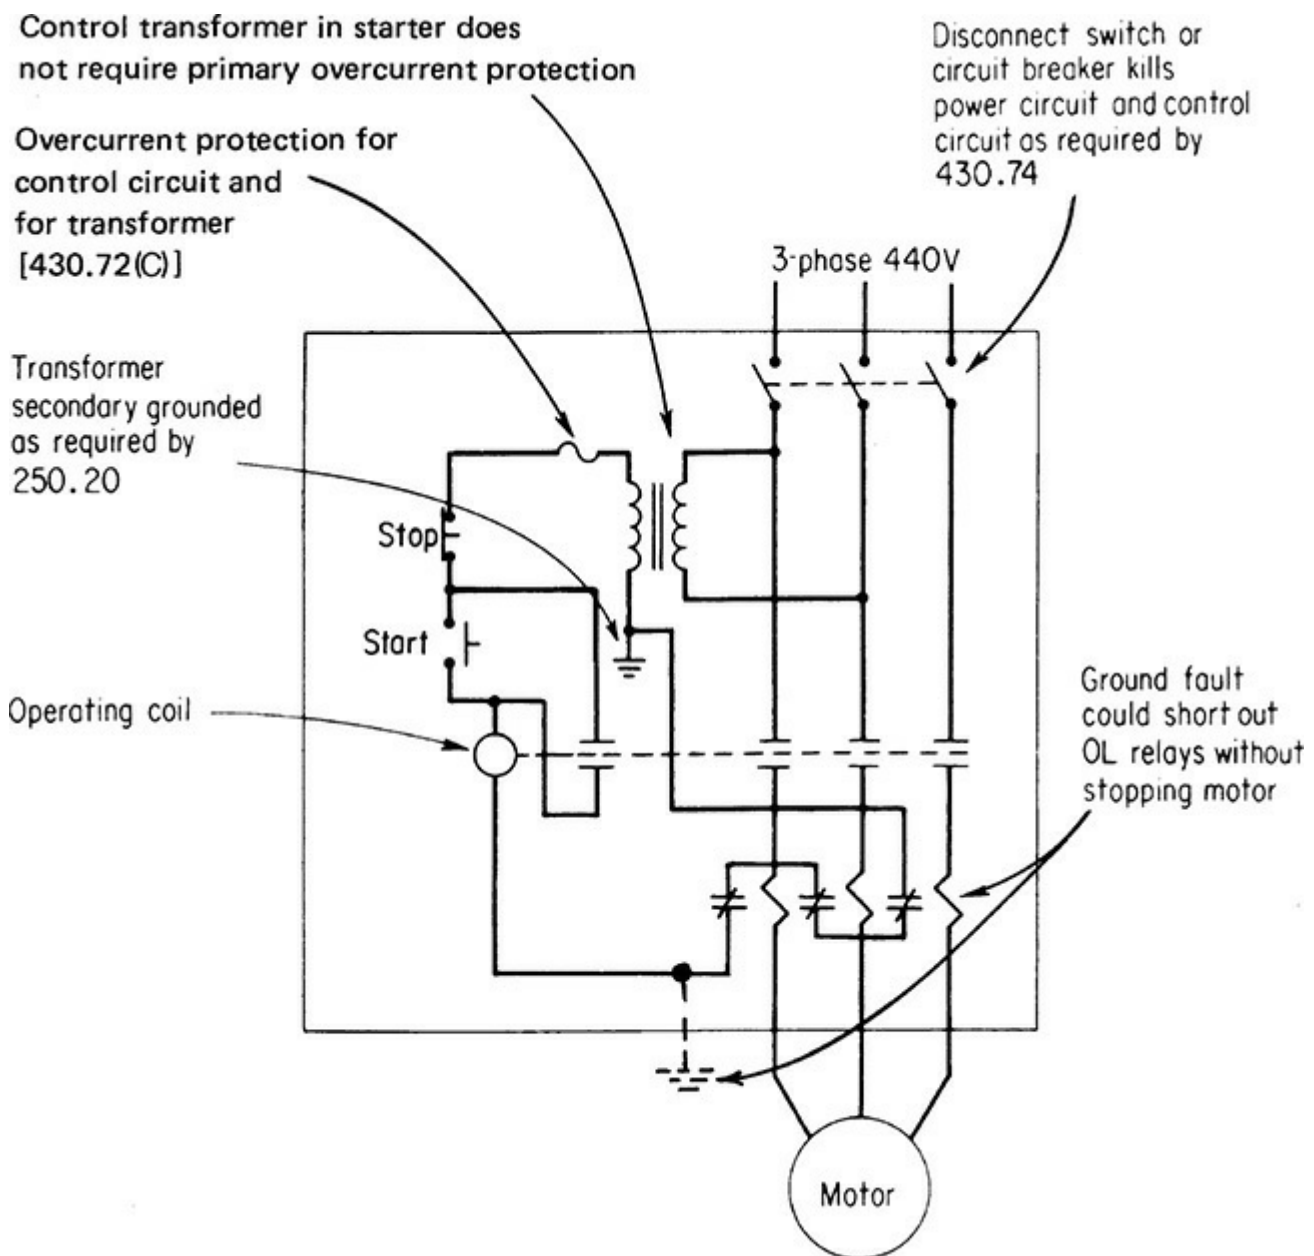

Fig. 430-52. Control transformer in starter must be on load side of disconnect. (Sec. 430.74.)

430.81. General. As used in Art. 430, the term *controller* includes any switch or device normally used to start and stop a motor, in addition to motor starters and controllers as such. As noted, the branch-circuit fuse or CBs are considered an acceptable control device for stationary motors not over $\frac{1}{8}$ hp where the motor has sufficient winding impedance to prevent damage to the motor with its rotor continuously at standstill. And a plug and receptacle connection may serve as the controller for portable motors up to $\frac{1}{3}$ hp.

As described in the definition in 430.2, a *controller* is a device that starts and stops a motor by “making and breaking the motor circuit current”—that is, the power current flow to the motor windings. A pushbutton station, a limit switch, a float switch, or any other pilot control device that “carries the electric signals directing the performance of the controller” (see the definition of *Motor Control Circuit* in 430.71) is not the controller where such a device is used to carry only the current to the operating coil of a magnetic motor controller. For purposes of Code application, the contactor mechanism is the motor “controller.”

430.82. Controller Design. Every controller must be capable of starting and stopping the

motor that it controls, must be able to interrupt the stalled-rotor current of the motor, and must have a horsepower rating not lower than the rating of the motor, except as permitted by 430.83.

430.83. Ratings. Figure 430-53 shows the basic requirements from part (A) for the required rating of a controller. Although the basic rule calls for a horsepower-rated switch or a horsepower-rated motor starter, there are acceptable alternative methods for specific applications as noted in 430.81 and as follows:

THESE ARE THE GENERAL RULES

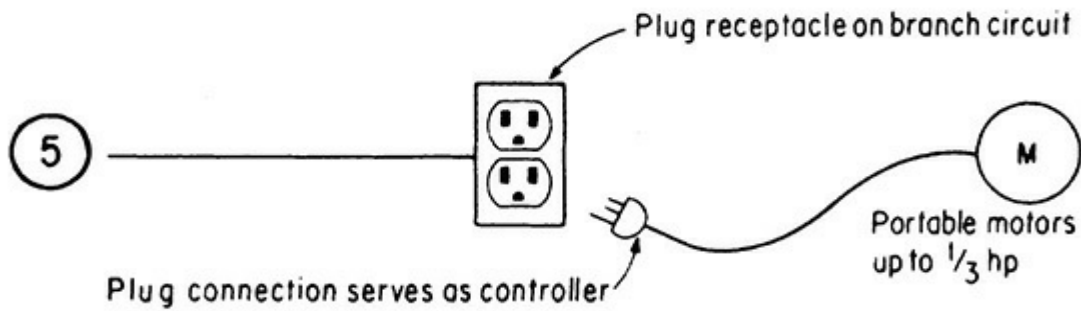

Fig. 430-53. Controller must be a horsepower-rated switch or CB—but other devices may satisfy. (Sec. 430.83.)

- The wording of 430.83(A)(1) calls for controllers—other than inverse time CBs and molded-case switches—to have a horsepower rating at least equal to that of the motor at the application voltage.
- A branch-circuit CB rated in amperes only, may be used as a controller. If the same CB is used as a controller and to provide overload protection for the motor circuit, it must be rated in accordance with 430.32.
- A molded-case switch may be used as a controller.
- A general-use switch rated at not less than twice the full-load motor current may be used as the controller for stationary motors up to 2 hp, rated 300 V or less. On ac circuits, a general-use snap switch suitable only for use on ac may be used to control a motor having a full-load current rating not over 80 percent of the ampere rating of the switch.

In the UL Guide Card information there is essential additional information on the use of switches in motor circuits, as follows:

1. Enclosed switches with horsepower ratings in addition to current ratings may be used for motor circuits as well as for general-purpose circuits. Enclosed switches with ampere-only ratings are intended for general use but may also be used for motor circuits (as controllers and/or disconnects) as permitted by **NEC** 430.83(A)(1), 430.109, and 430.111.
2. A switch that is marked “MOTOR CIRCUIT SWITCH” is intended for use *only* in motor circuits.
3. For switches with dual-horsepower ratings, the higher horsepower rating is based on the use of time-delay fuses in the switch fuseholders to hold in on the inrush current of the higher-horsepower-rated motor.
4. Although 430.83 permits use of horsepower-rated switches as controllers and UL lists horsepower-rated switches up to 500 hp, UL does state in its Guide Card information [see discussion at 110.3(B) for details] that “enclosed switches rated higher than 100 hp are restricted to use as motor disconnect means and are not for use as motor controllers.” But a horsepower-rated switch up to 100 hp may be used as both a controller and disconnect if it breaks all ungrounded legs to the motor, as covered in 430.111.

Figure 430-54 covers two of those points.

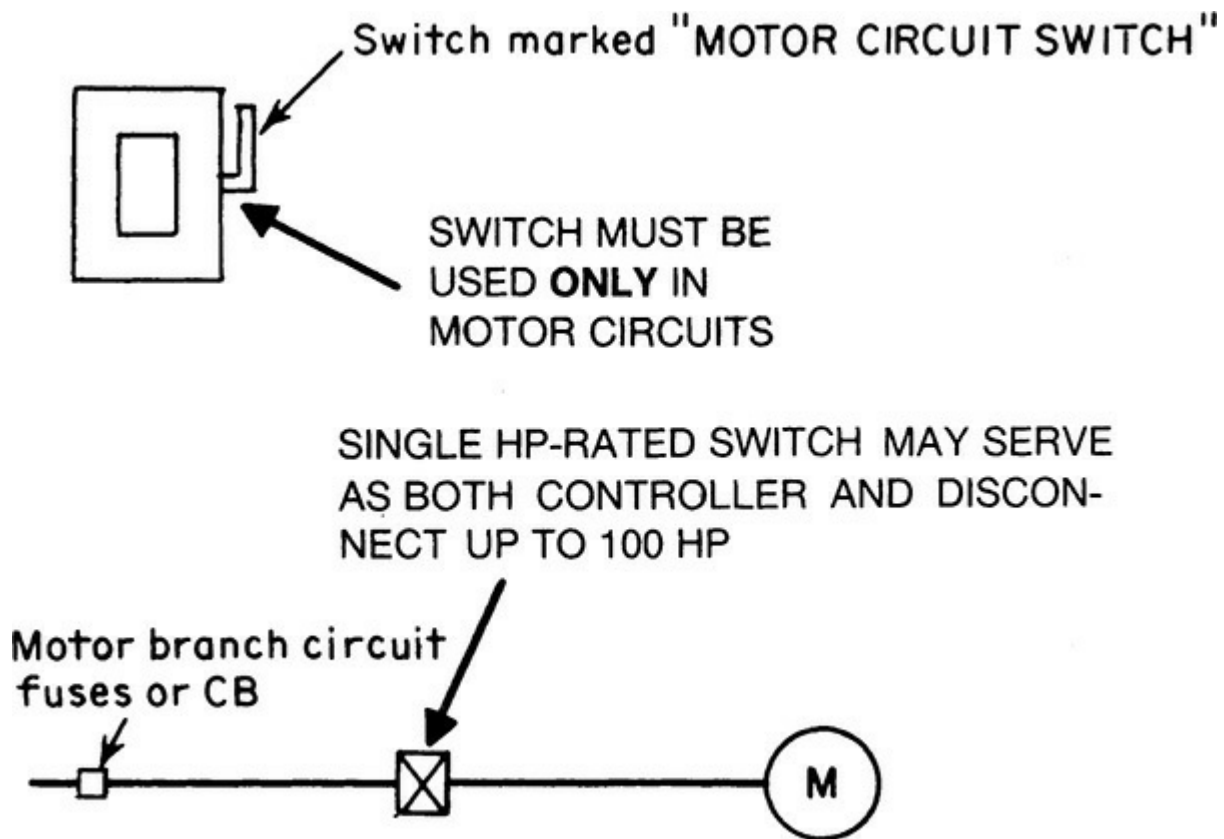

Fig. 430-54. UL rules limit Code applications. (Sec. 430.83.)

For selection of a controller for a sealed (hermetic-type) refrigeration compressor motor, refer to 440.41.

430.84. Need Not Open All Conductors. It is interesting to note that the NEC says that a controller need not open all conductors to a motor, except when the controller serves also as the required disconnecting means. For instance, a 2-pole starter of correct horsepower rating could be used for a 3-phase motor if running overload protection is provided in all three circuit legs by devices separate from the starter, such as by dual-element, time-delay fuses which are sized to provide running overload protection as well as short-circuit protection for the motor branch circuit. The controller must interrupt only enough conductors to be able to start and stop the motor.

However, when the controller is a manual (nonmagnetic) starter or is a manually operated switch or CB (as permitted by the Code), the controller itself also may serve as the disconnecting means if it opens all ungrounded conductors to the motor, as covered in 430.111. This eliminates the need for another switch or CB to serve as the disconnecting means. But, it should be noted that only a manually operated switch or CB may serve such a dual function. A magnetic starter cannot also serve as the disconnecting means, even if it does open all ungrounded conductors to the motor.

Figure 430-55 shows typical applications in which the controller does not have to open all conductors but a separate disconnect switch or CB is required ahead of the controller. In the drawing, the word *ungrounded* refers to the condition that none of the circuit conductors is grounded. These may be the ungrounded conductors of grounded systems.

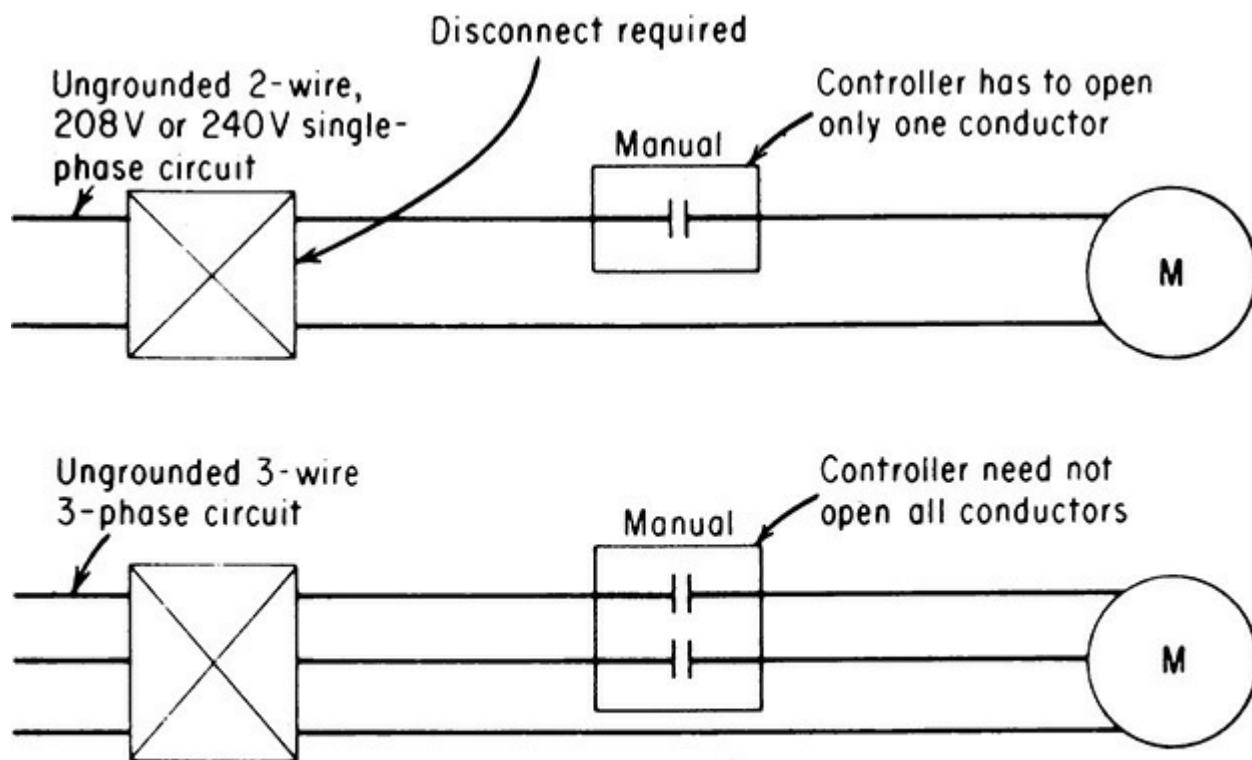

Fig. 430-55. Controller does not have to break *all* legs of motor supply circuit. (Sec. 430.84.)

Generally, one conductor of a 115-V circuit is grounded, and on such a circuit a single-pole controller may be used connected in the ungrounded conductor, or a 2-pole controller is permitted if both poles are opened together. In a 230-V circuit there is usually no grounded conductor, but if one

conductor is grounded, 430.85 permits a 2-pole controller.

430.85. In Grounded Conductors. This rule permits a 3-pole switch, CB, or motor starter to be used in a 3-phase motor circuit derived from a 3-phase, 3-wire, corner-grounded delta system—with the grounded phase leg switched along with the hot legs, as in 430.36.

430.87. Number of Motors Served by Each Controller. Generally, an individual motor controller is required for each motor. However, for motors rated not over 600 V, a single controller rated at not less than the sum of the horsepower ratings of all the motors of the group may be used with a group of motors if any one of the conditions specified is met. Where a single controller is used for more than one motor connected on a single branch circuit as permitted under condition *b*, it should be noted that the reference is to part (A) of 430.53. That use of a single controller applies only to cases involving motors of 1 hp or less and does not apply for several motors used on a single branch circuit in accordance with parts (B) and (C) of 430.53—unless the several motors satisfy conditions *a* or *c* of this section.

See 430.112, where the same conditions are set for a single disconnect means to serve a group of motors. Note that the reference to 430.110(C)(1) requiring an equivalent horsepower calculation can add unexpected sizing. For example, suppose you want to group control a 10-hp, a 15-hp, and a 20-hp, 460-V motor. The total horsepower by simple summation would be 45 hp, but that is not the correct result. The ampere ratings from Table 430.250 and the locked-rotor current numbers from Table 430.251(B) have to be summed as well: $14\text{ A} + 21\text{ A} + 27\text{ A} = 62\text{ A}$; and $81\text{ A} + 116\text{ A} + 145\text{ A} = 342\text{ A}$. Making a reverse lookup in Tables 430.250 and 251(B) using these summations results in a requirement for a 50-hp-capable controller.

430.88. Adjustable-Speed Motors. Field weakening is quite commonly used as a method of controlling the speed of dc motors. If such a motor were started under a weakened field, the counter emf is reduced commensurately and the starting current would be excessive unless the motor is specially designed for starting in this manner.

430.89. Speed Limitation. A common example of a separately excited dc motor is found in a typical speed control system that is widely used for electric elevators, hoists, and other applications where smooth control of speed from standstill to full speed is necessary. In Fig. 430-56, G_1 and G_2 are two generators having their armatures mounted on a shaft which is driven by a motor, not shown in the diagram. M is a motor driving the elevator drum or other machine. The fields of generator G_1 and motor M are excited by G_1 . By adjusting the rheostat R , the voltage generated by G_2 is varied, and this in turn varies the speed of motor M . It is evident that if the field circuit of motor M should be accidentally opened while the motor is lightly loaded, the motor would reach an excessive speed. In many applications of this system the motor is always loaded and no speed-limiting device is required.

Fig. 430-56. Typical speed control hookup involving the rule of 430.89.(Sec. 430.89.)

The speed of a series motor depends on its load and will become excessive at no load or very light loads. Traction motors are commonly series motors, but such a motor is geared to the drive wheels of the car or locomotive and hence is always loaded.

Where a motor generator, consisting of a motor driving a compound-wound dc generator, is operated in parallel with a similar machine or is used to charge a storage battery, if the motor circuit is accidentally opened while the generator is still connected to the dc buses or battery, the generator will be driven as a motor and its speed may become dangerously high. A synchronous converter operating under similar conditions may also reach an excessive speed if the ac supply is accidentally cut off.

A safeguard against overspeed is provided by a centrifugal device on the shaft of the machine, arranged to close (or open) a contact at a predetermined speed, thus tripping a CB, which cuts the machine off from the current supply.

430.90. Combination Fuseholder and Switch as Controller. The use of a fusible switch as a motor controller with fuses as motor-running protective devices is practicable when time-delay types of fuses are used. The rating of the fuses must not exceed 125 percent, or in some cases 115 percent, of the full-load motor current, and nontime-delay fuses of this rating would, in most cases, be blown by the starting current drawn by the motor, particularly where the motor turns on and off frequently. (See 430.35.)

It may be found that a switch having the required horsepower rating is not provided with fuse terminals of the size required to accommodate the branch-circuit fuses. For example, assume a $7\frac{1}{2}$ -hp, 230-V, 3-phase motor started at full-line voltage. A switch used as the disconnecting means for this motor must be rated at not less than $7\frac{1}{2}$ hp, but this would probably be a 60-A switch and therefore, if

fusible, would be equipped with terminals to receive 35- to 60-A fuses. 430.90 provides that fuse terminals must be installed that will receive fuses of 70-A rating. In such case a switch of the next higher rating must be provided, unless time-delay fuses are used.

430.92. General. This is the motor control center part of the article. Motor control centers are essentially switchboards adapted for this function, and many of the construction requirements came from Art. 408. It should be remembered that the clearances in 110.26 apply to this equipment generally, and 110.26(F), addressing what can go where in the dedicated wiring space above and below such equipment, specifically refers to motor control centers as a topic to which it applies. The fault current available at a motor control center must be determined and, together with the calculation data, be documented and made available to interested parties (430.99).

430.94. Overcurrent Protection. Motor control centers require individual overcurrent protection, either in the unit or ahead of it, rated or set not to exceed the rating of the common power bus. This is a significant departure from switchboards that do not have this limitation. Note that this limitation may limit the application of 430.62 or 430.63 because feeder protection determined by those sections, particularly with a very large motor in the load group, may significantly exceed the ampacity of the feeder conductors. The common power bus of a motor control center is a feeder, and this rule means that a motor control center supplying the same large motor will require a common power bus that is larger than the equivalent conductors installed as a conventional feeder. This is the reason for 430.62 Exception No. 2, which correlates these two provisions.

430.102. Location. Along with 430.101, this section specifically requires that a disconnecting means—basically, a motor-circuit switch rated in horsepower, or a CB—be provided in each motor circuit. [Figure 430-57](#) shows the basic rule on “in-sight” location of the disconnect means. This applies always for all motor circuits rated up to 600 V—even if an “out-of-sight” disconnect can be locked in the open position.

**THIS IS THE
BASIC RULE**

EXAMPLE

Fig. 430-57. The required disconnect must be visible from the controller. (Sec. 430.102.)

Because the basic rule here requires a disconnecting means to be within sight from the “controller location,” the question arises, “Is the magnetic contactor the controller or is the pushbutton station the controller?” The **NEC** makes clear that the contactor of a magnetic motor starter *is* the controller for the motor, *not* the pushbuttons that actuate the coil of the contactor. The **NEC** establishes that identification by the definition of *controller* in Art. 100 and by the definition of a *motor control circuit* in 430.2, as follows:

Controller: A device or group of devices that serves to govern, in some predetermined manner, the electric power delivered to the apparatus to which it is connected. Note that this definition is modified “for the purposes of this article” in 430.2 by a definition that goes on to state that it is “any switch or device that is normally used to start and stop a motor by making and breaking the motor circuit current.”

Motor control circuit: The circuit of a control apparatus or system that carries the electric signals directing the performance of the controller, but does not carry the main power current.

In a magnetic motor starter hookup, it is the contactor that actually governs the electric power delivered to the motor to which it is connected. The motor connects to the contactor and *not* to the

pushbuttons, which are in the control circuit that carries the electric signals directing the performance of the *controller* (i.e., the contactor). The pushbuttons do *not* carry “the main power current,” which is “delivered” to the motor by the contactor and which is, therefore, “the controller.” It is well established that the intent of the Code rule, as well as the letter of the rule, is to designate the *contactor* and *not* the pushbutton station as the controller, and the disconnect must be within sight from it and not from a pushbutton station or some other remotely located pilot control device that connects into the contactor.

There are three exceptions to this basic Code rule, requiring a disconnect switch or CB to be located in sight from the controller:

Exception No. 1 permits the disconnect for a medium-voltage (over 600 V) motor to be out of sight from the controller location, as shown in Fig. 430-58. But, such use of a lock-open type switch as an out-of-sight disconnect for a motor circuit rated 600 V or less is a clear Code violation.

Fig. 430-58. An out-of-sight disconnect may be used for a high-voltage motor. (Sec. 430.102.)

Exception No. 2 is aimed at permitting practical, realistic disconnecting means for industrial applications of large and complex machinery utilizing a number of motors to power the various interrelated parts of the machine. The exception recognizes that a single common disconnect for a number of controllers (as permitted by part (A) of the Exception of 430.112) is often impossible to install “within sight” of all the controllers, even though the controllers are “adjacent one to each other.” On much industrial process equipment, the components of the overall structure obstruct the view of many controllers. Exception No. 2 permits the single disconnect to be technically out of sight from some or even all the controllers if the disconnect is simply *adjacent* to them—that is, nearby on the equipment structure, as shown in Fig. 430-59.

Fig. 430-59. For multimotor machines, the disconnect may be "adjacent" to controller. (Sec. 430.102.)

Exception No. 3 was new as of the 2008 edition of the **NEC** and addresses instances where a local disconnect for "valve actuator motors" would introduce additional hazards, and there is a label applied giving the location of a lock-open disconnect.

These motors, defined in 430.2, are common in industrial facilities, where they control process fluids. The actual motors are short-time duty with high torque. They generally have a controller built into the assembly, and the motor incorporates a self-resetting running overload protection. They are reversible for obvious reasons, and available in a range of voltages and either single-or three-phase, and up to eight poles. The gearing differs from unit to unit, and therefore the typical rating is not in horsepower but in torque. The short-circuit and ground-fault protective device ratings for these motors are determined by Table 430.52 using the nameplate current and not current taken from the tables at the end of the article. This procedure is not new; as covered in the last sentence of 430.6(A) (1), "motors built for low speeds (less than 1200 rpm) or high torques may have higher full-load currents, . . . in which case the nameplate current ratings shall be used."

None of these three exceptions allows for an upstream, out-of-sight lock-open disconnect ahead of a controller for conventional motors operating at 600 volts and below. Do not confuse this controller disconnect with the motor disconnect in **(B)**. For more information on how this requirement and the disconnect provisions in Part **X** for variable speed drives may intersect, review the commentary at 430.128.

Part **(B)** basically requires a disconnect means (switch or CB) to be within sight and not more than 50 ft away from "the motor location and the driven machinery location." But the exception to that basic requirement says that a disconnect does not have to be within sight from the motor and its load

if the required disconnect ahead of the motor controller is capable of being locked in the open position. This exception has been severely limited in recent Code cycles. The disconnect in sight of the controller must be “individually capable of being locked in the open position” which eliminates the possibility of a locked panel door qualifying. In addition, as in most instances throughout [Chap. 4](#), the locking provisions must remain with the circuit breaker or switch even with the lock removed.

The above limitations apply in many comparable situations, but the following limitations are unique to the application of this exception. It only applies to (1) industrial occupancies with written safety procedures that ensure that only qualified persons will service the motor or (2) other installations if the additional disconnect would introduce additional hazards or would be impracticable.

For example, it would be plainly impracticable to place a disconnect 50 ft down a well shaft to be “in sight” (not over 50 ft distant) from a submersible pump motor 100 ft down the same shaft. Variable frequency drives should not have the motor disconnected unless the drive itself is disconnected, and multimotor equipment may cause hazards unless a coordinated stop is arranged. Large motors (over 100 hp) only need isolation switches anyway, so their disconnects can be remote, and additional disconnects in hazardous (classified) locations only exacerbate the explosion hazards. These issues are covered quite well in a note that follows the first part of the exception. Never again assume that a locking disconnect in the motor control center solves the local disconnect requirement.

According to the basic rule of part **(B)**, a manually operable switch, which will provide disconnection of the motor from its power supply conductors, must be placed within sight from the motor location. And this switch *may not* be a switch in the control circuit of a magnetic starter. (The **NEC** at one time permitted a switch in the coil circuit of the starter installed within sight of the motor. Such a condition is *not* acceptable to the present Code.)

These requirements are shown in [Fig. 430-60](#). Specific layouts of the two conditions are shown in [Fig. 430-61](#). (*Note:* The portions of these drawings covering the exception only apply when and if the restrictive conditions just discussed have been met.) The intent of the exception to part **(B)** is to permit maintenance workers to lock the disconnecting means ahead of the controller in the open position and keep the key in their possession so that the circuit cannot be energized while they are working on it.

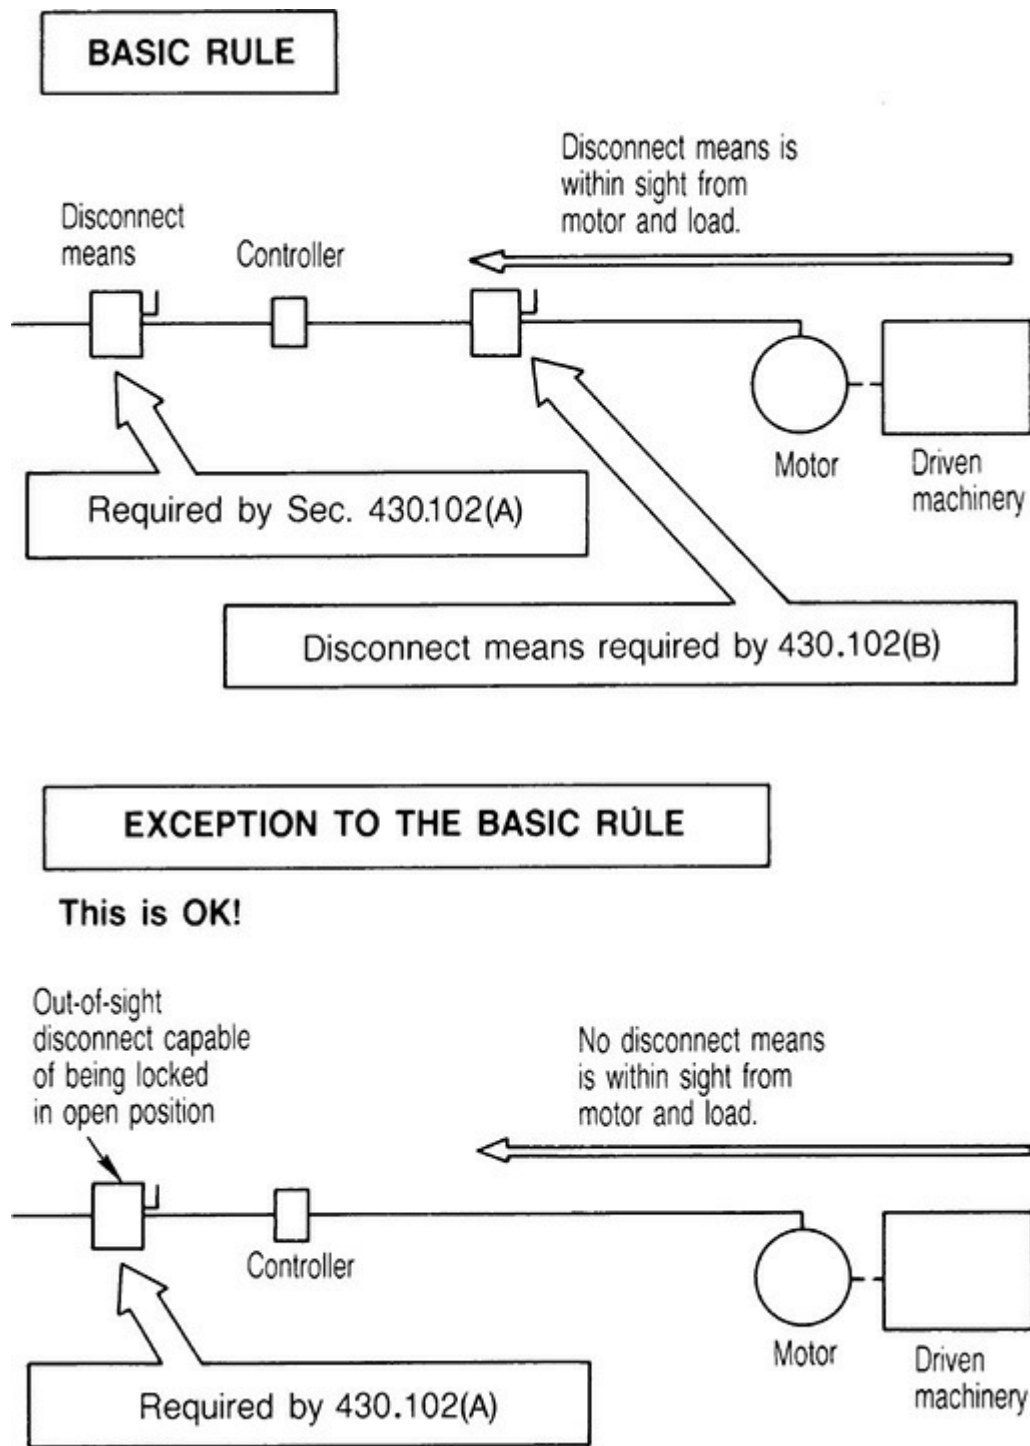

Fig. 430-60. Disconnect means must be within sight from the motor and its driven load, unless out-of-sight disconnect can be locked open. [Sec. 430.102(B).] This exception is now severely limited (see text).

The pushbutton station in Fig. 430-61 operates only the holding coil in the magnetic starter. The magnetic starter *controls* the current to the motor; for example, the control wires to a pushbutton station could become shorted after the motor is in operation, and pushing the STOP button would not release the holding coil in the magnetic starter and the motor would continue to run. This is the reason that a disconnecting means is required to be installed within sight from the motor and its load or a lock-open switch installed ahead of the controller. In this case, operating the disconnecting means will open the supply to the controller and shut off the motor.

Fig. 430-61. Here's an example of the rules, showing physical layout. [Sec. 430.102(B).] As previously noted, this exception is now severely limited. As illustrated here, it would probably only apply in an industrial occupancy under written safety procedures and with qualified supervision and staff.

430.103. Operation. This rule actually defines the meaning of *disconnecting means*.

In order that necessary periodic inspection and servicing of motors and their controllers may be done with safety, the Code requires that a switch, CB, or other device shall be provided for this purpose. Because the disconnecting means must disconnect the controller as well as the motor, it must be a separate device and cannot be a part of the controller, although it could be mounted on the same panel or enclosed in the same box with the controller. The disconnect must be installed ahead of the controller. And note that the disconnect need open only the *ungrounded* conductors of a motor circuit.

In case the motor controller fails to open the circuit if the motor is stalled, or under other conditions of heavy overload, the disconnecting means can be used to open the circuit. It is therefore required that a switch used as the disconnecting means shall be capable of interrupting very heavy

current.

A 2008 **NEC** amendment added the requirement that the disconnecting means be designed so it cannot close automatically. This addresses time-clock switches that can be placed in an open position, and even have the door locked shut, but unless the trippers are physically removed the clock will, in time, reclose the circuit.

430.105. Grounded Conductors. Although 430.103 requires a disconnect means only for the ungrounded conductors of a motor circuit, if a motor circuit includes a grounded conductor, one pole of the disconnect *may* switch the grounded conductor, provided all poles of the disconnect operate together—as in a multipole switch or CB. For instance, a 120-V, 2-wire circuit with one of its conductors grounded only requires a single-pole disconnect switch, but a 2-pole switch *could* be used, with one pole simultaneously switching the grounded leg.

430.107. Readily Accessible. Although a motor circuit may be provided with more than one disconnect means in series ahead of the controller—such as one at the panel where the motor circuit originates and one at the controller location—*only one* of the disconnects is required to be “readily accessible,” as follows:

Readily accessible: Capable of being reached quickly for operation, renewal, or inspection, without requiring those to whom ready access is requisite to climb over or remove obstacles or to resort to portable ladders, chairs, etc. (See “Accessible.”)

The disconnecting means must be reached without climbing over anything, without removing crates or equipment or other obstacles, and without requiring the use of portable ladders.

Note carefully: A disconnect that has to be “readily accessible” must be so only for “those to whom ready access is requisite”—which clearly and intentionally allows for making equipment *not* readily accessible to other than authorized persons, such as by providing a lock on the door, with the key possessed by or available to those who require ready access.

Because the definition of *readily accessible* contains a last phrase that says “See ‘Accessible,’” logic dictates that the installation must also satisfy the definition of *accessible*. And the wording of the definition clearly establishes that there is no Code violation in putting the disconnect means in a room or area under lock and key to make it accessible only to authorized persons.

The definition reads:

Accessible: (As applied to Equipment.) Admitting close approach because not guarded by locked doors, elevation, or other effective means. (See “Readily Accessible.”)

Again note carefully: That definition does not say that a door to an electrical room is prohibited from being locked. In fact, the wording of the definition, by referring to “locked doors,” actually presumes the existence and, therefore, the acceptability of locked doors in electrical systems. The only requirement implied by the wording is that locked doors, where used, must not *guard* against access—that is, disposition of the key to the lock must be such that those requiring access to the room are not positively excluded. The rule is satisfied if the key is available to provide access to authorized persons.

In reference to the definition of *accessible*, the critical word is *guarded*. The definition is *not* intended to mean that equipment *cannot* be behind locked doors or that equipment *cannot* be mounted up high where it *can* be reached with a portable ladder. To make equipment “not accessible,” a door lock or high mounting must be such that it positively *guards* against access. Equipment behind a

locked door for which a key is not possessed by or available to persons who require access to the equipment is *not* “accessible.” A common example of that latter condition occurs in multitenant buildings where a disconnect for the tenant of one occupancy unit is located behind the locked door of another tenant’s occupancy unit from which the first tenant is effectively and legally excluded. And even that application *is* Code-acceptable if the disconnect is *not required* by the **NEC** to be “readily accessible.”

Equipment may be fully “accessible” even though installed behind a locked door or at an elevated height. Equipment that is high-mounted but can be reached with a ladder that is fixed in place or a portable ladder *is* “accessible” (although the equipment would not be “readily accessible” if a portable ladder had to be used to reach it). Similarly, equipment behind a locked door *is* “accessible” to anyone who possesses a key to the lock or to a person who is authorized to obtain and use the key to open the locked door. In such cases, conditions do *not* guard against access.

Refer to the definitions of *accessible* and *readily accessible* in Art. 100 of this book.

430.109. Type. In a motor branch circuit, every switch or CB in the circuit, from where the circuit is tapped from the feeder to the motor itself, must satisfy the requirements on type and rating of disconnect means. A CB switching device with no automatic trip operation, a so-called molded-case switch, may be used as a motor disconnect instead of a conventional CB or a horsepower-rated switch. Such a device either must be rated for the horsepower of the motor it is used with or must have an amp rating at least equal to 115 percent of that of the motor with which it is used. [Figure 430-62](#) covers the basic rules on types of disconnect means. An instantaneous-trip circuit breaker, as part of a listed combination motor controller, has the status of a circuit breaker in this classification and is an acceptable disconnecting means. The following items also qualify, with the limitations as described.

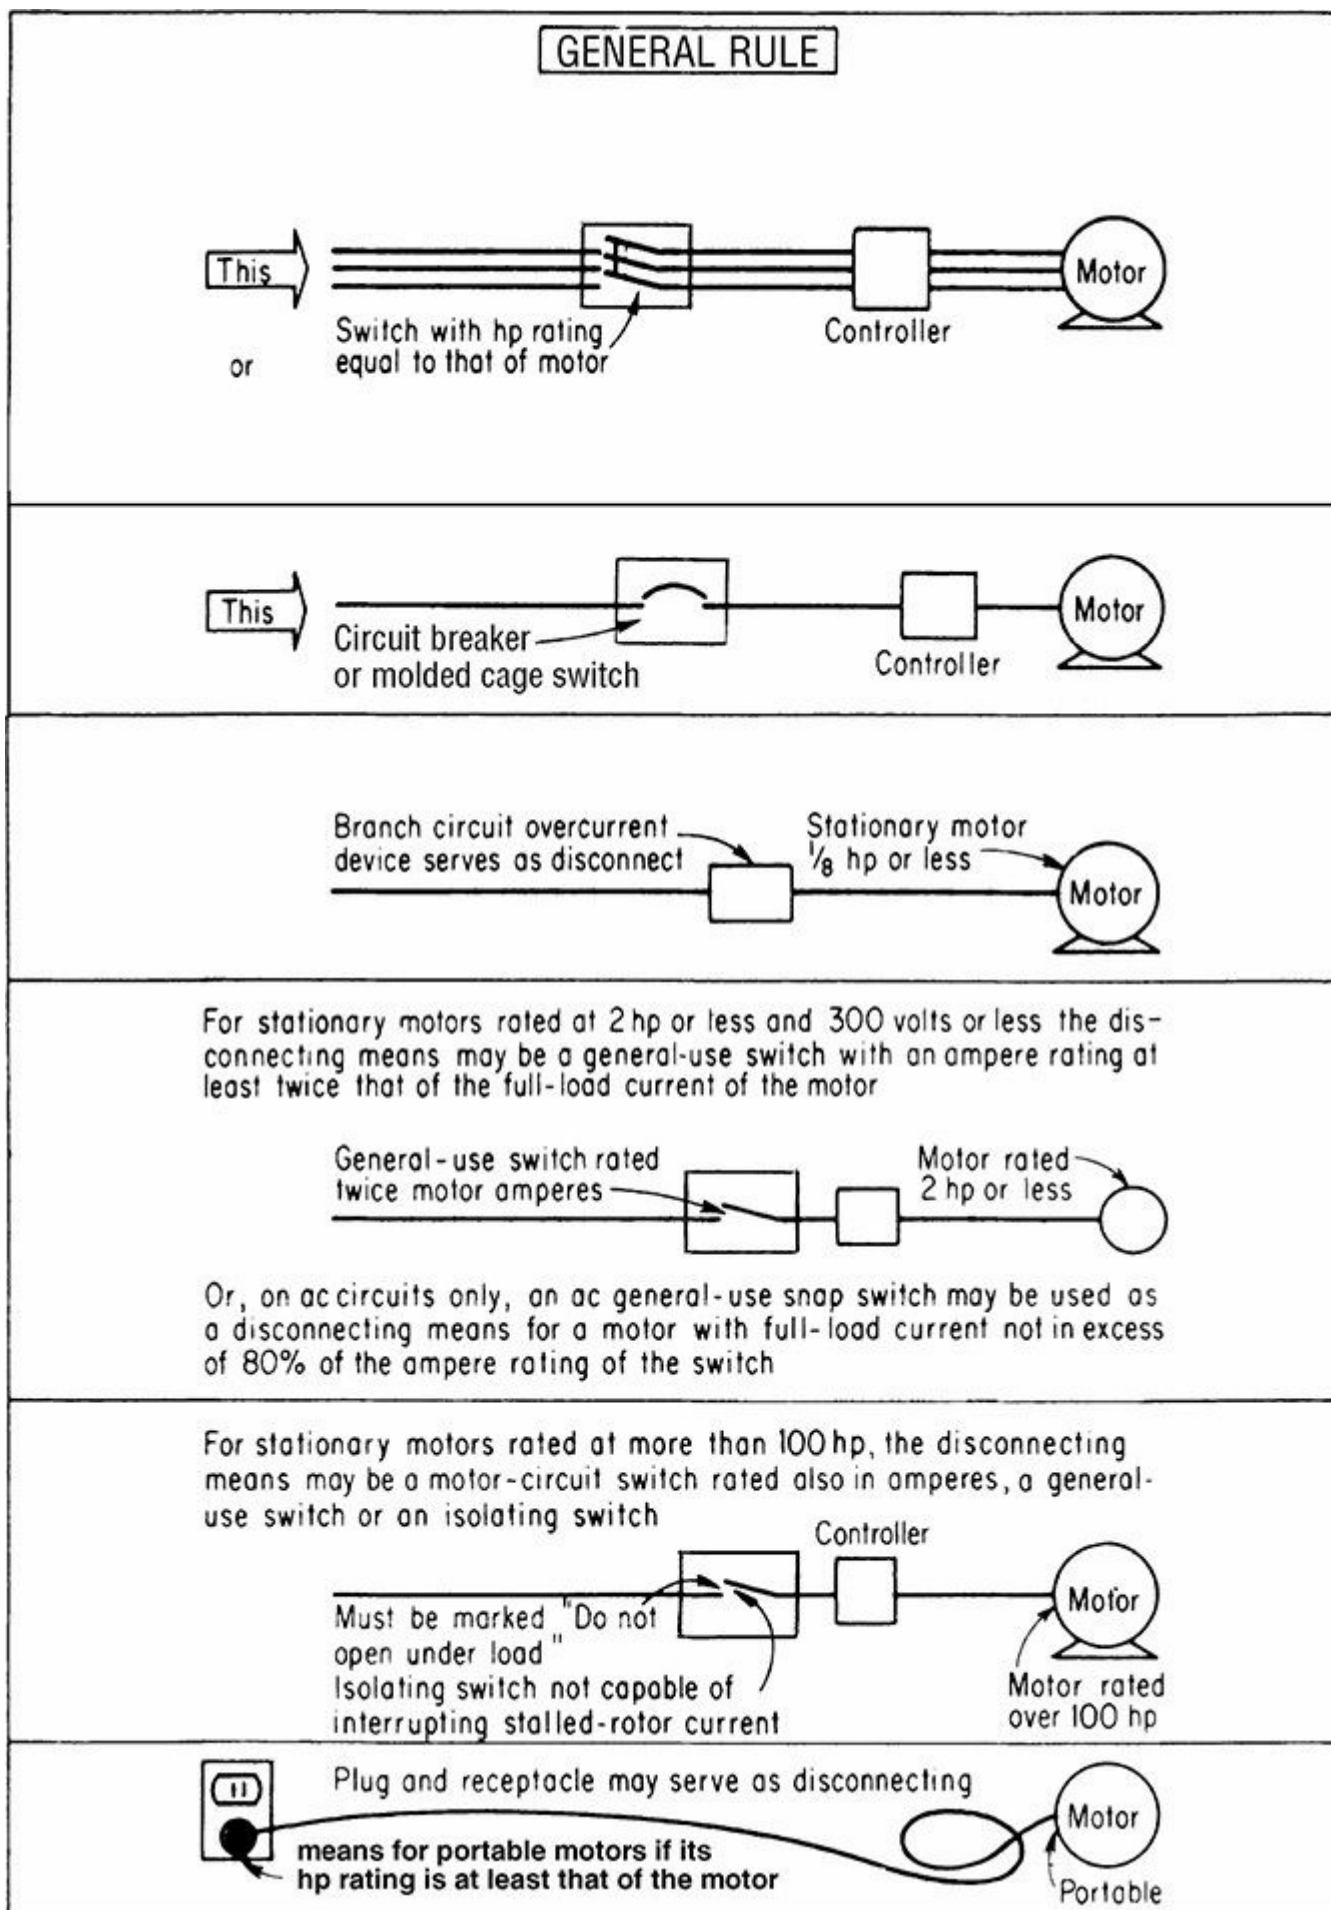

Fig. 430-62. One of these disconnects must be used for a motor branch circuit. (Sec. 430.109.) There are others; see text.

Self-protected combination controller—This combination device controls the motor’s performance, and qualifies as a disconnecting means. The device must be listed to qualify. It is also on the list of short-circuit and ground-fault protective devices, as covered in 430.52(C)(6).

Manual motor controller additionally marked SUITABLE AS MOTOR DISCONNECT—These devices carry principal listings as controllers, intended to turn a motor on and off manually. Even though it acts manually, and says OFF and ON, it does not qualify as a disconnecting means without meeting additional qualifications. Motor controllers, being designed as the manual equivalents of automatic controllers generally wired on the load side of a conventional disconnect, don’t have as robust internal spacings as full-fledged disconnect switches. The **NEC** allows these devices, if so listed, to be used as formal disconnects in two circumstances. The first, covering small motors, allows them to be used as disconnects for motors of 2 hp or less, just as snap switches (described later in this list). The second, covering larger motors, allows them to be used as disconnects provided they are on the load side of the final branch-circuit short-circuit and ground-fault protective device. In either case, their horsepower rating must not be less than the motor.

General-use switch—A switch intended for use in general distribution and branch circuits. It is rated in amperes, and is capable of interrupting its rated current at its rated voltage. Its ampere rating must be not less than twice the full-load current rating of the motor. It generally cannot be used for a motor larger than 2 hp, unless it additionally qualifies as a motor-circuit switch, as described earlier. It also qualifies if the installation (2 hp up to 100 hp) involves an autotransformer-type controller and the motor is driving a generator with overload protection, provided the controller has (1) no-voltage release (shuts off when power is discontinued, with manual restart only), (2) running overload protection limited to 125 percent of motor full-load current, and (3) the capability to interrupt locked-rotor current. In addition, the branch circuit must include separate fuses or an inverse-time circuit breaker not over 150 percent of the motor full-load current.

General-use snap switch—A form of general-use switch constructed so that it can be installed in flush device boxes or on outlet box covers, or otherwise used in conjunction with wiring systems recognized by the **NEC**. They are for ac motors only. To qualify, the switch must be rated ac-only (general-use ac-dc snap switches are not acceptable) and the motor full-load current must not exceed 80 percent of the ampere rating of the switch.

Isolating switch—A switch intended for isolating an electric circuit from the source of power. It has no interrupting rating, and it is intended to be operated only after the circuit has been opened by some other means. This is permitted only for dc motors over 40 hp and for ac motors over 100 hp. These switches are available in larger ratings, as covered at the end of this list.

Plug and receptacle—A cord-and-plug-connected motor need not have an additional disconnecting means if the plug and receptacle have a suitable horsepower rating. Refer to the UL Guide Card information under the heading “Receptacles for Attachment Plugs and Plugs” (Guide Card Designator RTRT) for the complete list, and manufacturer’s literature. The separate horsepower rating is not required for appliances, room air conditioners, or portable motors rated $\frac{1}{3}$ hp or less. Flanged inlets and cord connectors with equivalent motor circuit ratings, that follow the same UL Guide Card information, can equally be used for these purposes. See [Fig. 406-3](#) for an example.

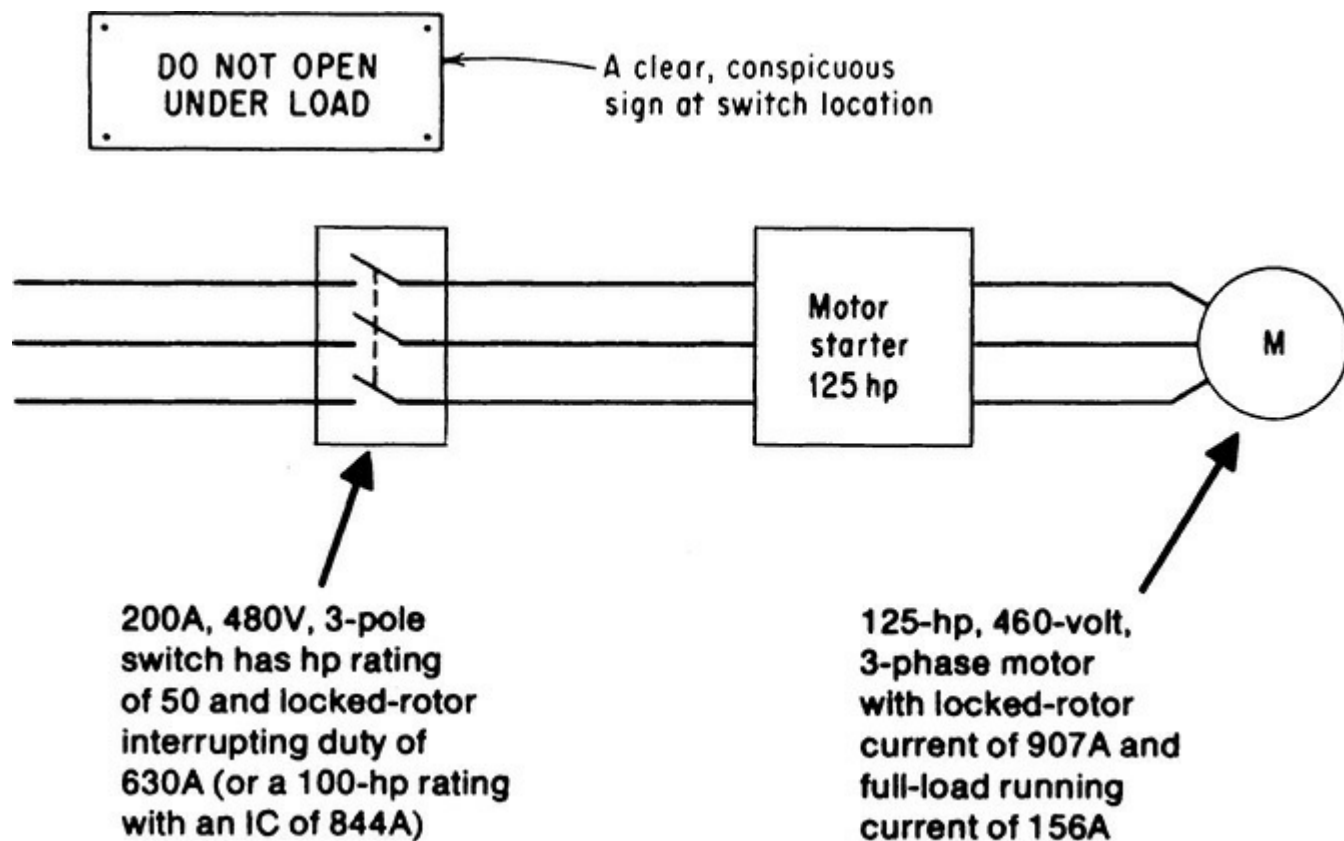

Fig. 430-63. Above 100 hp, a switch does not have to be horsepower-rated. (Sec. 430.109.)

System isolation equipment—New in the 2005 **NEC** (and defined in 430.2), this concept uses a contactor on the load side of a motor circuit switch, circuit breaker, or molded case switch as a disconnecting means. Because contactors can be closed inadvertently, these devices must be listed and include means to redundantly monitor the contactor position. This equipment is designed for extremely large industrial applications, typically involving multiple personnel entry points to a piece of equipment and therefore making remote lockout provisions in a control circuit desirable.

Section 430.109(E) sets the maximum horsepower rating required for motor-circuit switches at 100 hp. Higher-rated switches are now available and will provide additional safety. The first sentence of this section makes a basic requirement that the disconnecting means for a motor and its controller be a motor-circuit switch rated in horsepower. For motors rated up to 500 hp, this is readily complied with, inasmuch as the UL lists motor-circuit switches up to 500 hp and the manufacturers mark switches to conform. But for motors rated over 100 hp, the Code does not require that the disconnect have a horsepower rating. It makes an exception to the basic rule and permits the use of an ampere-rated switch or isolation switch, provided the switch has a carrying capacity of at least 115 percent of the nameplate current rating of the motor [430.110(A)]. And UL notes that horsepower-rated switches over 100 hp *must not* be used as motor controllers. And part (E) notes that isolation switches for motors over 100 hp must be plainly marked “Do not operate under load,” if the switch is not rated for safely interrupting the locked-rotor current of the motor. [Figure 430-63](#) shows an example of disconnect switch application for a motor rated over 100 hp.

example Provide a disconnect for a 125-hp, 3-phase, 460-V motor. Use a nonfusible switch, inasmuch as short-circuit protection is provided at the supply end of the branch circuit.

The full-load running current of the motor is 156 A, from **NEC** Table 430.250. A suitable disconnect must have a continuous carrying capacity of 156×1.15 , or 179 A, as required by 430.110(A).

This calls for a 200-A, 3-pole switch rated for 480 V. The switch may be a general-use switch, a current- and horsepower-marked motor-circuit switch, or an isolation switch. A 200-A, 3-pole, 480-V motor-circuit switch would be marked with a rating of 50 hp, but the horsepower rating is of no concern in this application because the switch does not have to be horsepower-rated for motors larger than

100 hp.

If the 50-hp switch were of the heavy-duty type, it would have an interrupting rating of 10×65 A (the full-load current of a 460-V, 50-hp motor), or 650 A. But the locked-rotor current of the 125-hp motor might run over 900 A. In such a case, the switch is required by part (E) to be marked “Do not operate under load.”

If a fusible switch had to be provided for the example motor to provide both disconnect and short-circuit protection, the size of the switch would be determined by the size and type of fuses used. Using a fuse rating of 250 percent of motor current (which does not exceed the 300 percent maximum in Table 430.152) for standard fuses, the application would call for 400-A fuses in a 400-A switch. This switch would certainly qualify as the motor disconnect. However, if time-delay fuses are used, a 200-A switch would be large enough to take the time-delay fuses and could be used as the disconnect (because it is rated at 115 percent of motor current).

In the foregoing, the 400-A switch might have an interrupting rating high enough to handle the locked-rotor current of the motor. Or the 200-A switch might be of the CB-mechanism type or some other heavy current construction that has an interrupting rating up to 12 times the rated load current of the switch itself. In either of these cases, there would be no need for marking “Do not operate under load.”

Up to 100 hp, a switch that satisfies the Code on rating for use as a motor controller may also provide the required disconnect means—the two functions being performed by the one switch—provided it opens all ungrounded conductors to the motor, is protected by an overcurrent device (which may be the branch-circuit protection or may be fuses in the switch itself), and is a manually operated air-break switch or an oil switch not rated over 600 V or 100 A—as permitted by 430.111.

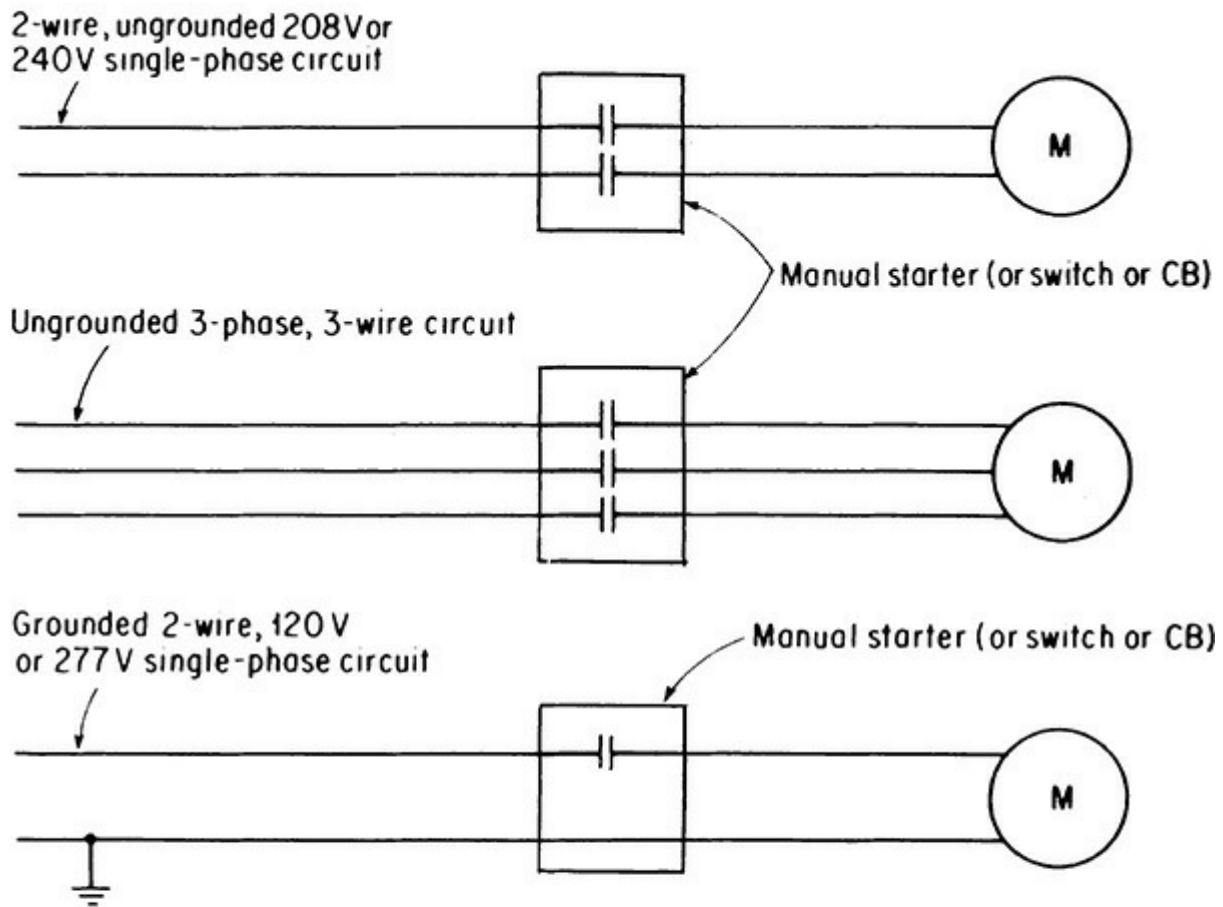

430.110. Ampere Rating and Interrupting Capacity. An ampere-rated switch or a CB must be rated at least equal to 115 percent of a motor’s full-load current if the switch or CB is the disconnect means for the motor.

When two or more motors are served by a single disconnect means, as permitted by 430.112, or where one or more motors plus a nonmotor load (such as electric heater load) make use of a single common disconnect, part (C) must be used in sizing the disconnect. Refer to the discussion at 430.87 for a worked-out example of the front half of this process, that of coming up with the equivalent horsepower rating. Now the second half of the calculation must be done, that is, determining the required ampere rating of the disconnect. This is the sum of the current ratings of the components, all multiplied by 1.15. In this case $62 \text{ A} \times 1.15 = 71 \text{ A}$. The combined disconnect must have a horsepower rating of 50 hp and the current rating must not be less than 71 A at the stated voltage of 460 V. If the disconnect is not rated in horsepower, such as a molded case switch, this ampere rating is sufficient.

430.111. Switch or Circuit Breaker as Both Controller and Disconnecting

Means. As described under 430.84, a manual switch—capable of starting and stopping a given motor, capable of interrupting the stalled-rotor current of the motor, and having the same horsepower rating as the motor—may serve the functions of controller and disconnecting means in many motor circuits, if the switch opens all ungrounded conductors to the motor. That is also true of a manual motor starter. A single manually operated CB may also serve as controller and disconnect (Figs. 430-64 and 430-65). However, in the case of an autotransformer type of controller, the controller itself, even if manual, may not also serve as the disconnecting means. Such controllers must be provided with a separate means for disconnecting controller and motor.

SINGLE DEVICE FOR CONTROL AND DISCONNECT

BUT, MAGNETIC STARTER REQUIRES SEPARATE DISCONNECT

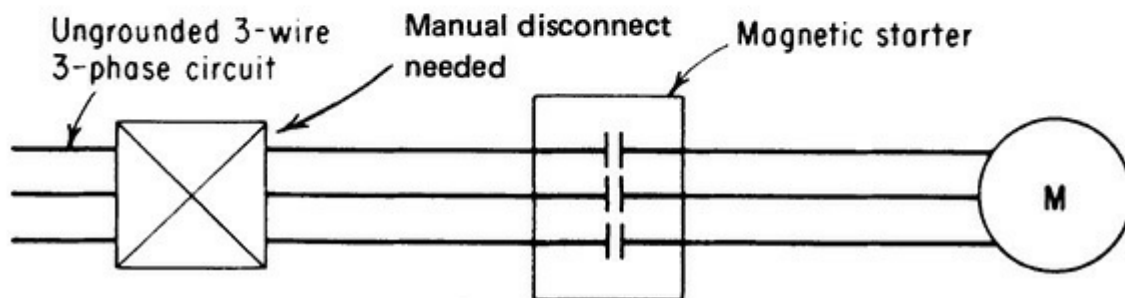

Fig. 430-64. A manual switch or CB may serve as both controller and disconnect means. (Sec. 430.111.)

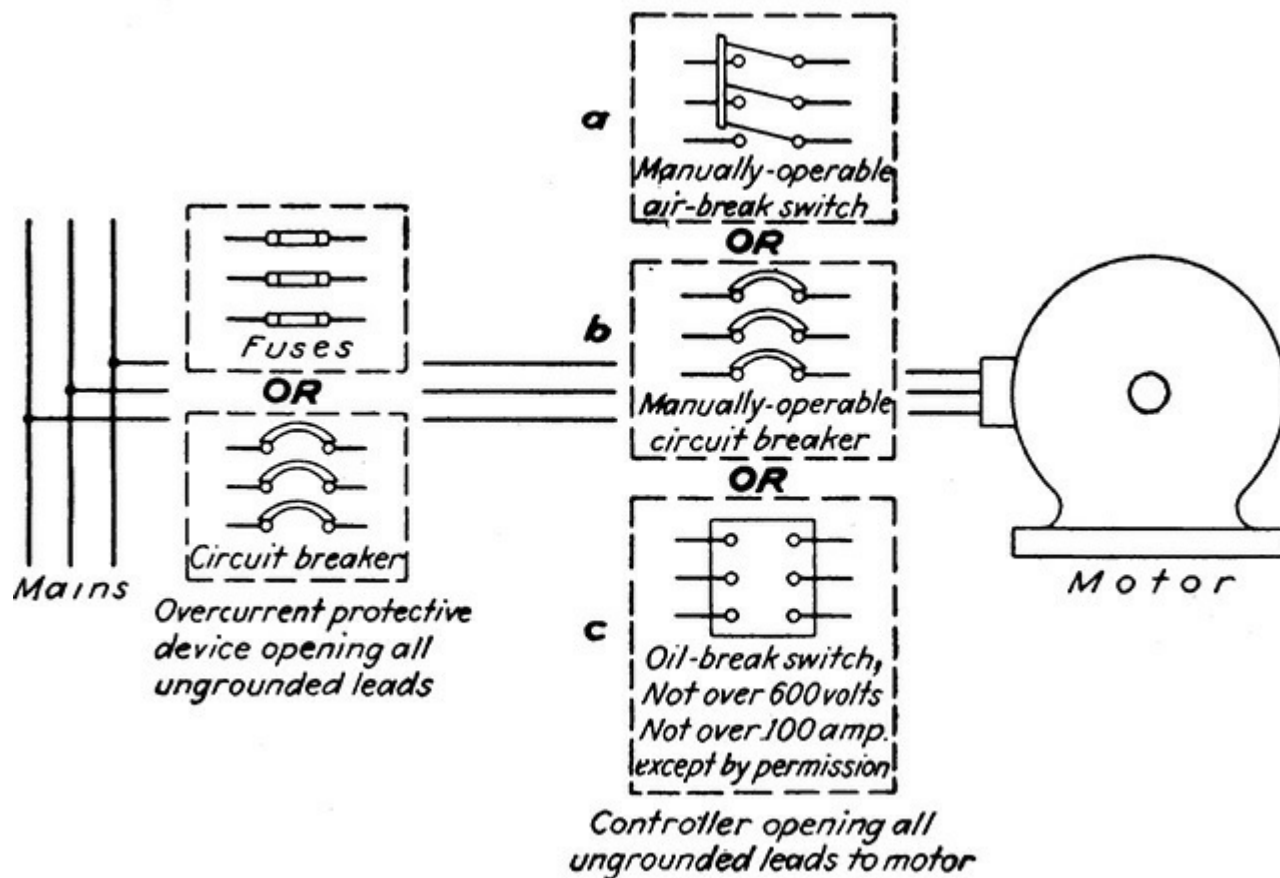

Fig. 430-65. Use of a single controller disconnect is limited. (Sec. 430.111.)

Although this Code section permits a single horsepower-rated switch to be used as both the controller and the disconnect means of a motor circuit, UL rules note that “enclosed switches rated higher than 100 hp are restricted to use as motor disconnecting means and are not for use as motor controllers.”

The acceptability of a single switch for both the controller and the disconnecting means is based on the single switch satisfying the Code requirements for a controller and for a disconnect. It finds application where general-use switches or horsepower-rated switches are used, as permitted by the Code, in conjunction with time-delay fuses that are rated low enough to provide both running overload protection and branch-circuit (short-circuit) protection. In such cases, a single fused switch may serve a total of four functions: (1) controller, (2) disconnect, (3) branch-circuit protection, and (4) running overload protection. And it is possible for a single CB to also serve these four functions.

For sealed refrigeration compressors, 440.12 gives the procedure for determining the disconnect rating, based on nameplate rated-load current or branch-circuit selection current, whichever is greater, and locked-rotor current of the motor-compressor.

430.112. Motors Served by Single Disconnecting Means. In general, each individual motor must be provided with a separate disconnecting means. However, a single disconnect sometimes may serve a group of motors under the conditions specified, which are the same as in 430.87. Such a disconnect must have a rating sufficient to handle a single load equal to the sum of the horsepower ratings or current ratings.

Exception A

In 610.32 it is required that the main collector wires of a traveling crane shall be controlled by a

switch located within view of the wires and readily operable from the floor or ground. This switch would serve as the disconnecting means for the motors on the crane. When repair or maintenance work is to be done on the electrical equipment of the crane, it is safer to cut off the current from all this equipment by opening one switch, rather than to use a separate switch for each motor. Also, in the case of a machine tool driven by two or more motors, a single disconnecting means for the group of motors is more serviceable than an individual switch for each motor, because repair and maintenance work can be done with greater safety when the entire electrical equipment is “dead.”

Exception B

Such groups may consist of motors having full-load currents not exceeding 6 A each, with circuit fuses not exceeding 20 A at 125 V or less, or 15 A at 600 V or less. Because the expense of providing an individual disconnecting means for each motor is not always warranted for motors of such small size, and also because the entire group of small motors could probably be shut down for servicing without causing inconvenience, a single disconnecting means for the entire group is permitted.

Exception C

“Within sight” should be interpreted as meaning so located that there will always be an unobstructed view of the disconnecting switch from the motor, and Sec. 430.102 limits the distance in this case between the disconnecting means and any motor to a maximum of 50 ft.

These conditions are the same as those under which the use of a single controller is permitted for a group of motors. (See 430.87.) The use of a single disconnecting means for two or more motors is quite common, but in the majority of cases the most practicable arrangement is to provide an individual controller for each motor.

If a switch is used as the disconnecting means, it must be of the type and rating required by 430.109 for a single motor having a horsepower rating equal to the sum of the horsepower ratings of all the motors it controls. Thus, for six 5-hp motors the disconnecting means should be a motor-circuit switch rated at not less than 30 hp. If the total of the horsepower ratings is over 2 hp, a horsepower-rated switch must be used.

430.113. Energy from More than One Source. The basic rule of this section, which is similar to that of 430.74, requires a disconnecting means to be provided from each source of electrical energy input to equipment with more than one circuit supplying power to it, such as the hookup shown in [Fig. 430-66](#), where two switches or a single 5-pole switch could be used. And each source is permitted to have a separate disconnecting means. This Code rule is aimed at the need for adequate disconnects for safety in complex industrial layouts. But an exception to the Code rule states that where a motor receives electrical energy from more than one source (such as a synchronous motor receiving both alternating current and direct current energy input), the disconnecting means for the main power supply to the motor shall *not* be required to be immediately adjacent to the motor—provided that the controller disconnecting means, which is the disconnect ahead of the motor starter in the main power circuit, is capable of being locked in the open position. If, for instance, the motor control disconnect can be locked in the open position, it may be remote; but the disconnect for the other energy input circuit would have to be adjacent to the machine itself, as indicated in [Fig. 430-67](#).

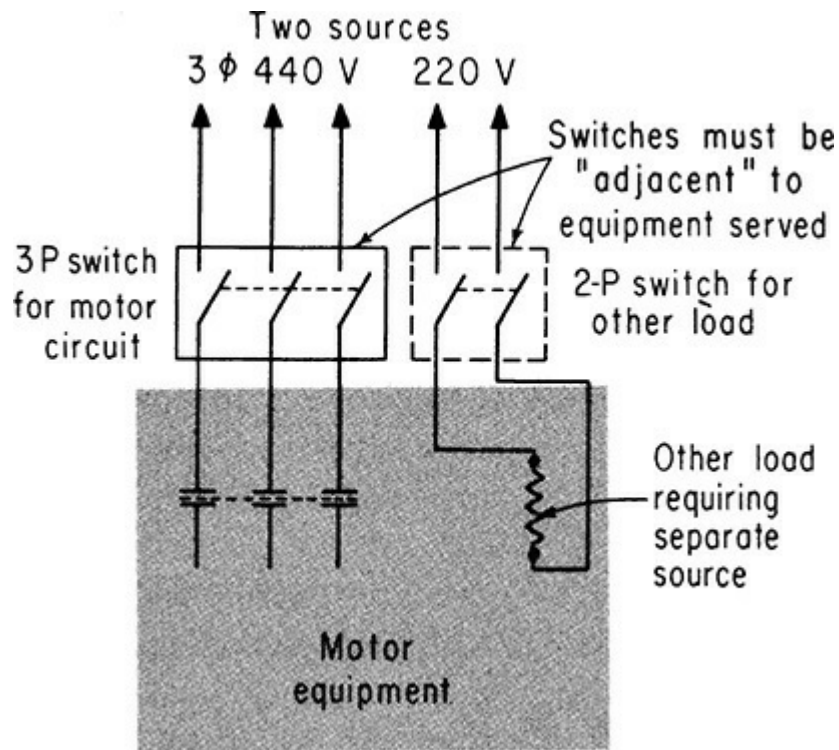

Fig. 430-66. A disconnect must be used for each power input to motorized equipment. (Sec. 430.113.)

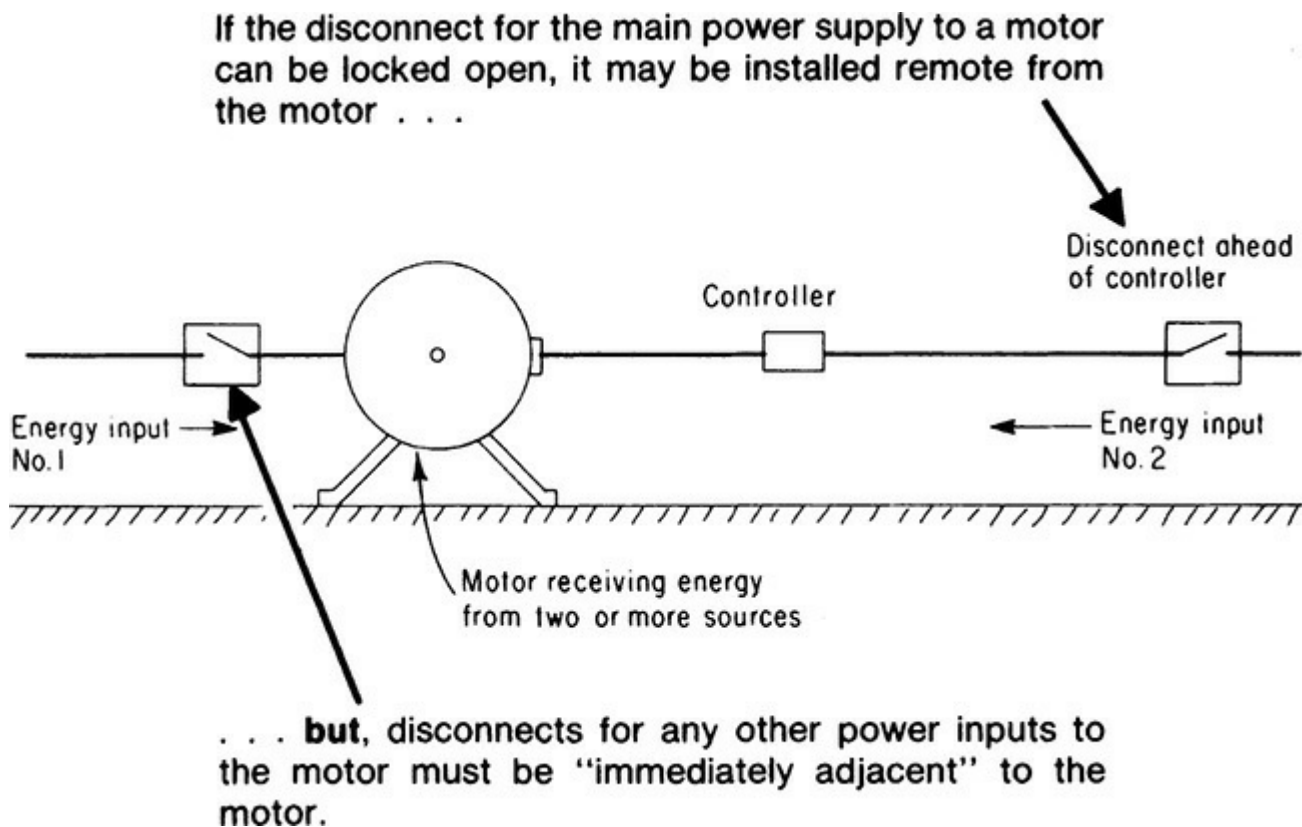

Fig. 430-67. An exception is made for disconnects for multiple power sources. (Sec. 430.113.)

430.122. Conductors—Minimum Size and Ampacity. The majority of motors going into industrial and commercial occupancies are going in with adjustable speed drives for both customization of output and energy efficiency. The incoming branch circuit or feeder to power conversion equipment included as part of an adjustable-speed drive system must be based on the

rated input to the power conversion equipment, and is to be taken at 125 percent of that value. If the drive has a bypass mechanism that allows the motor to run directly across the line, the conductors must meet the larger of two calculations, one being 125 percent of the input rating to the drive, and the other being 125 percent of the 430.6 determined rating (usually, therefore, the Table 430.250 rating), as applicable.

430.126. Motor Overtemperature Protection. Adjustable speed drive systems must be capable of detecting overheated motors that are in that condition not because of excessive load resulting in additional current draw, but for other reasons. Traditional methods that monitor current will protect the circuit conductors from overload, but not the motor if it is drawing its nameplate current but operating below its rated speed because of factors involved with the application, because a low speed may not produce enough ventilation or coolant circulation, etc. A thermal protector (see 430.32) may be required in addition to the drive programming. This section is followed by an extensive informational note calling attention to the problem and offering suggestions as to causes and remedies.

430.128. Disconnecting Means. This rule (Fig. 430-68) merely permits a disconnect in the incoming line, but makes no distance or in-sight requirement. Frequently adjustable speed drives meet the definition of a controller in 430.2; they routinely start and stop the motor by making and breaking the power circuit, as well as changing its frequency for speed regulation purposes. The question then arises as to whether 430.102(A) applies to such a drive, requiring an in-sight disconnect. Many smaller drives are located in areas where a local disconnect might not be desired and would qualify for omission under 430.102(B) Exception. However, that exception applies only to the local motor disconnect and not to a controller disconnect. The vagueness of the disconnect rule in this part of the article has been used to justify the omission of local drive disconnects, with the understanding that a locking disconnect could be arranged at some point upstream, just not in sight of the remote drive.

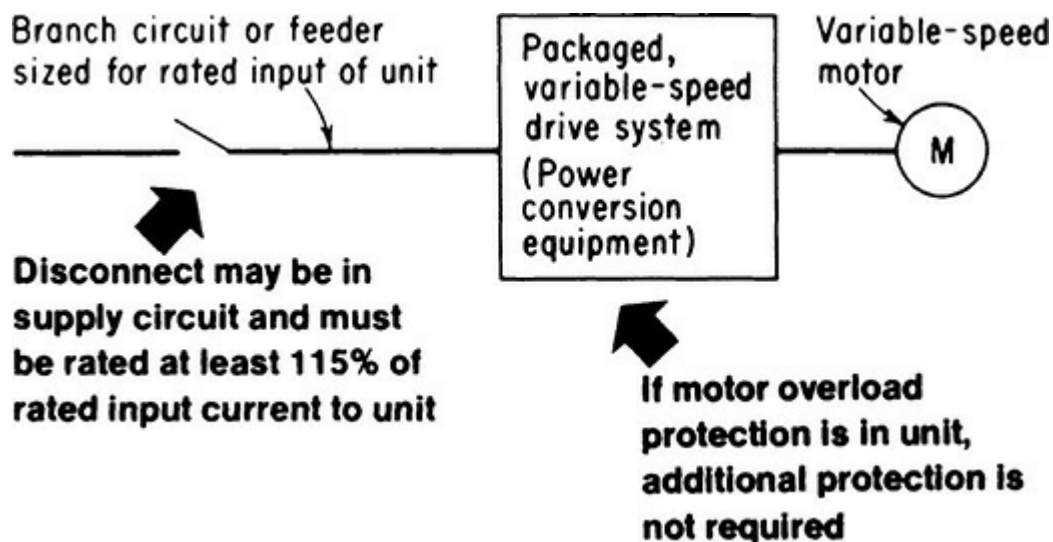

Fig. 430-68. Circuit to packaged drive systems is sized for rating of unit, essentially considering the drive to be as a motor. (Art. 430 Part X.)

The conservative response is to apply 430.102(A) to the remote drive without variance, since this rule is vague and not violated in any way by such an interpretation. This approach also agrees with the general statement in 430.120 that Parts I through IX of the article are applicable unless modified, and no modifications to disconnect locations have been made in this part of the article. Further, an

attempt to relax this rule failed in the 2014 **NEC** cycle.

430.130. Branch-Circuit Short-Circuit and Ground-Fault Protection for Single Motor Circuits Containing Power Conversion Equipment. This section is new as of the 2014 **NEC** and establishes unambiguous requirements for sizing this equipment. The first step is to bring the actual full-load current rating of the motor “as determined by 430.6” (which means the usual table approach by horsepower and voltage) into either 430.52(C)(1) (i.e., using Table 430.52) or (C)(3) (i.e., instantaneous trip circuit breakers) or (C)(5) (i.e., semiconductor fuses). Although (C)(6) (i.e., self-protected combination controller) is also listed, note that this is only permitted where it has been specifically identified by the power conversion equipment manufacturer. The final step, similar to that involved with 430.52(C)(2), is to review the manufacturers’ instructions or equipment markings, because those cannot be exceeded even if the default calculations permitted in 430.52 would otherwise indicate a higher setting would be acceptable.

If the power conversion equipment includes a bypass contactor or similar circuiting, the bypass device must also be protected against faults based on the normally applicable rules in 430.52 for the type of control. However, in the frequent case where the fault protection protects both the bypass and the normal power conversion equipment, then that protection must be selected and arranged so both circuits are protected in accordance with relevant Code provisions.

The 2017 **NEC** added another provision intended to further curb the practice of field selection of certain overcurrent devices that are intended to be solely within the province of the manufacturer and testing laboratories. 430.52(C)(3) on instantaneous-trip circuit breakers and 430.52(C)(5) on semiconductor fuses have very strict limitations that preclude field selection decisions. These rules should apply here anyway, and now there is a fourth condition spelling this out. These devices are to be provided as an integral part of a single listed assembly. Review also [Fig. 430-21](#) and the associated coverage for more information.

430.131. Several Motors or Loads on One Branch Circuit Including Power Conversion Equipment. If power conversion equipment is connected ahead of multiple motors, the rules in 430.53 continue to apply based on the full-load current rating of the connected motor load. Any applicable limits on the style of circuit protection permitted for the power conversion equipment will apply as well, and the final selection must be made accordingly. In this case the power conversion equipment is formally declared to be a motor controller, and the rules for the in-sight disconnecting means in 430.102(A) will apply.

430.224. Size of Conductors. For motors rated over 1000 V, the circuit conductors to the motor are selected to have a current rating equal to or greater than the trip setting of the running overload protective device for the motor.

430.225. Motor Circuit Overcurrent Protection. Overload protection must protect the motor and other circuit components against overload currents up to and including locked-rotor current of the motor. A CB or fuses must be used for protection against ground faults or short circuits in the motor circuit. Because there are no prescriptive settings in the Code for these motors, these protective device settings must be evaluated for each motor circuit under engineering supervision.

430.242. Stationary Motors. Usually, stationary motors are supplied by wiring in a metal raceway or metal-clad cable. The motor frames of such motors must be grounded, the raceway or cable armor being attached to the frame and serving as the grounding conductor. (See 250.118.)

Any motor in a wet location constitutes a serious hazard to persons and should be grounded unless

it is so located or guarded that it is out of reach. *All* water pump motors, including those in the submersible-type pump, must be grounded, regardless of location, to comply with 250.112(L).

430.245. Method of Grounding. Good practice requires in nearly all cases that the wiring to motors that are not portable shall, at the motor, be installed in rigid or flexible metal conduit, electrical metallic tubing, or metal-clad cable and that such motors should be equipped with terminal housings. The method of connecting the conduit to the motor where some flexibility is necessary is shown in Fig. 430-69. The motor circuit is installed in rigid conduit and a short length of liquidtight flexible metal conduit is provided between the end of the rigid conduit and the terminal housing on the motor. But because the size of flex is over metric designator 35 (trade size 1¼), a separate equipment grounding conductor (or bonding jumper) must be used within or outside the flex as noted in 350.60 and 250.118. Refer to 430.12(E), which requires provision of a suitable termination for an equipment grounding conductor at every motor terminal housing, as shown in Fig. 430-70.

Fig. 430-69. Liquidtight flex provides flexible connection from rigid conduit supply to motor terminals but does require a separate equipment grounding conductor run within the flex with the circuit conductors or a separate external bonding jumper from the rigid metal conduit to the metal terminal box for each of the two runs. (Sec. 430.245.)

Fig. 430-70. Motor terminal housings must include some lug or terminal for connecting an equipment grounding conductor that may be run inside the raceway with the circuit wires or may be run as a bonding jumper around a length of flex or liquidtight flex, as commonly used for vibration-free motor connections. The terminal box here must have internal provision for connecting the equipment grounding conductor, required for this short length of liquidtight flex, that is larger than metric designator 35 (trade size $1\frac{1}{4}$) in size. The static grounding connection shown here (arrow) on the box does not satisfy 350.60 and 250.102(E) as a bonding jumper for the flex, and it does not satisfy 250.134 as an equipment ground for an ac motor. (Sec. 430.245.)

This section permits the use of fixed motors without terminal housings. If a motor has no terminal housing, the branch-circuit conductors must be brought to a junction box not over 6 ft (1.8 m) from the motor. Between the junction box and the motor, the specified provisions apply.

According to 300.16, the conduit, tubing, or metal-clad cable must terminate close to the motor in a fitting having a separable bushed hole for each wire. The method of making the connection to the motor is not specified; presumably, it is the intention that the wire brought out from the terminal fitting shall be connected to binding posts on the motor or spliced to the motor leads. The conduit, tubing, or cable must be rigidly secured to the frame of the motor.

Table 430-251(B). This is the locked-rotor table that is necessary to determine equivalent horsepower ratings and other activities. It does not apply to Design A motors, which are not covered in this table and not limited to its provision; the manufacturer would need to be consulted in such

cases.

ARTICLE 440. AIR-CONDITIONING AND REFRIGERATING EQUIPMENT

440.2. Definitions. The first definition for “Branch-Circuit Selection Current” is extremely important because of the differences between it and the last definition, covering “rated-load current.” The latter corresponds to full-load current in many other places. The former includes the effects of the degree of sustained overload that the unit is capable of under defined test conditions. It always at least equals, and usually exceeds the rated-load current. The definition is critical because, where given, it becomes the number upon which the other size or ratings of elements of the circuit are determined, including conductors, overcurrent protective devices, and disconnects.

The third definition, “Leakage Current Detection and Interruption,” describes a device capable of detecting and interrupting current flow “from the cord conductor,” such as where a ground fault has occurred, and “between” the “cord conductors,” such as where the device is unintentionally submerged. This definition ties into the rule of 440.65, which mandates such protective devices for all single-phase (generally, 120- or 220-V) cord-and-plug-connected room air conditioners. Although this is a manufacturer’s concern, designers and installers must ensure that any such cord-and-plug-connected room air conditioners are factory equipped with a leakage current detector and interrupter (LCDI) or an arc-fault circuit interrupter (AFCI).

440.3. Other Articles. Article 440 is patterned after Art. 430, and many of its rules, such as on disconnecting means, controllers, conductor sizes, and group installations, are identical or quite similar to those in Art. 430. This article contains provisions for such motor-driven equipment and for branch circuits and controllers for the equipment, taking into account the special considerations involved with sealed (hermetic-type) motor-compressors, in which the motor operates under the cooling effect of the refrigeration.

It must be noted that the rules of Art. 440 are *in addition to* or are *amendments to* the rules given in Art. 430 for motors in general. The basic rules of Art. 430 also apply to A/C (air-conditioning) and refrigerating equipment unless exceptions are indicated in Art. 440.

Article 440 further clarifies the application of **NEC** rules to air-conditioning equipment and refrigeration equipment as follows:

1. A/C and refrigerating equipment that does not incorporate a sealed (hermetic-type) motor-compressor must satisfy the rules of Art. 422 (Appliances), Art. 424 (Space Heating Equipment), or Art. 430 (Conventional Motors)—whichever apply. For instance, where refrigeration compressors are driven by conventional motors, the motors and controls are subject to Art. 430, not Art. 440. Furnaces with air-conditioning evaporator coils installed must satisfy Art. 424. Other equipment in which the motor is not a sealed compressor and which must be covered by Arts. 422, 424, or 430 includes fan-coil units, remote forced-air-cooled condensers, remote commercial refrigerators, and similar equipment.
2. Room air conditioners are covered in Part **VII** of Art. 440 (440.60 through 440.64), but must also comply with the rules of Art. 422.
3. Household refrigerators and freezers, drinking-water coolers, and beverage dispensers are considered by the Code to be appliances, and their application must comply with Art. 422 and must also satisfy Art. 440, because such devices contain sealed motor-compressors.

Air-conditioning equipment (other than small room units and large custom installations) is

manufactured in the form of packaged units having all necessary components mounted in one or more enclosures designed for floor mounting, for recessing into walls, for mounting in attics or ceiling plenums, for locating outdoors, and so forth. Figure 440-1 shows the difference between room A/C units (such as window units) and the larger so-called packaged units or central air conditioners. Room units consist of a complete refrigeration system in a unit enclosure intended for mounting in windows or in the wall of the building, with ratings up to 250 V, single phase. Unitary assemblies may be console type for individual room use, rated up to 250 V, single phase, or central cooling units rated up to 600 V for commercial or domestic applications. This type may consist of one or more factory-made sections. If it is made up of two or more sections, each section is designed for field interconnection with one or more matched sections to make the complete assembly. Dual-section systems consist of separate packaged sections installed remote from each other and interconnected by refrigerant tubing, with the compressor either within the outdoor section or within the indoor section.

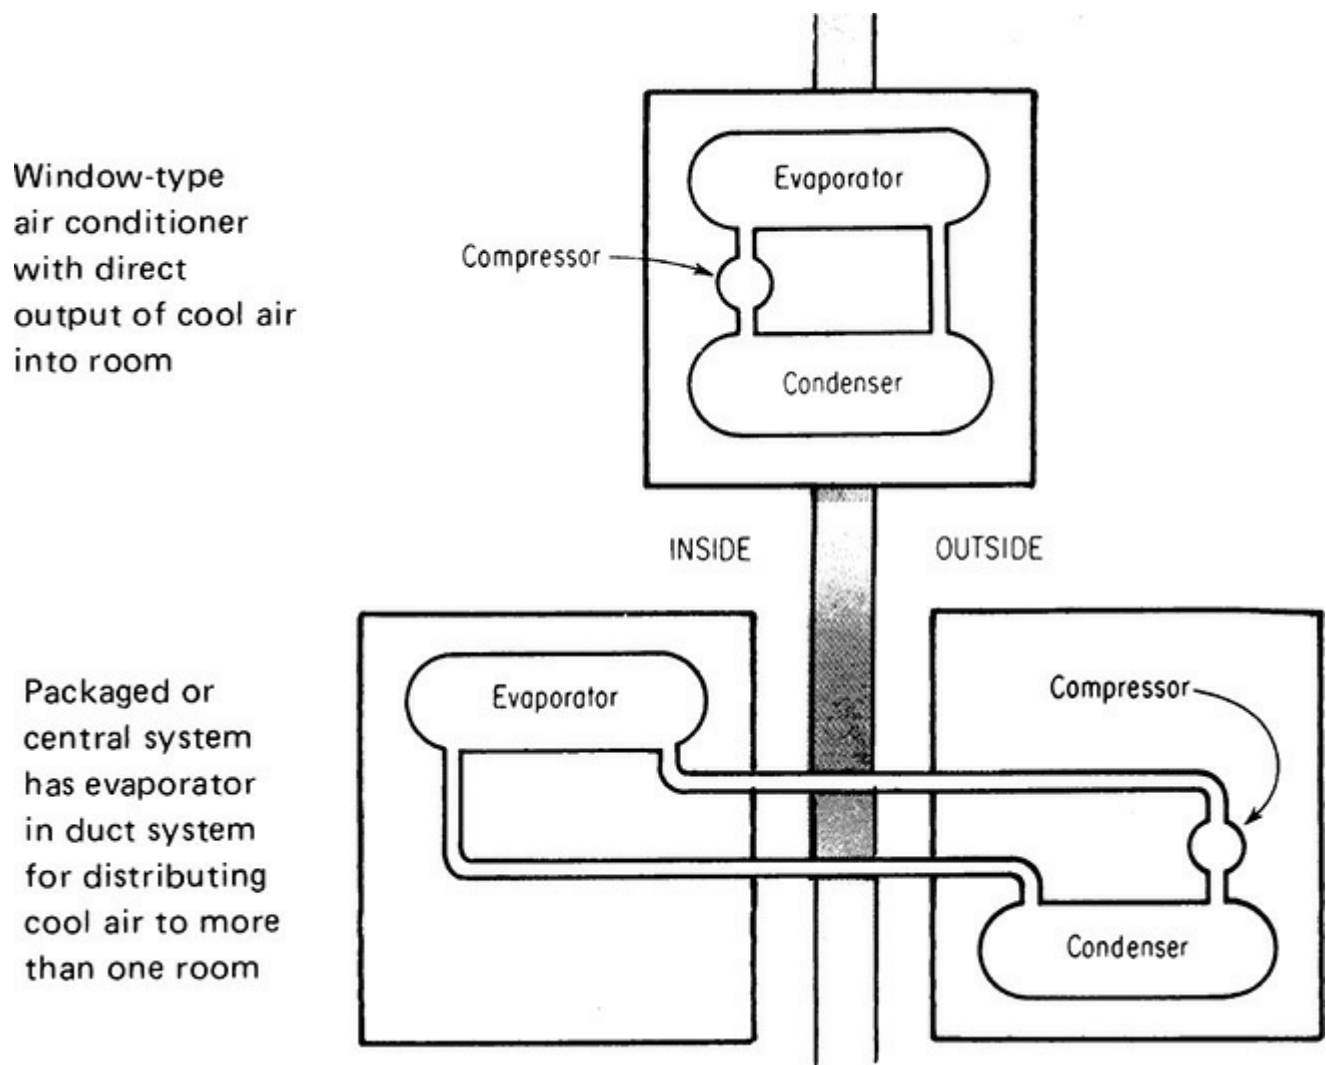

Fig. 440-1. Code rules differentiate between unit room conditioners and central systems. (Sec. 440.3.)

Electrical wiring in and to units varies with the manufacturer, and the extent to which the electrical contractor need be concerned with fuse and CB calculations depends on the manner in which the units' motors are fed and the type of distribution system to which they are to be connected. A packaged unit is treated as a group of motors. This is different from the approach used with a plug-in room air conditioner, which is treated as an individual single-motor load of amp rating as marked on

the nameplate.

A variation on this topic frequently arises with respect to whether the disconnect rule in 440.14 applies to a fan-forced heat exchange coil that is powered by the branch circuit serving the compressor, from the load side of a fully compliant, lock-open disconnect at the compressor. Specifically, since the coil fan is associated with the compressor, some inspectors have insisted on a full-fledged disconnect at the inside unit. Such a ruling ignores the content of this part [440.3(B)]. The issue of disconnects for internal heat exchange equipment that does not contain a hermetic refrigerant motor-compressor is entirely beyond the scope of Art. 440. In addition, 440.3(B) contains express language that sends the user into Art. 430 for this coverage, language that is unchanged since the 1971 NEC when this article first appeared. Article 440 contains the necessary special rules for motors that are deliberately operated in what would normally be an overloaded state, but that can function closer to the edge only because the windings are submerged in refrigerant. For example, this is why the default short-circuit protection in 440.22(A) is set at 175 percent instead of the higher values in 430.52(C) for conventional motors. Other motors need only follow requirements in Art. 430 and elsewhere in the Code. And 430.109(B), which governs this topic, allows the branch-circuit device to serve as the disconnect for motors not over $\frac{1}{8}$ hp. A full disconnect cluttering the wall of living space for a little fan motor is usually excessive.

440.4. Marking on Hermetic Refrigerant Motor-Compressors and Equipment.

Important in the application of hermetic refrigerant motor-compressors are the terms *rated-load current* and *branch-circuit selection current*. As previously noted, definitions of these terms are given in 440.2. When the equipment is marked with the branch-circuit selection current, this greatly simplifies the sizing of motor branch-circuit conductors, disconnecting means, controllers, and overcurrent devices for circuit conductors and motors.

For some A/C equipment that is not required to have a branch-circuit selection current, the value of rated-load current will appear on the equipment nameplate; and that same value of current will also appear in the nameplate space reserved for branch-circuit selection current. In such cases, the branch-circuit selection current is to be equal to the rated-load current. The short-circuit current rating of either the motor controllers or the industrial control panel in which they are components must also be marked, so the ability of these components to function within the context of the fault current that is available at the point of application can be determined.

440.5. Marking on Controllers. Note that a controller may be marked with “full-load and locked-rotor current (or horsepower) rating.” That possibility of two methods of marking requires careful application of the rules in 440.41 on selecting the correct rating of controller for motor-compressors.

440.6. Ampacity and Rating. Selection of the rating of branch-circuit conductors, controller, disconnect means, short-circuit (and ground-fault) protection, and running overload protection is *not* made the same for hermetic motor-compressors as for general-purpose motors. In sizing those components, the rated-load current marked on the equipment and/or the compressor must be used in the calculations covered in other rules of this article. That value of current must always be used, instead of full-load currents from Code Tables 430.248 to 430.250, which are used for sizing circuit elements for nonhermetic motors. And if a branch-circuit selection current is marked on equipment, that value must be used instead of rated-load current.

440.8. Single Machine. Even for split systems that have the compressor located remote from

the associated fans to distribute conditioned air, the system is to be classified as a single machine, and therefore permitted to have a single controller under the provisions of part (a) of 430.87 Exception No. 1. The components are also permitted to operate under a single disconnect in accordance with part (a) of 430.112 Exception. For calculating required conductor ampacity of multimotor equipment, the provisions of 440.6(B) cover fan or blower components, and 440.7 covers the determination of which motor is to be taken as the largest. However, the mandatory exception to 440.7 again reverts the calculation to the branch-circuit selection current in all cases where one has been established and marked.

440.9. Grounding and Bonding. The 2017 **NEC** decided to disqualify metal raceways for Art. 440 wiring on a rooftop as an equipment grounding return conductor, unless they had been assembled with threaded couplings and connectors. Primarily aimed at EMT, the panel responded to substantial documentation that conventional set-screw and compression fittings were allowing the raceway joints to open over time. EMT can still be used, but a wire-type equipment grounding conductor must be pulled into it so the steel does not constitute the sole ground return path.

440.10. Short-Circuit Rating. This new 2017 **NEC** requires that an available short-circuit current analysis be done to establish the fault current available at multimotor and combination load equipment locations as part of the installation process. The calculation requirement applies in instances when the equipment is required to be marked with that rating. This means that it will not be required in one- and two-family dwellings, and to comparatively small circuits (not over 60 amps.) as covered in 440.4(B) Exception No. 3. In other instances it will be required, and part (B) of the new rule requires that the calculated result be documented, including the date of the calculation, and made available to the inspector. Note that this calculation must be made, documented, and provided to the inspector, but not provided on a label on the equipment. This fundamentally differs from similar calculations made under 110.16(B). The existence of a label may be misconstrued by future workers having present-day accuracy. Periodic utility activities can easily affect any such calculations, and current conditions must always be re-evaluated prior to work.

440.12. Rating and Interrupting Capacity. Note that the rules here are qualifications that apply to the rules of 430.109 and 430.110 on disconnects for general-purpose motors.

A disconnecting means for a hermetic motor, as covered in part **(A)(2)**, must be a motor-circuit switch rated in horsepower or a CB—as required by 430.109.

If a CB is used, it must have an amp rating not less than 115 percent of the nameplate rated-load current or the branch-circuit selection current—whichever is greater.

But, if a horsepower-rated switch is to be selected, the process is slightly involved for hermetic motors marked with locked-rotor current and rated-load current or rated-load current plus branch-circuit selection current—but *not* marked with horsepower. In such a case, determination of the equivalent horsepower rating of the hermetic motor must be made using the locked-rotor current and either the rated-load current or the branch-circuit selection current—whichever is greater—based on Code Tables 430.248, 430.249, or 430.250 for rated-load current or branch-circuit selection current and Table 430.251(B) for locked-rotor current, as follows:

For example, a 3-phase, 460-V hermetic motor rated at 11-A branch-circuit selection and 60-A locked-rotor is to be supplied with a disconnect switch rated in horsepower. The first step in determining the equivalent horsepower rating of that motor is to refer to Code Table 430.250. This table lists 7½ hp as the required size for a 460-V, 11-A motor. To ensure adequate interrupting capacity, Code Table 430.251(B) is used. For a 60-A locked-rotor current, this table also shows 7½

hp as the equivalent horsepower rating for any locked-rotor current over 45 to 66 A for a 400-V motor. Use of both tables in this manner thus establishes a 7½ hp disconnect as adequate for the given motor in both respects. Had the two ratings as obtained from the two tables been different, the higher rating would have been chosen.

Figure 440-2 shows an example of disconnect sizing for a horsepower-rated switch when a hermetic motor is used, in accordance with 430.53(C) and (D), along with fan motors on a single circuit, as covered in part (B) and in 440.34. Fan motors are usually wired to start slightly ahead of the compressor motor through use of interlock contacts or a time-delay relay. In some units, however, all motors start simultaneously, and that is covered by part (B) of this section in sizing the horsepower-rated disconnect switch. Where this is the case, the starting load will be treated like a single motor to the disconnect switch, and the sum of the locked-rotor currents of all motors should be used with Code Table 430.251(B) to determine the horsepower rating of the disconnect. The disconnect normally must handle the sum of the rated-load or branch-circuit selection currents; hence the rating as checked against Code Table 430.250 will be on the basis of the sum of the higher of those currents for all the motors. Code Table 430.250, using the full-load total of 38 A (6.0 A + 26 A + 6.0 A) in this example, indicates a 15-hp disconnect. Code Table 430.251(B), assuming simultaneous starting of all three motors and using the total locked-rotor current of 230 A (40 A + 150 A + 40 A), also shows 15 hp as the required size.

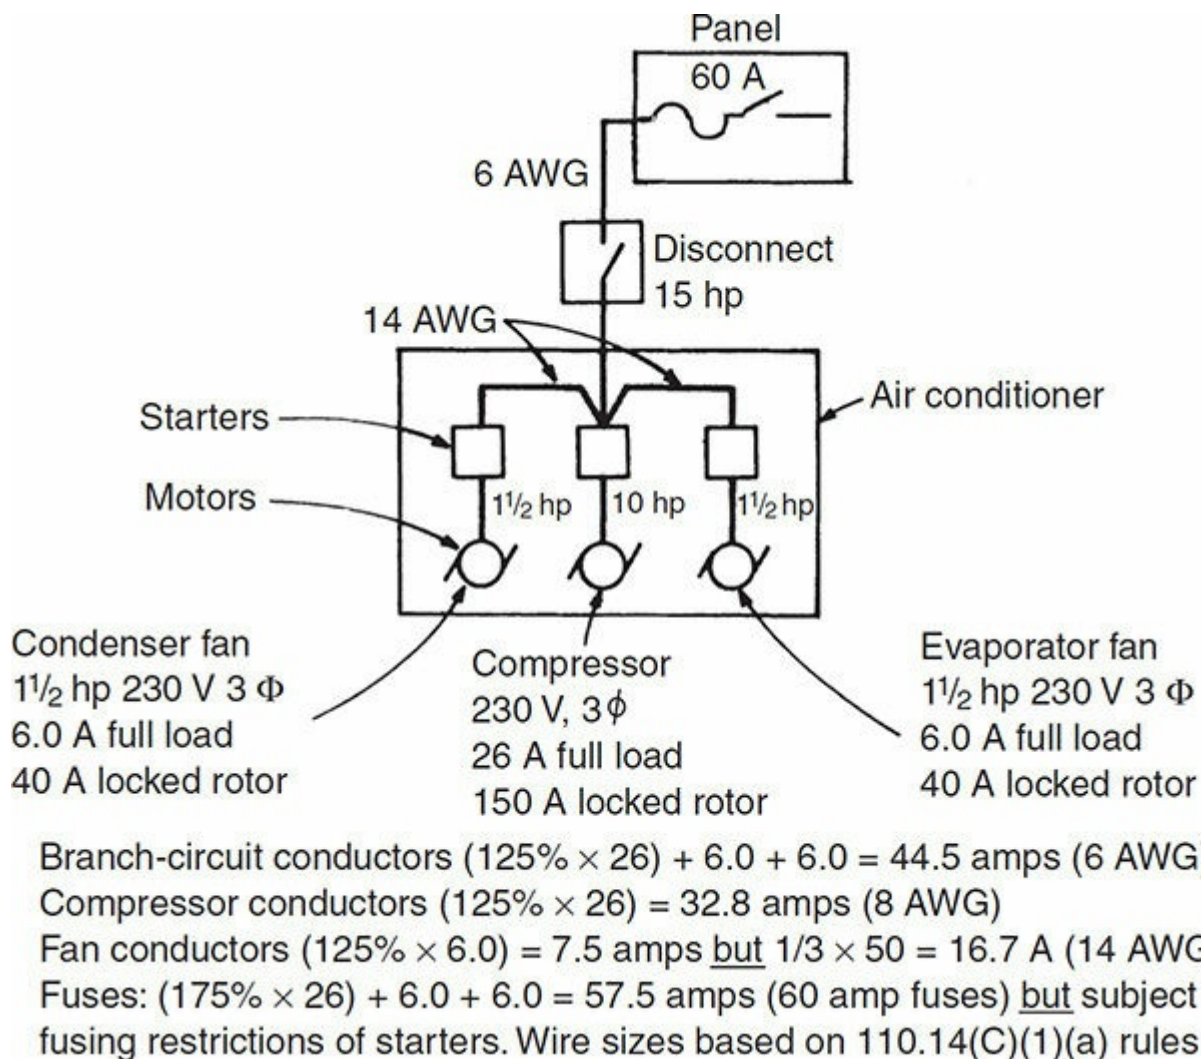

Fig. 440-2. Disconnect for multiple motors is sized from rated-load or branch-circuit selection currents and locked-rotor currents. (Sec. 440.12.)

If motors do not start simultaneously, the compressor locked-rotor current (150 A) used with Code Table 430.251(B) gives a 10-hp rating. However, the higher of the two horsepower ratings must be used; hence, the running currents impose the more severe requirements and dictate use of a 15-hp switch. See data under 440.22.

As required by part (D) of this section, all disconnects in a branch circuit to a refrigerant motor-compressor must have the required amp or horsepower rating and interrupting rating. This provides for motor-compressor circuits the same conditions that 430.108 requires for other motor branch circuits.

440.14. Location. 440.13 recognizes use of a cord-plug and receptacle as the disconnect for such cord-connected equipment as a room or window air conditioner. But this section (440.14) applies to fixed-wired equipment—such as central systems or units with fixed circuit connection. For conditioners with fixed wiring connection to their supply circuits, the rule poses a problem. If the branch-circuit breaker or switch which is to provide disconnect means is located in a panel that is out of sight (or more than 50 ft [15.0 m] away) from the unit conditioner, another breaker or switch must be provided at the equipment. If the panel breaker or switch does not satisfy the rule here, a separate disconnect means would have to be added in sight from the conditioner, as shown in Fig. 440-3. This is also true if the service switch is installed as shown in Fig. 440-4.

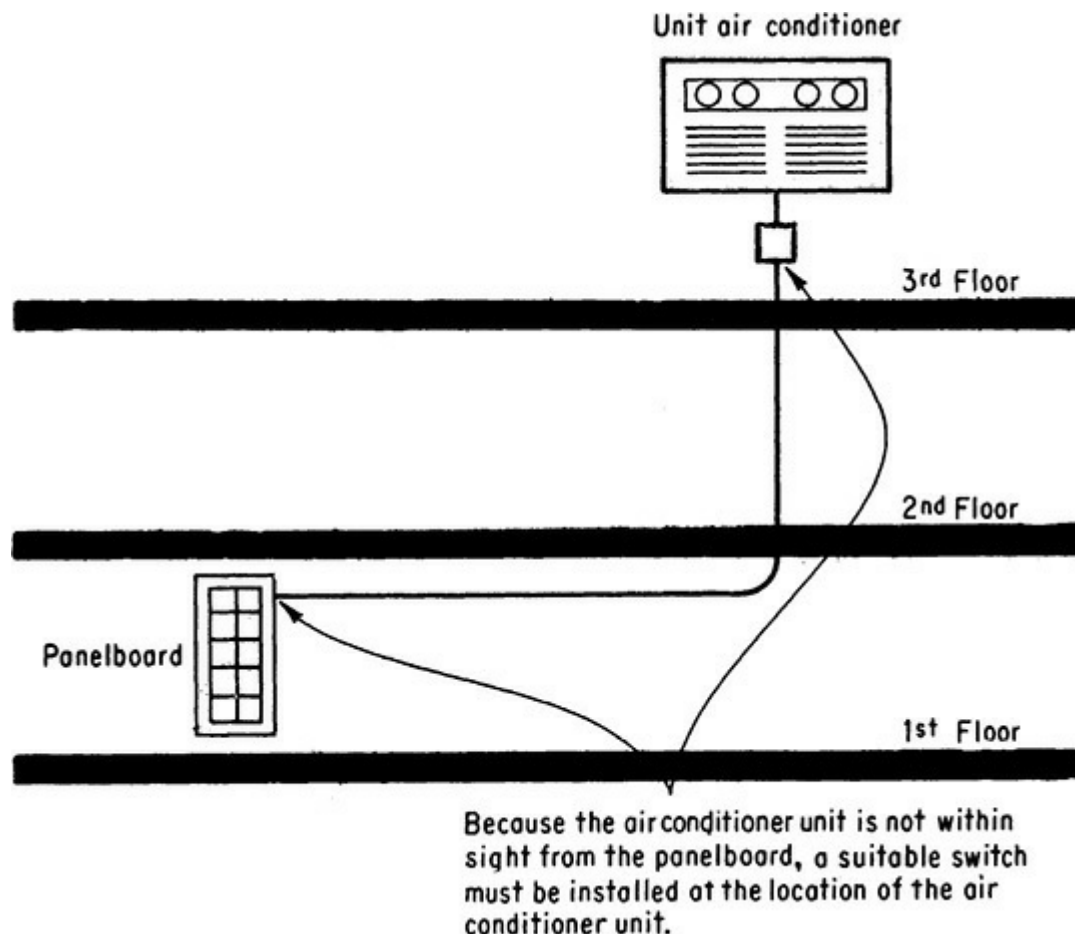

Fig. 440-3. For any fixed-wire A/C equipment, disconnect must be “within sight.” (Sec. 440.14.)

Answer: In cases of this layout, inspectors usually state that the branch switch or breaker in the panel is not really in sight of the controller. A separate disconnect is required outside adjacent to the motor controller. Of course, a combination motor starter would completely satisfy the Code if installed in place of the motor controller shown.

Fig. 440-4. “Within sight” disconnect must also be “readily accessible” at the equipment. (Sec. 440.14.)

As stated in the second sentence, the required disconnect means for air-conditioning or refrigeration equipment may be installed on or within the equipment enclosure; however, it must not be mounted in a way that obstructs the removal of service panels or the visibility of nameplates. If suitably located on the unit, the location is recognized as an equivalent of the basic rule that the disconnect must be readily accessible and within sight (visible and not over 50 ft [15.0 m] away) from the A/C or refrigeration equipment. Such equipment is being manufactured now with the disconnect incorporated as part of the assembly.

440.21. General. Part III of this article covers details of branch-circuit makeup for A/C and refrigeration equipment; 440.3(A) says that the provisions of Art. 430 apply to A/C and refrigeration equipment for any considerations that are not covered in Art. 440. Thus, because Art. 440 does *not* cover feeder sizing and feeder overcurrent protection for A/C and refrigeration equipment, it is necessary to use applicable sections from Art. 430. 430.24 covers sizing of feeder conductors for standard motor loads and for A/C and refrigeration loads. 430.62 and 430.63 cover rating of overcurrent protection for feeders to both standard motors and A/C and refrigeration equipment. That fact is noted in the language at the end of the first paragraph of 430.62(A).

440.22. Application and Selection. Part (A) of this section is illustrated in Fig. 440-5, where a separate circuit is run to the compressor and to each fan motor of a packaged assembly, containing a compressor with 26-A rated-load current and fan motors rated at 6.0-A full load each. The compressor protection is sized at 1.75×26 A (175 percent of rated-load current), or 45.5 A—calling for 45-A fuses, maximum. Note carefully that the wording of this rule makes it a “not to exceed” or “round down” rule. Hermetic compressor windings sit in their own refrigerant, and in effect operate overloaded, which is only possible because of the refrigerant. This makes them more sensitive to problems and the overcurrent protection boundaries are more tightly drawn accordingly. In this case, if and only if the basic rule doesn’t work, then a modest increase to 225 percent is allowable, and that too is a not to exceed number. However, it is never necessary to decrease the protection below 15 A.

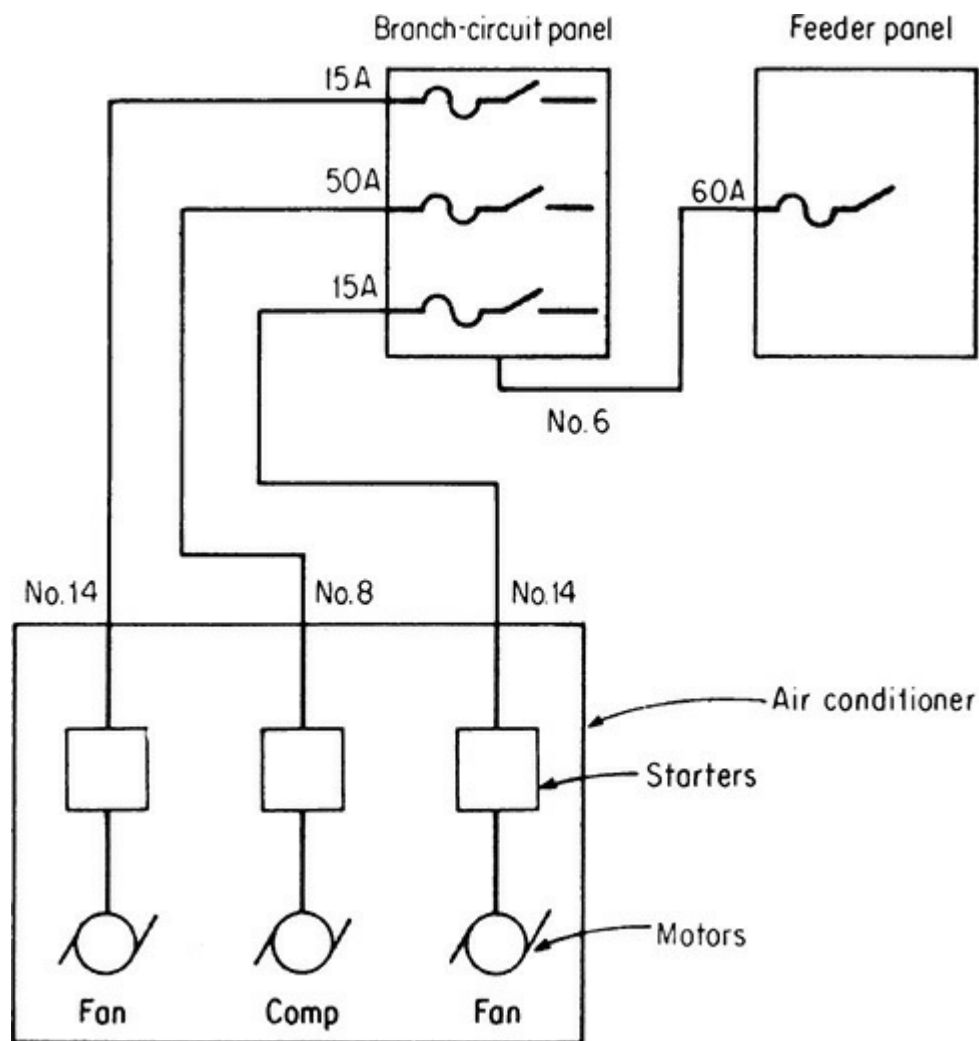

Fig. 440-5. A separate circuit may be run to each motor of A/C assembly. (Sec. 440.22.)

Sizing of branch-circuit protection for a single branch circuit to the same three motors is permitted by 430.53(C) as well as by 440.22(B) and is shown in Fig. 440-6. That layout is a specific example of the general rules covered in 440.22(B)(1), which ties the rules of 430.53(C) and (D) into the rules of 440.22(B), as shown in Fig. 440-7. Such application is based on certain factors, as covered in the UL *Electrical Appliance and Utilization Directory*, listed under “Heating and Cooling Equipment,” as follows:

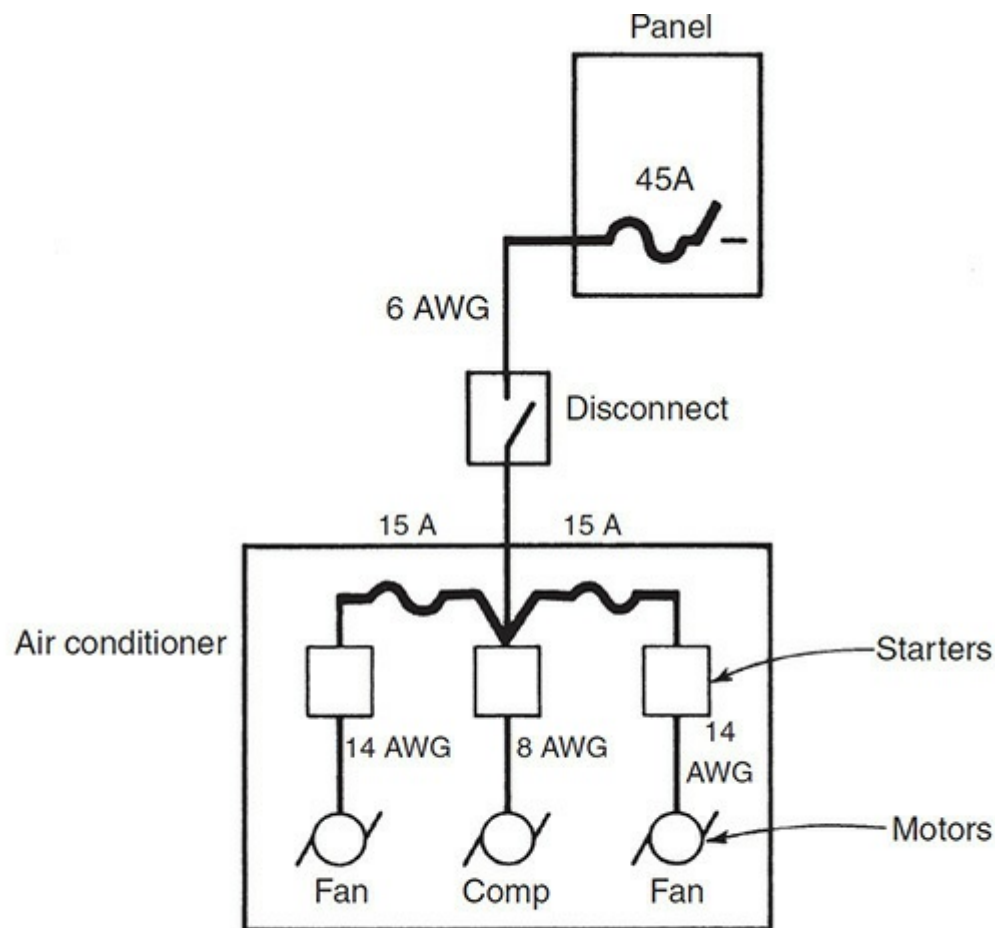

Fig. 440-6. Single multimotor branch circuit must conform to several rules. (Sec. 440.22.)

Main fuses: $(175\% \times 26) = 45.5$ amps (45-amp fuses)
 Fan fuses: $(300\% \times 6.0) = 18$ amps (15-amp fuses unless exceptions used)
 Fan conductors: $(125\% \times 6.0) = 7.5$ amps (14 AWG)

Fig. 440-7. Fan circuits are sometimes fused in multimotor assemblies. (Sec. 440.22.) For the internal compressor conductors, refer to the discussion at 440.33.

In permanently connected units employing two or more motors or a motor(s) and other loads operating from a single supply circuit, the motor running overcurrent protective devices (including thermal protectors for motors) and other factory-installed motor circuit components and wiring are investigated on the basis of compliance with the motor-branch-circuit short circuit and ground fault protection requirements of 430.53(C) as referenced in Sec. 440.22 of the **National Electrical Code**. Such multimotor and combination load equipment is intended to be connected only to a circuit protected by fuses or a circuit breaker with a rating which does not exceed the value marked on the data plate. This marked protective device rating is the maximum for which the equipment has been investigated and found acceptable. Where the marking specifies fuses, or "HACR Type" circuit breakers, the circuit is intended to be protected by the type of protective device specified.

The electrical contractor and inspector charged with wiring and approving such an installation can be sure that Code requirements have been met, provided that the branch-circuit protection as specified on the unit is not exceeded and the wiring and equipment is as indicated on the wiring diagram. Provision is made in such a unit for direct connection to the branch-circuit conductors; motors are wired internally by the manufacturer.

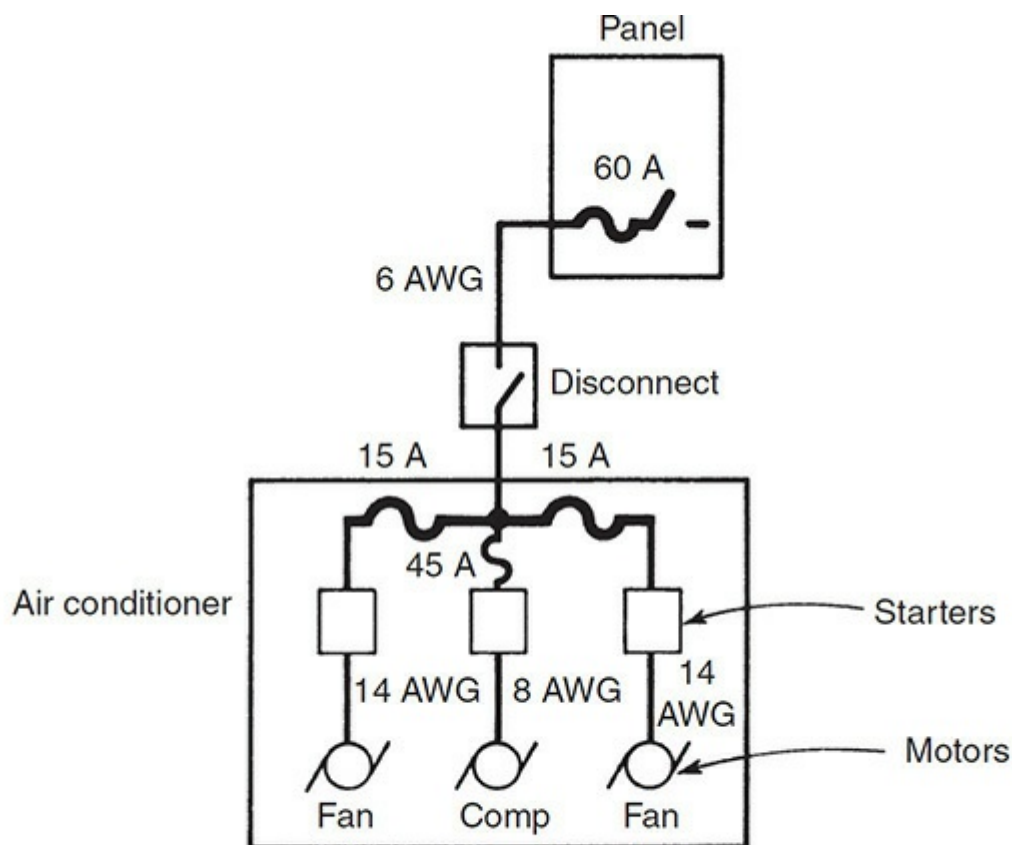

Units are sometimes encountered in which the manufacturer has wired separate fuse cutouts for the fan motors inside the enclosure to avoid meeting the requirements of 430.53(C) for group fusing, as shown in Fig. 440-8. The cutouts are normally fed from the line terminals of the compressor starter.

Starter and disconnect sizes are the same as in Fig. 440-2, but starters and their overcurrent protection no longer need be approved for group fusing, and wiring inside the unit need not conform to 430.53(C). Fan motors may now be wired with 14 AWG wire and protected with 15-A fuses with

no $\frac{1}{3}$ ratio calculation involved. The supply circuit, feeding the same motors, will again be 6 AWG.

Since the fan motors are not subject to group fusing requirements, they will not restrict the maximum value of the main fuses. However, these fuses provide the only short-circuit protection for the compressor starter and conductors. Unless the compressor starter is approved for group fusing at a higher fuse rating, the fuses must not exceed 175 percent of the compressor full-load rating, or 45.5 A, calling for 45-A fuses. The wire from the panel now gets sized more as a conventional motor feeder needing to accommodate the 45-A main compressor protective device plus the other full-load current supplying the fans, or 8.8 A, for a total of 54 A. The 6 AWG wire on a 60-A fuse is appropriate for this hookup.

Figure 440-9 shows an arrangement which includes, in addition to the branch-circuit panel, a feeder panel for distribution to other units. The breakers in the branch-circuit panel serve as branch-circuit protection as well as the disconnecting means, and their ratings are computed from 430.52 and 440.22. Code Tables 430.250 and 430.251 would not be involved, because breakers are not rated in horsepower. Ratings of CBs in the branch-circuit panel are computed at 175 percent of motor current for the hermetic motor and at 250 percent of full-load current for the fan motors, to satisfy Table 430.52. Breakers in subfeeder panel are rated using 430.62 and the conductors by 440.33. Because 440.22(A) does not distinguish between types of short-circuit and ground-fault protective devices in setting the upper limits on short-circuit protection, most of these numbers agree with those developed in Fig. 440-8 for fuses.

Main fuses: $[(\text{Comp. fuses} \leq 175\% \cdot 26) = 45 \text{ A}] + 6.0 + 6.0 = 57 \text{ amps (60-amp fuses)}$
 Compressor fuses: $(175\% \cdot 26) = 45.5 \text{ amps (45-amp fuses)}$

Fig. 440-8. Each motor may have individual short-circuit protection. (Sec. 440.22.)

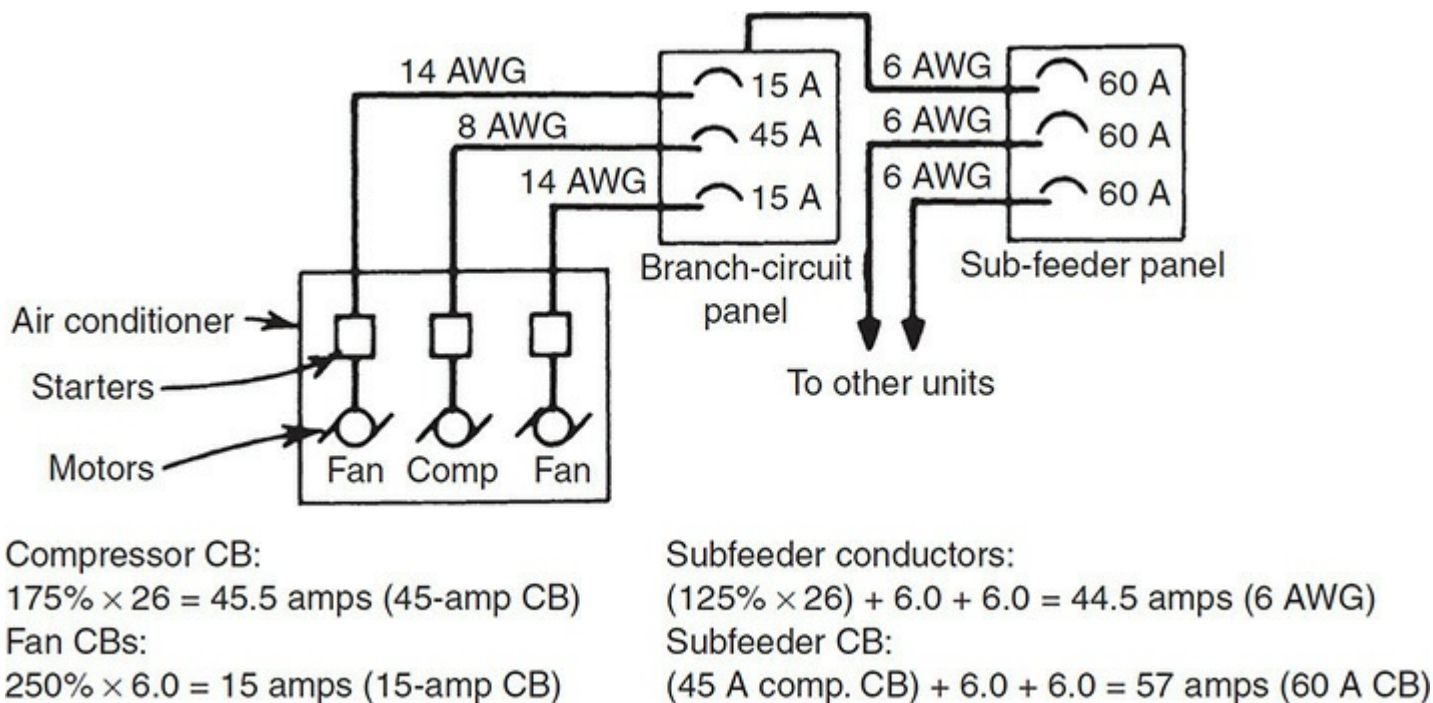

Fig. 440-9. Circuit breakers may be used for multimotor A/C assemblies. (Sec. 440.22.)

Part (C) points out that data on a manufacturer's heater table take precedence over the maximum ratings set by 440.22(A) or (B). This is the correlating language in this article to 430.52(C)(2) on the same subject.

440.32. Single Motor-Compressor. Branch-circuit conductors supplying a motor in a packaged unit are not sized in the same manner as other motor loads (430.22). Instead of using the full-load current from Code Tables 430.248 to 430.250, the *marked* rated-load current or the *marked* branch-circuit selection current must be used in determining minimum required conductor ampacity. Note that branch-circuit selection current must be used where it is given.

Examples are shown in the typical circuits shown in [Figs. 440-2](#) and [440-6](#).

For a wye-start, delta-run compressor, the conductors between the controller and the unit are sized, just exactly as in the case of the same wires in 430.22(C), based on 58 percent of the full-load current of the compressor. When you apply the mandatory 125 percent factor to that base number, as covered in the first paragraph, the result is a 72 percent ampacity requirement. This number does not need to be increased further.

440.33. Motor-Compressor(s) With or Without Additional Motor Loads. Where more than one motor is connected to the same feeder or branch circuit, calculation of conductor sizes must provide ampere capacity at least equal to the sum of the nameplate rated-load currents or branch-circuit selection currents (using the higher of those values in all cases) plus 25 percent of the current (either rated-load or branch-circuit selection current for a hermetic motor or **NEC** table current for standard motor) of the largest motor of the group. Examples are shown in [Figs. 440-2](#) and [440-7](#).

In [Fig. 440-7](#), the question arises as to whether the No. 6 conductors feeding the unit may be decreased to No. 8 inside the unit to feed the compressor motor in the absence of fuses for this motor at the point of reduction. The status of the main feed to the unit—whether it should be considered a feeder or a branch circuit—is in doubt, since it is a branch circuit as far as the compressor motor is concerned and a feeder in that it also supplied the two fused fan circuits.

Considered solely as a branch circuit to the compressor, these conductors normally would be No. 8 to handle the 26-A compressor motor full-load current, protected at not more than 175 percent or 50-A fuses. Therefore, since 45-A fuses (or less) will actually be used for the main feed, they constitute proper protection for No. 8 conductors and their use should be permitted. The existence of No. 6 conductors over part of the circuit adds to its capacity and safety rather than detracting from it.

It is particularly important to keep in mind when selecting conductor sizes that the nameplate current ratings of air-conditioning motors are not constant maximum values during operation. Ratings are established and tested under standard conditions of temperature and humidity. Operation under weather conditions more severe than those at which the ratings are established will result in a greater running current, which can approach the maximum value permitted by the overcurrent device. Operating voltage less than the limits specified on the motor nameplate also contributes to higher full-load current values, even under standard conditions. Conductor capacity should be sufficient to handle these higher currents. Motor branch-circuit conductors are sized according to 440.33. Because overload protection may permit motors to run continuously overloaded (up to 140 percent full load), feeders must be sized to handle such overload. By basing calculations on the largest motor of the group, the extra capacity thus provided will normally be enough to handle any unforeseen overload on the smaller motors involved with enough diversity existing in any normal group of motors to make consistent overloads on all motors at one time unlikely. However, a group of air-conditioning compressor motors all of the same size on a single feeder has a common function—reducing the ambient temperature. Except for slight possible variations, weather conditions affect each conditioner to the same degree and at the same time. Therefore, if one unit is operating at an overload, it is likely that the rest are also. Here again, the branch-circuit selection current ratings are evaluated through the listing process to accommodate adverse climatic conditions, and where they have been established and duly marked on the equipment, they are to be used to make conductor-selection decisions.

440.35. Multimotor and Combination-Load Equipment. This rule ties into the data required by UL to be marked on such equipment. Refer to the UL data quoted in 440.22.

440.41. Rating. The basic rule calls for a compressor controller to have a full-load current rating and a locked-rotor current rating not less than the compressor nameplate rated-load current or branch-circuit selection current (whichever is greater) and locked-rotor current. But, as noted for the disconnect under 440.12, for sealed (hermetic-type) refrigeration compressor motors, selection of the size of controller is slightly more involved than it is for standard applications. Because of their low-temperature operating conditions, hermetic motors can handle heavier loads than general-purpose motors of equivalent size and rotor-stator construction. And because the capabilities of such motors cannot be accurately defined in terms of horsepower, they are rated in terms of full-load current and locked-rotor current for polyphase motors and larger single-phase motors. Accordingly, selection of controller size is different from the case of a general-purpose motor where horsepower ratings must be matched, because controllers marked in horsepower only must be carefully related to hermetic motors that are *not* marked in horsepower.

For controllers rated in horsepower, selection of the size required for a particular hermetic motor can be made after the nameplate rated-load current, or branch-circuit selection current, whichever is greater, and locked-rotor current of the motor have been converted to an equivalent horsepower rating. To get this equivalent horsepower rating, which is the required size of controller, the tables in Art. 430 must be used. First, the nameplate full-load current at the operating voltage of the motor is located in Code Tables 430.248, 430.249, or 430.250 and the horsepower rating which corresponds

to it is noted. Then the nameplate locked-rotor current of the motor is found in Code Table 430.251(B), and again the corresponding horsepower is noted. In all tables, if the exact value of current is not listed, the next higher value should be used to obtain an equivalent horsepower, by reading horizontally to the horsepower column at the left side of those tables. If the two horsepower ratings obtained in this way are not the same, the larger value is taken as the required size of controller.

A typical example follows:

Given: A 230-V, 3-phase, squirrel-cage induction motor in a compressor has a nameplate rated-load current of 25.8 A and a nameplate locked-rotor current of 90 A.

Procedure: From Code Table 430.250, 28 A is the next higher current to the nameplate current of 25.8 under the column for 230-V motors and the corresponding horsepower rating for such a motor is 10 hp.

From Code Table 430.251(B), Art. 430, a locked-rotor current rating of 90 A for a 230-V, 3-phase motor requires a controller rated at 5 hp. The two values of horsepower obtained are not the same, so the higher rating is selected as the acceptable unit for the conditions. A 10-hp motor controller must be used.

Some controllers may be rated not in horsepower but in full-load current and locked-rotor current. For use with a hermetic motor, such a controller must simply have current ratings equal to or greater than the nameplate rated-load current and locked-rotor current of the motor.

440.52. Application and Selection. The basic rule of part (A)(1) calls for a running overload relay set to trip at not more than 140 percent of the rated-load current of a motor-compressor. As shown in the other subpart (3), if a fuse or inverse time CB is used to provide overload protection, it must be rated not over 125 percent of the compressor rated-load current. Note that those are absolute maximum values of overload protection and no permission is given to go to “the next higher standard rating” of protection where 1.4 or 1.25 times motor current does not yield an amp value that exactly corresponds to a standard rating of a relay or of a fuse or CB.

Running overload protective devices for a motor are necessary to protect the motor, its associated controls, and the branch-circuit conductors against heat damage due to excessive motor currents. High currents may be caused by the motor being overloaded for a considerable period of time, by consistently low or unbalanced line voltage, by single-phasing of a polyphase motor, or by the motor stalling or failing to start.

Damage may occur more quickly to a hermetic motor which stalls or fails to start than to a conventional open-type motor. Due to the presence of the cool refrigerant atmosphere under normal conditions, a hermetic motor is permitted to operate at a rated current that is closer to the locked-rotor current than is the same rated current of an open-type motor of the same nominal horsepower rating. The curves of Fig. 440-10 show the typical relation between locked-rotor and full-loaded currents of small open-type and hermetic motors. Because a hermetic motor operates within the refrigerant atmosphere, it is constantly cooled by that atmosphere. As a result, a given size of motor may be operated at a higher current than it could be if it were used as an open, general-purpose motor without the refrigerant cycle to remove heat from the windings. In effect, a hermetic motor is operated overloaded because the cooling cycle prevents overheating. For instance, a 5-hp open motor can be loaded as if it were a 7½-hp motor when it is cooled by the refrigerant. The full-load operating current of such a motor is higher than the normal current drawn by a 5-hp load and is, therefore, closer to the value of locked-rotor current, which is the same no matter how the motor is used.

Fig. 440-10. Hermetic motors operate at full-load currents closer to locked-rotor currents. (Sec. 440.52.)

When the rotor of a hermetic motor is slowed down because of overload or is at a standstill, there is not sufficient circulation of the refrigerant to carry away the heat; and heat builds up in the windings. Special quick-acting thermal and hydraulic-magnetic devices have been developed to reduce the time required to disconnect the hermetic motor from the line before damage occurs when an overload condition develops.

Room air conditioners and packaged unit compressors are normally required to incorporate running overload protection, which will restrict the heat rise to definite maximum safe temperatures in case of locked-rotor conditions. Room conditioners normally use inherent protectors built into the compressor housing, which respond to the temperature of the housing. Larger units also often use inherent protection in addition to quick-acting overload heaters installed in the motor starter, which respond only to current. These protective methods are covered in paragraphs (2) and (4) of 440.52(A).

The electrical installer will normally be concerned with the running overcurrent protection of a hermetic motor only when it becomes necessary to replace the existing devices supplied with the equipment. For this purpose, compressor manufacturers' warranties explicitly specify catalog numbers of replacements that are to be used to ensure proper operation of the equipment.

440.60. General. These rules on room air-conditioning units recognize that such units are basically appliances, are low-capacity electrical loads, and may be supplied either by an individual branch circuit to a unit conditioner or by connection to a branch circuit that also supplies lighting and/or other appliances. For all Code discussion purposes, an air-conditioning unit of the window, console, or through-the-wall type is classified as a *fixed appliance*—which is described in Art. 100 as “fastened or otherwise secured at a specific location.” Such an appliance may be cord-connected or it may be fixed-wired (so-called permanently connected). Any such units rated over 250 V or 3-phase must be directly connected and the provisions of this part of Art. 440 do not apply. There have been numerous attempts over the years to bring 277 V units within this part of the article, but they never succeeded.

210.23 in Art. 210 on “Branch Circuits” must also be applied in cases where a unit room air conditioner is connected to a branch circuit supplying lighting or other appliance load.

When a unit air conditioner is connected to a circuit supplying lighting and/or one or more appliances that are not motor loads, the rules of Art. 210 (and 406) must be observed:

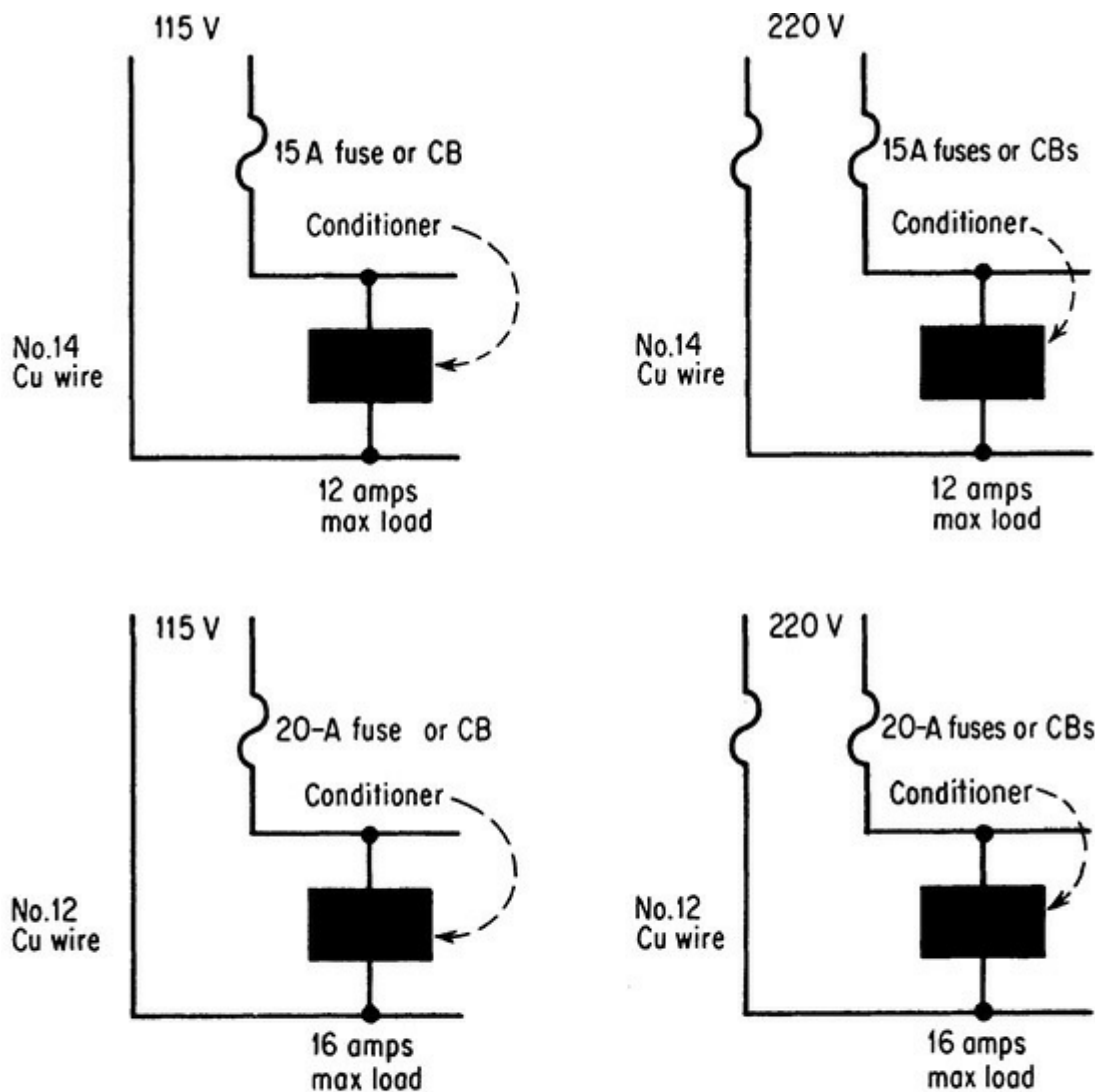

1. For plug connection of the A/C unit, 406.4(A) says that receptacles installed on 15- and 20-A branch circuits must be of the grounding type and must have their grounding terminals effectively connected to a grounding conductor or grounded raceway or metal cable armor.
2. On 15- and 20-A branch circuits, the total rating of a unit air conditioner (“utilization equipment fastened in place”) must not exceed 50 percent of the branch-circuit rating when lighting units or portable appliances are also supplied [210.23(A)]. It was on the basis of that rule that the 7½-A air conditioner was developed. Being 50 percent of a 15-A branch circuit, such units are acceptable for connection to a receptacle on a 15- or 20-A circuit that supplies lighting and receptacle outlets.
3. A branch circuit larger than 20 A may *not* be used to supply a unit conditioner plus a lighting load. Circuits rated 25, 30, 40, or 50 A may be used to supply fixed lighting or appliances—but not both types of loads.

440.61. Grounding. Air-conditioner units that are connected by permanent wiring must be grounded in accordance with the basic rules of 250.110 covering equipment that is “fastened in place or connected by permanent wiring.” 250.114 covers grounding of cord-and-plug-connected air conditioners by means of an equipment grounding conductor run within the supply cord for each such unit.

440.62. Branch-Circuit Requirements. Even though a room air conditioner contains more than one motor (usually the hermetic compressor motor and the fan motor), this rule notes that for a

cord-and-plug-connected air conditioner the entire unit assembly may be treated as a single-motor load under the conditions given. The nameplate marking of a room air conditioner shall be used in determining the branch-circuit requirements, and each unit shall be considered as a single motor unless the nameplate is otherwise marked. If the nameplate is marked to indicate two or more motors, 430.53 and 440.22(B)(1) must be satisfied, covering the use of several motors on one branch circuit.

Examples of the rule of part (B) are shown in Fig. 440-11. The total marked rating of any cord-and-plug-connected air-conditioning unit must *not* exceed 80 percent of the rating of a branch circuit that does not supply lighting units or other appliances, for units rated up to 40 A, 250 V, single phase.

NOTE: 30-A circuits with No. 10 wire may supply units rated 17 to 24 A ; 40- A circuits with No. 8 wire may supply units rated 25 to 32 A ; and 50- A circuits with No. 6 wire may supply units rated 33 to 40-A .

Fig. 440-11. Room air conditioners must not load an individual branch circuit over 80 percent of rating. (Sec. 440.62.)

As noted under 440.60, 210.2 seems to say that only Art. 440 and not Art. 210 applies when the circuit supplies only a motor-operated load. But, since Arts. 430 and 440 do not *rate* branch circuits—either on the basis of the size of the short-circuit protective device or the size of the conductors—a question arises about the meaning of the phrase “80 percent of the rating of a branch circuit.” Does

that mean 80 percent of the rating of the fuse or CB? The answer is: It means 80 percent of the rating of the protective device, which rating is not more than the amp rating of the circuit wire. The circuit as described here is taken to be a circuit with “rating” as given in Art. 210 and covered by part (4) of 440.62(A).

As part (C) of this section notes, the total marked rating of air-conditioning equipment must *not* exceed 50 percent of the rating of a branch circuit that *also* supplies lighting or other appliances. (See Fig. 440-12.) From the rule, we can see that the Code permits air-conditioning units to be plugged into existing circuits that supply lighting loads or other appliances. By the provisions of this section, such a conditioner must not draw more than 7½-A full load (nameplate rating) when connected to a 15-A circuit and not more than 10 A when connected to a 20-A circuit. This rule effectively makes the 50 percent limitation for fixed loads on general purpose branch circuits in 210.23(A) applicable to a load that is cord-and-plug-connected.

Fig. 440-12. Room air conditioner must not exceed 50 percent of circuit rating if other loads are supplied. (Sec. 440.62.)

A problem exists in connecting two or more conditioners to the same circuit. Compressor and fan motors and their controls, when installed in the same enclosure and fed by one circuit, are approved by UL for group installation when tested as a unit appliance. However, an air conditioner’s component parts carry no general group-fusing approval, which would permit the several separate conditioners to operate on the same circuit in accordance with 430.53(C). To connect more than one conditioner to the same branch circuit, the provisions of either 430.53(A) or 430.53(B) must be fulfilled, treating each cord-connected conditioner as a single-motor load. Note that 440.62(A) does classify a room air conditioner as a single motor load (that permission is conditional, but the terms are met in most cases).

According to 430.53(A), which applies only to motors rated not over 6 A, two 115-V, 6-A conditioners could be used on a 15-A circuit; three 5-A conditioners could be used on a 20-A circuit which supplies no other load; and two 220-V, 6-A units could be operated on a 15-A circuit, as shown in Fig. 440-13. But it could be argued that the maximum load in any such application may be

calculated at 125 percent times the current of the largest air conditioner plus the sum of load currents of the additional air conditioners, with that total current being permitted right up to the rating of the circuit.

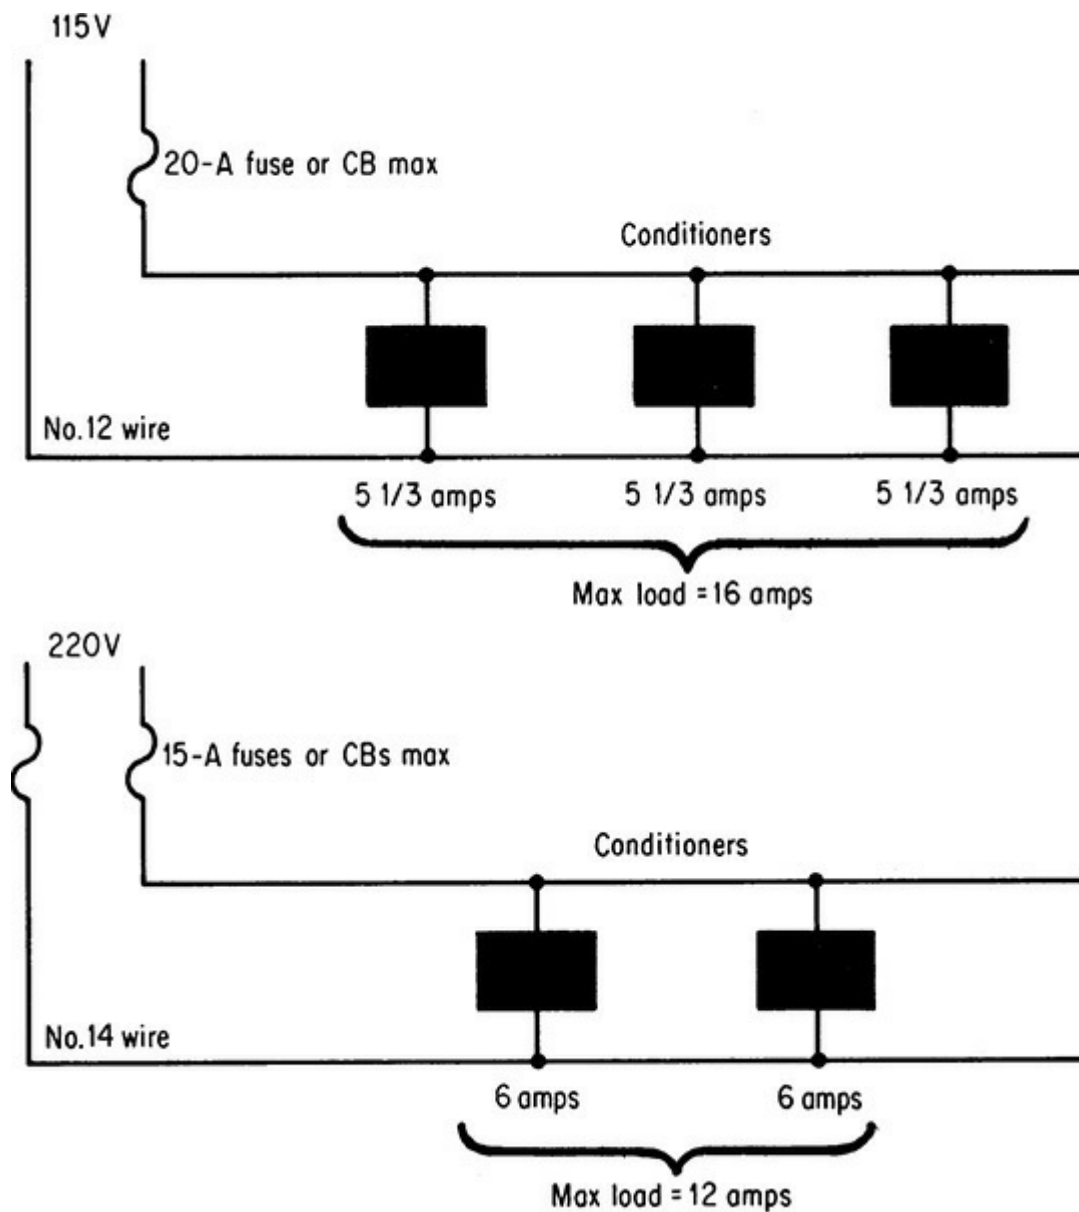

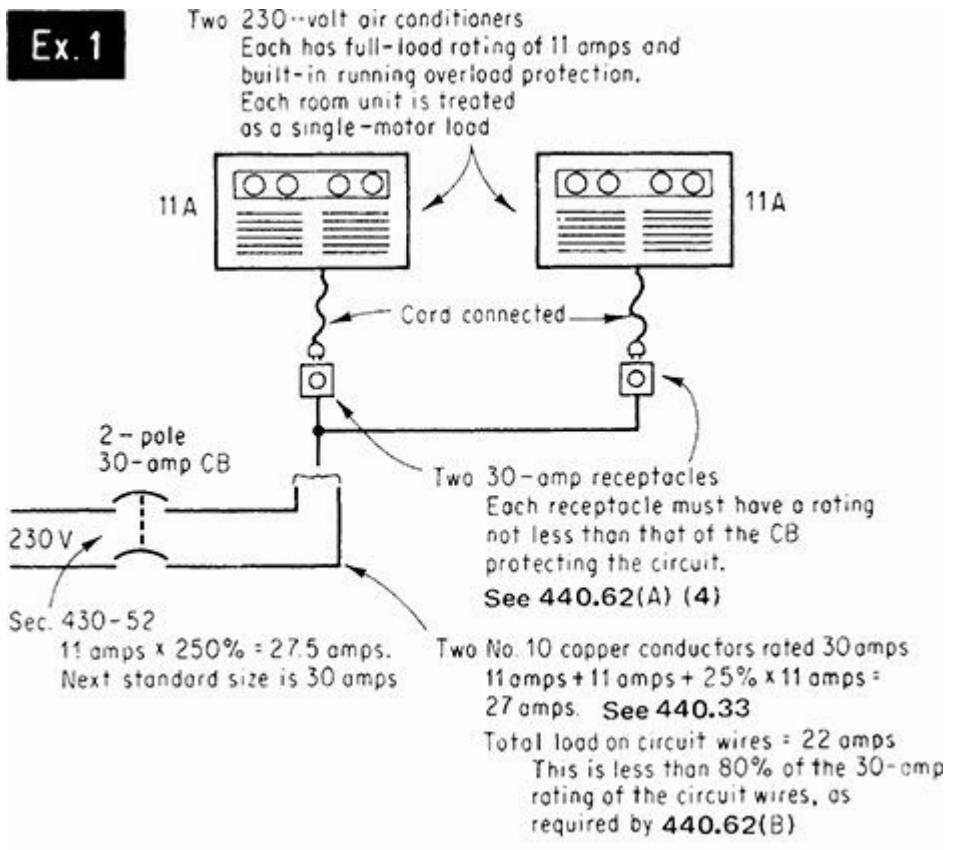

Fig. 440-13. Rules limit use of two or more room conditioners on single circuit. (Sec. 440.62.)

However, most conditioners sold today exceed 6-A full-load current. As a result, the application of two or more units as permitted by 430.53(A) is limited. But 430.53(B) does offer considerable opportunity for using more than one air conditioner on a single circuit. [Figure 440-14](#) shows two examples of such application, which can be used if the branch-circuit protective device will not open under the most severe normal conditions that might be encountered. Although that usage is a complex connection among several Code rules and requires clearance with inspection authorities, it can provide very substantial economies.

NOTE: Fuse or CB sizing may be required to conform to 440.22 (B), with a maximum rating of 175% times load current of one conditioner plus the current of the other conditioner. Or the 175% value itself may be held as the maximum rating of branch-current protection.

Fig. 440-14. These hookups have been accepted as conforming to rules of Arts. 440 and 430. (Sec. 440.62.) Generally speaking, if the branch-circuit and receptacle ratings match up to the rating of the plug on the cord as supplied by the manufacturer, the units can be expected to function safely. That would likely be the case in Example 2, but questionable in the first example.

Many local codes avoid the complications of connecting conditioners to existing circuits and

connecting more than one conditioner to the same circuit by requiring a separate branch circuit for each conditioner. Multiple installations involving many room conditioners such as are frequently encountered in hotels, offices, and so forth, require careful planning to meet Code requirements and yet minimize expensive branch-circuit lengths.

Watch Out!

The **NEC** refers to motor-operated appliances and/or to room air conditioners in Arts. 210, 422, and 440. Great care must be exercised in correlating the various Code rules in these different articles to ensure effective compliance with the letter and spirit of Code meaning. There is much crossover in terminology and references, making it difficult to tell whether a room air conditioner should be treated as an appliance circuit load or a motor load. However, a step-by-step approach to the problem, which keeps in mind the intent of these provisions, can resolve confusing points. Since the manufacturer is required to supply the motor-running overcurrent protection, no problems should arise concerning these devices. For larger units connected permanently to the distribution system, these can be treated directly as hermetic motor loads, using the provisions of Art. 440.

It may be assumed that a window or through-the-wall unit will operate satisfactorily on a standard fuse of the same rating as its attachment plug cap if there is no marking to the contrary on the unit. In any event, a time-delay fuse of the same or smaller rating could be substituted. If CBs are used for branch-circuit protection, a 15-A breaker will normally hold the starting current if a standard 15-A fuse will, because such breakers have inherent time delay. If the unit is marked to require a 15-A time-delay fuse and a 15-A breaker will not hold the starting current, few inspectors will object to the use of a 20-A breaker, because Art. 430 permits such a procedure for motor loads.

Normally, starting problems are not severe with these units, because the low inertia of present-day motor-compressor combinations permits them to reach full speed within a few cycles. Such a rapid drop in starting current is usually well within the time permitted by the trip or rupture characteristics of the breaker or fuse.

Similarly, the question of wire size may be resolved by application of Arts. 210, 422, or 440. Rarely do room conditioners even as large as 2 tons take more than 13-A running current; hence No. 12 copper or No. 10 aluminum conductors are more than sufficient. In addition, many local codes prohibit use of conductors smaller than No. 12. In localities where No. 14 wire may be used, provisions of 440.62(B), restricting the loading to 80 percent of the circuit rating, must determine the wire size, where “rating” is interpreted as referring to the conductor carrying capacity. If Art. 440 is used to determine the wire size, the 125 percent requirement of 440.32 gives the same result.

Figure 440-15 shows one feeder of an installation involving many room conditioners, which practically eliminates branch-circuit wiring and will serve to illustrate the complications of circuit calculations for a multiple-unit installation. Total running current of each unit is 12 A as shown; hence, No. 14 copper wire could be used for branch-circuit conductors, protected by a 15-A fuse—either standard or time-delay. However, if the appropriate conductors of a 4-wire, 3-phase feeder were routed to the location of each conditioner and a combination fuseholder and receptacle was installed as shown, the only existing branch-circuit conductors would be the jumpers between the feeder, the fuseholder, and the receptacles. These jumpers, then, could be No. 14 wire. Assuming that the fuse-receptacle unit is mounted directly on or in close proximity with the junction box in which the tap to the feeder is made, the No. 14 wire is justified from the fuse to the feeder since it is not over 10 ft (3.0 m) long and is sufficient for the load supplied [240.21(B)(1)]. Since all three motors

might start simultaneously, to be conservative the total unit current is used to compute feeder conductor size and protection: 125 percent times 12 plus 24 is 39 A, permitting No. 8 conductors. However, this is practically the limit of the circuit's capacity; there is no provision for overload, and voltage drop is very likely to be a factor at the end of the feeder. Therefore No. 6 conductors should be used.

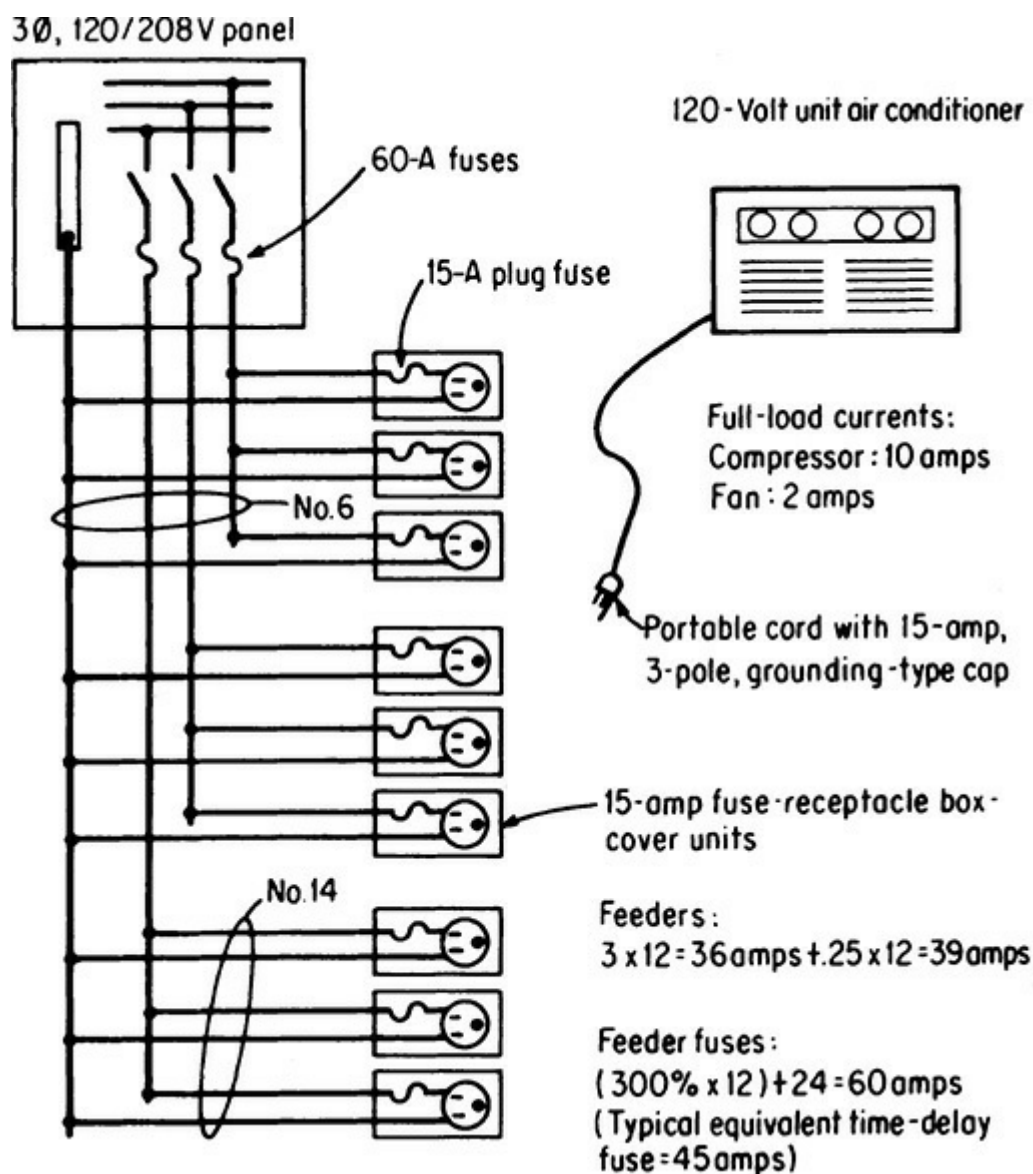

Fig. 440-15. This type of circuiting was used for air conditioners in a hotel modernization project. (Sec. 440.62.)

Feeder protection is calculated on the basis of 300 percent times 12 plus 24, or 60-A fuses. Substitution of time-delay fuses for this 39-A feeder load would likely permit 45-A fuses.

Important: The rules of 440.62 apply only to cord-and-plug-connected room air conditioners. A unit room air conditioner that has a *fixed* (not cord-and-plug) connection to its supply must be treated as a group of several individual motors and protected in accordance with 430.53 and 440.22(B), covering several motors on one branch. If the fixed units were wired to individual branch-circuit protection similar to that presented in Fig. 440-15, then the wires originating in the panel are feeders and the calculation follows 430.62.

440.63. Disconnecting Means. A disconnect is required for every unit air conditioner. An attachment plug and receptacle or a separable connector may serve as the disconnecting means (Fig.

440-16). However, if the manual controls are not both readily accessible and within 1.8 m (6 ft) of the floor, then an additional disconnecting means must be provided in the circuit that is readily accessible and within sight of the air conditioner.

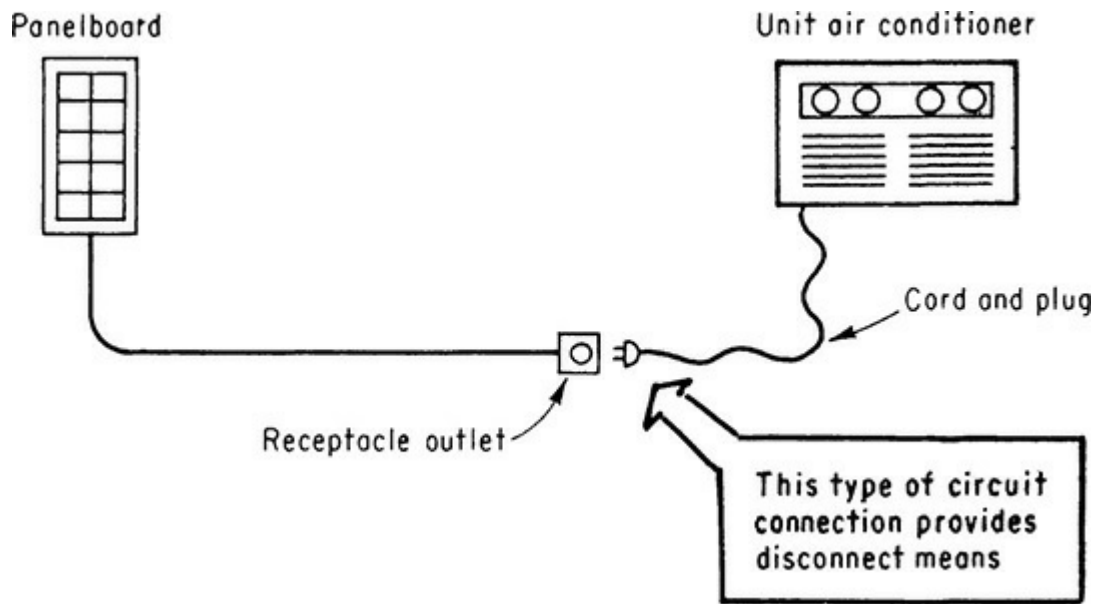

Fig. 440-16. Plug-and-receptacle serves as required disconnect means. (Sec. 440.63.)

If a fixed connection is made to an A/C unit from the branch-circuit wiring system (i.e., not a plug-in connection to a receptacle), consideration must be given to a means of disconnect, as required in 422.33 and 422.34 for appliances:

- For unit air conditioners in any type of occupancy, the branch-circuit switch or CB may, where readily accessible to the user of the appliance, serve as the disconnecting means. Figure 440-17 shows this, but the switch or CB is permitted to be out of sight by the exception to 422.31(C) when the A/C unit has an internal OFF switch—which all units do have.

Fig. 440-17. Branch-circuit CB or switch may serve as disconnect. (Sec. 440.63.)

Because air conditioners have unit switches within them, the disconnect provisions of 422.34 may

be applied. The internal unit switch with a marked OFF position that opens all ungrounded conductors may serve as the disconnect and is considered within sight as required by 422.34 in any case where there is another disconnect means as follows:

- In multifamily (more than two) dwellings, the other disconnect means must be within the apartment where the conditioner is installed or on the same floor as the apartment.
- In two-family dwellings, the other disconnect may be outside the apartment in which the appliance is installed. It may be the feeder disconnect, or the service disconnect if the two-family dwelling is equipped with multiple service disconnects such that opening the disconnect amounts to the opening of an “individual switch or circuit breaker for the dwelling unit.”
- In single-family dwellings, the service disconnect may serve as the other disconnect means—whether the branch circuit to the conditioner is fed from plug fuses or from a breaker or switch (Fig. 440-18).

Fig. 440-18. Service disconnect may be the “other disconnect” for A/C unit in a single-family dwelling. (Sec. 440.63.)

440.65. Protection Devices. This rule requires a factory installed LCDI or AFCI protective device in the cord and within 300 mm (12 in.) of the plug cap for all single-phase, cord-and-plug-connected room A/Cs. The 2017 **NEC** recognized a “heat detecting circuit interrupter” (HDCI) that is designed to function as a leakage current detector (LCDI), plus detect if the compressor is overheating. This is not mandatory, but it is a permitted option and joins the other two devices as a third protection option for this equipment.

ARTICLE 445. GENERATORS

445.11. Marking. Generators must be marked with the manufacturer’s name, the frequency and number of phases for ac units, the output rating in kilowatts or kilovolt-amperes, the corresponding normal volts and amperes, the rated RPM, and the rated ambient temperature or temperature rise,

along with the power factor. In addition, generators over 15 kW must have the reactances (transient, synchronous, and subtransient, along with zero sequence), the power rating category, and the insulation class marked as well. Inverter-based generators need the maximum short-circuit current provided, in place of all the reactances except the zero sequence number. The nameplate must also stipulate how the generator is protected against overload, whether by fuse or circuit breaker, or by a protective relay, or by its inherent design.

The 2014 **NEC** has added a critical marking requirement relative to whether or not the generator, when connected to the premises wiring system, must be considered to be the source of a separately derived system. The marking must state whether the neutral is bonded to the frame. And if that bonding is modified, then the resulting bonding status must be reflected in an additional corrective marking.

445.12. Overcurrent Protection. Alternating-current generators can be so designed that on excessive overload the voltage falls off sufficiently to limit the current and power output to values that will not damage the generator during a short period of time. Whether automatic overcurrent protection of a generator should be omitted in any particular case is a question that can best be answered by the manufacturer of the generator. It is a common practice to operate an exciter without overcurrent protection, rather than risk the shutdown of the main generator due to accidental opening of the exciter fuse or CB. In the case of constant-voltage generators, the **NEC** leaves this to the manufacturer, providing various options including “inherent design” as well as conventional overcurrent devices.

Figure 445-1 shows the connections of a 2-wire dc generator with a single-pole protective device. If the machine is operated in multiple with one or more other generators, and so has an equalizer lead connected to the positive terminal, the current may divide at the positive terminal, part passing through the series field and positive lead and part passing through the equalizer lead. The entire current generated passes through the negative lead; therefore the fuse or CB, or at least the operating coil of a CB, must be placed in the negative lead. The protective device should not open the shunt-field circuit, because if this circuit were opened with the field at full strength, a very high voltage would be induced, which might break down the insulation of the field winding.

Fig. 445-1. With this connection, a single-pole CB can protect a 2-wire dc generator. (Sec. 445.12.)

Paragraph (C) is intended to apply particularly to generators used in electrolytic work. Where such a generator forms part of a motor-generator set, no fuse or CB is necessary in the generator leads if the motor-running protective device will open when the generator delivers 150 percent of its rated full-load current.

In paragraph (D), use of a balancer set to obtain a 3-wire system from a 2-wire main generator is covered, as shown in Fig. 445-2. Each of the two generators used as a balancer set carries approximately one-half the unbalanced load; hence these two machines are always much smaller than the main generator. In case of an excessive unbalance of the load, the balancer set might be overloaded while there is no overload on the main generator. This condition may be guarded against by installing a double-pole CB, with one pole connected in each lead of the main generator and with the operating coil properly designed to be connected in the neutral of the 3-wire system. In Fig. 445-2, the CB is arranged so as to be operated by either one of the coils *A* in the leads from the main generator or by coil *B* in the neutral lead from the balancer set.

Fig. 445-2. A balancer set supplies the unbalanced neutral current of a 3-wire system, with each generator carrying 25 of the 50-A unbalance. (Sec. 445.12.)

445.13. Ampacity of Conductors. The first three sentences clarify sizing of circuit conductors connecting a generator to the control and protective device(s) it serves:

1. The ampacity of the conductors between the generator terminals and the first panelboard, switchboard, or other comparable equipment that contains overcurrent protective devices must not be less than 115 percent of the generator nameplate current rating. Note that there is no requirement that the conductors arrive at the terminals of a single overcurrent device of a particular rating, or that the sum of the ratings of the overcurrent devices at the terminating location not exceed some quantity. The tap rules in 240.21(G) recognize whatever protection is provided under 445.12, and allow the generator output conductors indefinite length without additional protection as long as they meet the 115 percent ampacity criterion.
2. The neutral of the generator feeder may have its size reduced from the minimum capacity required for the phase legs. As with any feeder or service circuit, the neutral has to have only enough ampacity for the unbalanced load it will handle—as covered by 220.61.
3. Where a generator is operating as a standalone power source on a system employing a grounded neutral, and that neutral is not connected to ground and the equipment grounding system at the generator housing, the generator neutral must be sized to carry ground-fault

currents in addition to its normal function as feeder conductor sized in accordance with 220.61. Depending on the amount of line-to-neutral load, the fault-return capability requirements in 250.24(C) for nonseparately derived systems as shown in Fig. 445-3, or those for separately derived systems as covered in 250.30(A)(3), may require a larger neutral conductor. The third sentence of 445.13 attempts to convey this concept, but the Art. 250 reference is in part erroneous because it only points to separately derived system rules within Art. 250. For nonseparately derived systems the relevant reference is 250.24(C) as noted. Fortunately the sizing rules in both locations are essentially identical. Part (B) allows the load terminals of a generator overcurrent protective device, or a current transformer operating with an overcurrent relay, to serve as a feeder for code purposes. With this established, the installer therefore has a choice of feeder tap rules under 240.21(B) to apply when wiring the load conductors from the generator. This procedure is not permitted on smaller generators rated 15 kW or less with unavailable field wiring connections.

Fig. 445-3. Neutral must have adequate capacity for generator that is not a “separately derived” system source (i.e., does not have its neutral bonded and grounded). (Sec. 445.13.)

445.14. Protection of Live Parts. As a general rule, no generator should be “accessible to unqualified persons.” If necessary to place a generator operating at over 50 V to ground in a location where it is so exposed, the commutator or collector rings, brushes, and any exposed terminals should be provided with guards that will prevent any accidental contact with these live parts.

445.18. Disconnecting Means and Shutdown of Prime Movers. Lockable disconnect(s) are required for generators other than cord-and-plug-connected portable generators, unless the generator’s driving machine can be readily shut down and it is not running in parallel with another source of voltage, such as another generator. The phrasing “one or more” reflects the useful idea that an excellent design option is to establish multiple disconnects right at the generator so

multiple systems can originate at the generator (such as emergency, legally required standby, and optional standby) without issues of system separation at the occupancy served.

Part (B) addresses the prime mover, which must have provisions to be shut down. The applicable means must be capable of two things, first, disabling all starting control circuits so as to make the prime mover incapable of starting. It must also initiate a shutdown, one that requires mechanical intervention to be reset. A prime mover shutdown mechanism that satisfies these rules is permitted to constitute the generator disconnecting means if it can be locked in the position that so disables the prime mover and prevents its restart. Generators over 15 kW must have an additional “requirement” (an obvious mistake, which presumably means a redundant mechanism) to disable the prime mover, located outside of the generator room or outside the generator enclosure, that also meets the full shutdown requirements of this part.

Part (C) addresses generators operating in parallel. The disconnecting requirements in part (A) must be capable of separating the generator output terminals from the paralleling equipment, and it need not be located on the generator.

445.20 Ground-Fault Circuit-Interrupter Protection for Receptacles on 15-kW or Smaller Portable Generators. This rule addresses the GFCI status of 125-volt 15- and 20-ampere convenience receptacles furnished as part of smaller portable generators covered here. That status depends in part on whether the generator’s neutral connection is bonded to the generator frame, and that can be established by test, or preferably, by the marking, if present, that is required by 445.11. If the neutral is floating (unbonded), then two things are true. First, the 125-volt circuits will be functionally ungrounded and incapable of meeting the construction site requirements in 590.6(A)(3) because the GFCI receptacles will not trip reliably. Secondly, such a generator will be appreciated in terms of providing back-up power for a house or other building because it will qualify to be wired as a non-separately derived system with a far less expensive transfer switch (need not transfer the neutral) and much simpler wiring connections.

If the neutral is bonded, then there will be a ground-fault return path over the equipment grounding conductor within any cord plugged into a generator receptacle and the GFCI functionality will be completely operational. The generator will fully qualify for use at construction sites. The unbonded (floating) option comes with an exception that offers some important flexibility. It recognizes a method of interlocking the receptacles on the generator so that when the generator is providing standby power to a house, for example, through the 125.250-volt 30- or 50-ampere 3-pole 4-wire grounding receptacle, the 125-volt GFCI receptacles are unpowered. This prevents those receptacles from being used under a circumstance where they would not be actually functional. There are also small generators manufactured with neutral bonding connections that are easily made or unmade in the field, together with directions that fully discuss the reasons and appropriate times for either connection.

This new rule must be understood in its historical context. UL released a new product standard for “Engine Generators for Portable Use” (UL2201, Guide Card designation FTCN) in March 2009. The Guide Card information includes a condition that “[The generators] are provided only with receptacle outlets for the ac output circuits.” The standard also requires that the generator neutral be bonded to its frame. This has the effect of requiring portable generators used to power grounded systems, such as dwellings and small commercial enterprises, to be wired as separately derived systems through transfer equipment with a pole in the neutral conductor along with the implicit requirement to separate equipment grounding conductors and neutral conductors in what had been a service panel. The

portable generator industry has generally opposed the attempted abolition of floating neutrals and has voted with its feet. In the entire history of UL 2201 there is yet, as of this writing, to be a single listee in the category.

The generator industry would prefer to be able to make unbonded generators generally on the basis that a functionally ungrounded 125-volt circuit is not a shock hazard. There is some technical substantiation for that point of view, but at this point it is very unlikely to persuade the panel, which voted overwhelmingly (only two negative votes) for the compromise language. Given the contentiousness of this issue, that was an impressive result. On the other hand, the fact that the entire generator industry has refused to participate in the UL listing process for 7 years is also impressive and shows real discipline. Time will tell whether the present wording is a workable compromise.

ARTICLE 450. TRANSFORMERS AND TRANSFORMER VAULTS (INCLUDING SECONDARY TIES)

450.1. Scope. The exceptions indicate those transformer applications that are not subject to the rules of Art. 450. The exceptions shown in [Fig. 450-1](#) are as follows:

Exception No. 2

Exception No. 6

Exception No. 8

If a transformer is used for research, development or testing . . .

. . . it is exempt from the rules of Article 450 – provided personnel are protected from energized parts.

Fig. 450-1. These transformer applications are exempt from the rules of Art. 450. (Sec. 450.1.)

Exception No. 2 excludes any dry-type transformer that is a component part of manufactured equipment, provided that the transformer complies with the requirements for such equipment. Those

requirements include UL standards on the construction of the particular equipment. This exclusion applies, for instance, to control transformers within a motor starter or within a motor control center. However, although such transformers do not have to be protected in accordance with 450.3(B), such control transformer circuits must have their control conductors protected as described under 430.72(B). But a separate control transformer—one that is external to other equipment and is not an integral part of any other piece of equipment—must conform to the protection rules of 450.3 and other rules in Art. 450.

Exception No. 6 points out that ballasts for electric-discharge lighting (although they *are* transformers—either autotransformers or separate-winding, magnetically coupled types) are treated as lighting accessories rather than transformers.

Exception No. 8 notes that liquid-filled or dry-type transformers used for research, development, or testing are exempt from the requirements of Art. 450, provided that effective arrangements are made to safeguard any persons from contacting energized terminals or conductors. Again, in the interest of the unusual conditions that frequently prevail in industrial occupancy, this rule recognizes that transformers used for research, development, or testing are commonly under the sole control of entirely competent individuals and exempts such special applications from the normal rules that apply to general-purpose transformers used for distribution within buildings and for energy supply to utilization equipment, controls, signals, communications, and the like. (See [Fig. 450-2](#).)

Fig. 450-2. Transformers that are set up in a laboratory to derive power for purposes of testing other equipment or powering an experiment are exempt from the rules of Art. 450, provided care is taken to protect personnel from any hazards due to exposed energized parts. (Sec. 450.1.)

UL listing The UL Guide Card information that covers this equipment carries the heading: “Transformers—Power and General Purpose, Dry Type.” To satisfy **NEC** and OSHA regulations, as

well as local code rules on acceptability of equipment, any transformers of the types and sizes covered by UL listing must be so listed. Use of an unlisted transformer of a type and size covered by UL listing would certainly be considered a violation of the spirit of **NEC** 110.3. UL listing covers *air-cooled* types rated up to 500 kVA for single-phase transformers and up to 1500 kVA for 3-phase units (all up to 1000-V rating).

450.2. Definitions. A *transformer* is an individual transformer, single or polyphase, identified by a single nameplate, unless otherwise indicated in this article. Three single-phase transformers connected for a 3-phase transformation must be taken as three transformers, not one. This definition helps to clarify the contents of some of the rules of Art. 450.

450.3. Overcurrent Protection. This section covers overcurrent protection in great detail, and other Code rules (240.21, 240.40, and 408.16 in particular) usually get involved in transformer applications. Both protection tables [450.3(A) and 450.3(B)] require primary protection in some form. This protection will now need to be considered in the context of 450.14, which as of the 2011 **NEC** imposes a disconnection requirement on most transformers. Both tables also cover secondary protection, which is required in many but not all cases. Where it is required, there is an allowance for multiple overcurrent devices to serve as secondary protection, up to a maximum of six devices, which must be grouped. Refer to Notes 2 to both tables for details.

It should be understood that the overcurrent protection required by this section is for transformers *only*. Such overcurrent protection will not necessarily protect the primary or secondary conductors or equipment connected on the secondary side of the transformer. Using overcurrent protection to the maximum values permitted by these rules would require much larger conductors than the full-load current rating of the transformer (other than permitted in the 25-ft [7.5-m] tap rule in 240.21). Accordingly, to avoid using oversized conductors, overcurrent devices should be selected at about 110 to 125 percent of the transformer full-load current rating. And when using such smaller overcurrent protection, devices should be of the time-delay type (on the primary side) to compensate for inrush currents, which reach 8 to 10 times the full-load primary current of the transformer for about 0.1 s when energized initially.

In approaching a transformer installation it is best to use a one-line diagram, such as shown in the accompanying sketches. Then by applying the tap rules in 240.21, proper protection of the conductors and equipment, which are part of the system, will be achieved. See comments following 240.21.

240.4(F) is the only Code rule that considers properly sized primary overcurrent devices to protect the secondary conductors without secondary protection and no limit to the length of secondary conductors.

On 3- and 4-wire transformer secondaries, it is possible that an unbalanced load may greatly exceed the secondary conductor ampacity, which was selected assuming balanced conditions. Because of this, the **NEC** does not permit the protection of secondary conductors by overcurrent devices operating through a transformer from the primary of a transformer having a 3-wire or 4-wire secondary. For other than 2-wire to 2-wire or 3-wire to 3-wire delta-delta transformers, protection of secondary conductors has to be provided completely separately from any primary-side protection. In designing transformer circuits, the rules of 450.3 can be coordinated with 240.21(C), which provides special rules for tap conductors used with transformers. This general procedure allows for simultaneous protection of both the transformer and the conductors connected on both sides of it. Refer to the extensive discussion in 240.21 in [Chap. 2](#) of this book. Those rules need not be covered again here.

Part (A) of this section mandates compliance with Table 450.3(A). That table sets rules for overcurrent protection of any transformer (dry-type or liquid-filled) rated over 1000 V, and, as covered in Note 4 to Table 450.3(A), electronically actuated fuses that are adjustable to a “specific current” may also be rated at 300 percent. Protection may be provided either by a protective device of specified rating on the transformer primary or by a combination of protective devices of specified ratings on both the primary and secondary. Figure 450-3 shows the basic rules of such overcurrent protection. The fact that E-rated fuses used for high-voltage circuits are given melting times at 200 percent of their continuous-current rating explains why this Code rule used to set 150 percent of primary current as the maximum fuse rating but permits CBs up to 300 percent. In effect, the 150 percent for fuses times 2 becomes 300 percent—the maximum value allowed for a CB. Now such fuses may be rated up to 250 percent (instead of 150 percent) for transformers with 6 percent or less impedance. The 2014 **NEC** clarified that the next higher rating of medium-voltage circuit protection, which is not covered in 240.6(A), is taken as the next higher “commercially available rating.”

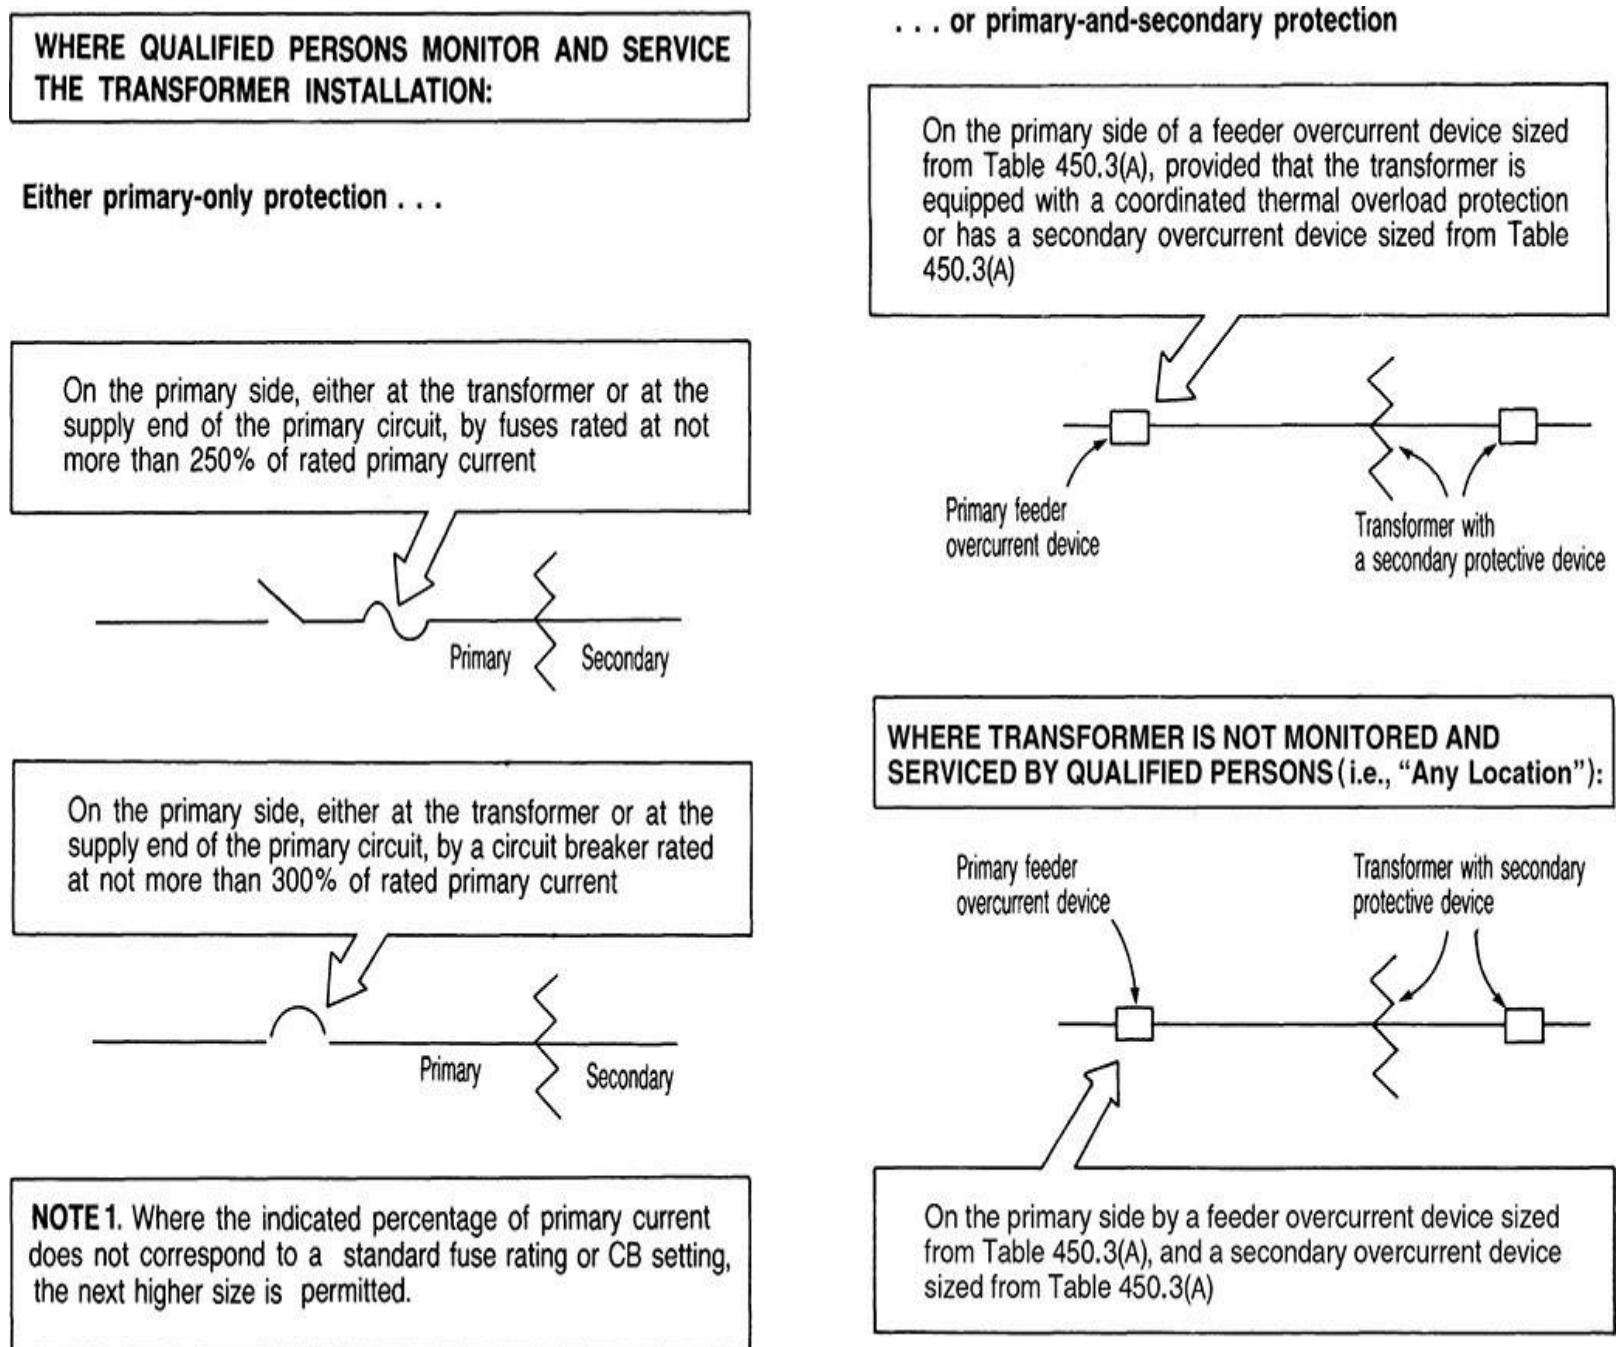

Fig. 450-3. High-voltage transformers (rated over 1000 V, dry or fluid-filled) with any impedance

must be protected in one of these ways. However, the value of OC protection for transformers with known internal impedances as indicated in Table 450.3(A) may be based on the particular impedance. [Table 450.3(A).]

- The basic requirement for “Any Location” in Table 450.3(A) says that *any* high-voltage transformer must have *both* primary and secondary protection based on Table 450.3(A) for maximum ratings of the primary and secondary fuses or circuit breakers.
- The rules under “supervised locations only” give two alternative ways of protecting high-voltage transformers where “conditions of maintenance and supervision assure that only qualified persons will monitor and service the transformer.” The two alternatives are as follows:
 1. Primary protection only may be used, with fuses set at not over 250 percent of the primary current or circuit breakers set at not over 300 percent of primary current. And if that calculation results in a fuse or CB rating that does not correspond to a standard rating or setting, the next higher standard rating or setting may be used.
 2. Primary and secondary protection based on Table 450.3(A) is the alternative.

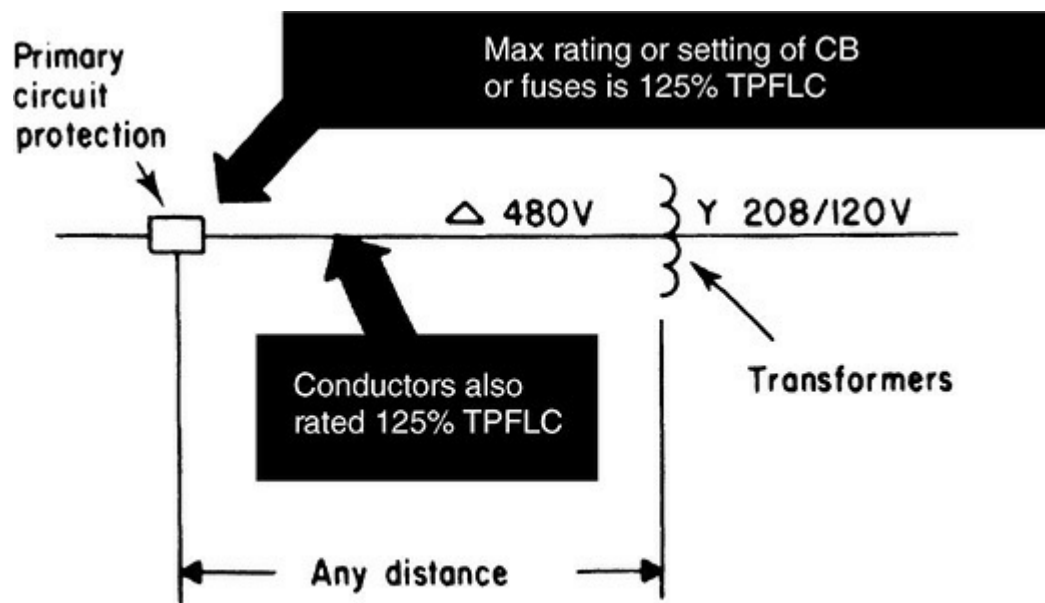

These rules resulted from concerted industry action to provide better transformer protection. As stated in the substantiation for 450.3(A), “It is felt that this approach will aid in reducing the number of transformer failures due to overload, as well as maintaining the flexibility of design and operation by industry and the more-complex commercial establishments.”

Part **(B)** of this section covers all transformers—oil-filled, high-fire-point liquid-insulated, and dry-type—rated up to 1000 V. The step-by-step approach to such protection is as follows:

Transformers operating 1000 V and less, with primary side protection only

For any transformer rated 1000 V or less (i.e., the rating of neither the primary nor the secondary winding is over 1000 V), the basic overcurrent protection may be provided just on the primary side [Table 450.3(B) (top row)] or may be a combination of protection on *both* the primary and secondary sides [Table 450.3(B) (bottom row)].

If a transformer is to be protected by means of a CB or set of fuses only on the primary side of the transformer, the basic arrangement is as shown in [Fig. 450-4](#).

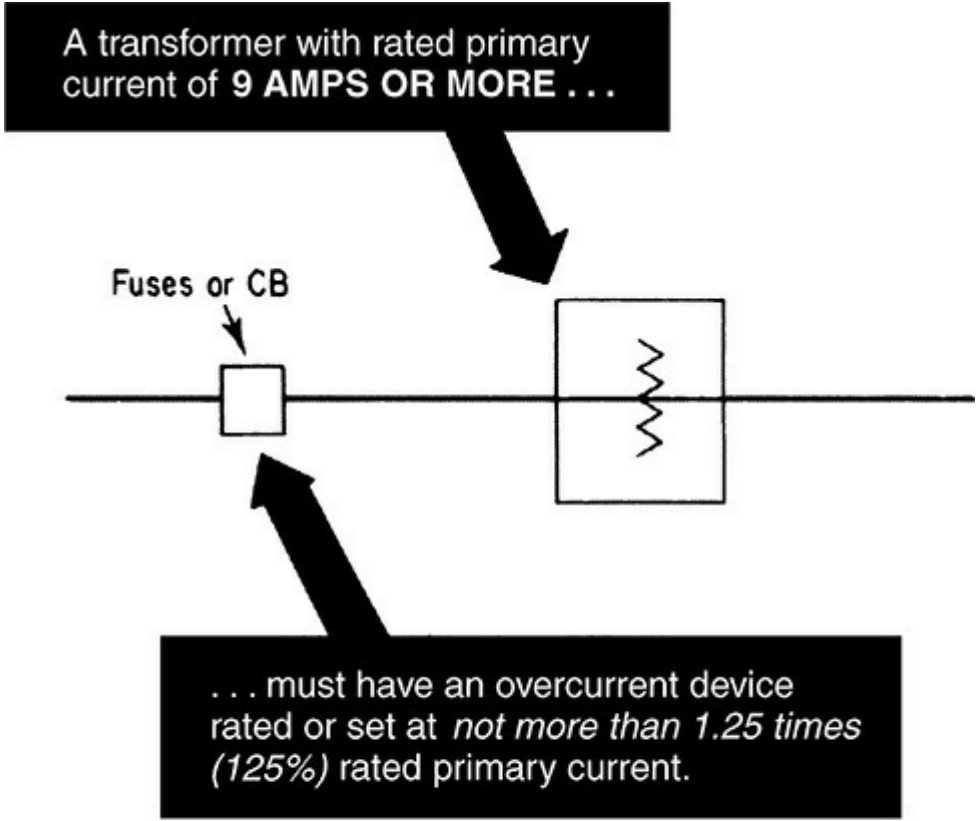

TPFLC = transformer primary full-load current (nameplate rating)

Fig. 450-4. This is the basic rule on primary-side protection for trans-formers with primary current over 9 A. (Table 450.3.)

In that layout, a CB or a set of fuses rated not over 125 percent of the transformer rated primary full-load current provides all the overcurrent protection required by the **NEC** for the transformer. This overcurrent protection is in the feeder circuit to the transformer and is logically placed at the supply end of the feeder, so the same overcurrent device may also provide the overcurrent protection required for the primary feeder conductors. There is no limit on the distance between primary protection and the transformer. When the correct maximum rating for transformer protection is selected and installed at any point on the supply side of the transformer (either near or far from the transformer), then feeder circuit conductors must be sized so that the CB or fuses selected will provide the proper protection as required for the conductors. The ampacity of the feeder conductors must be at least equal to the amp rating of the CB or fuses unless 240.4(B) is satisfied. That is, when the rating of the overcurrent protection selected is not more than 125 percent of rated primary current, the primary feeder conductor may have an ampacity such that the overcurrent device is the next higher standard rating.

The rules set down for protection of a 1000-V transformer by a CB or set of fuses in its primary circuit are given in [Fig. 450-5](#) for transformers with rated primary current of 9 A or more. Note 1 to Table 450.3(B) says that “the next higher standard” rating of protection may be used, if needed. [Figure 450-6](#) shows the *absolute* maximum values of protection for smaller transformers. When using the 1.67 or 3 times factor, if the resultant current value is not exactly equal to a standard rating of fuse or CB, then the next *lower* standard rated fuse or CB must be used.

NOTE: Where 1.25 times primary current does not correspond to a standard rating of protective device, the next higher standard rating from 240.6 is permitted.

Fig. 450-5. Protection sizing for larger transformers is 125 percent of primary current. (Sec. 450.3.)

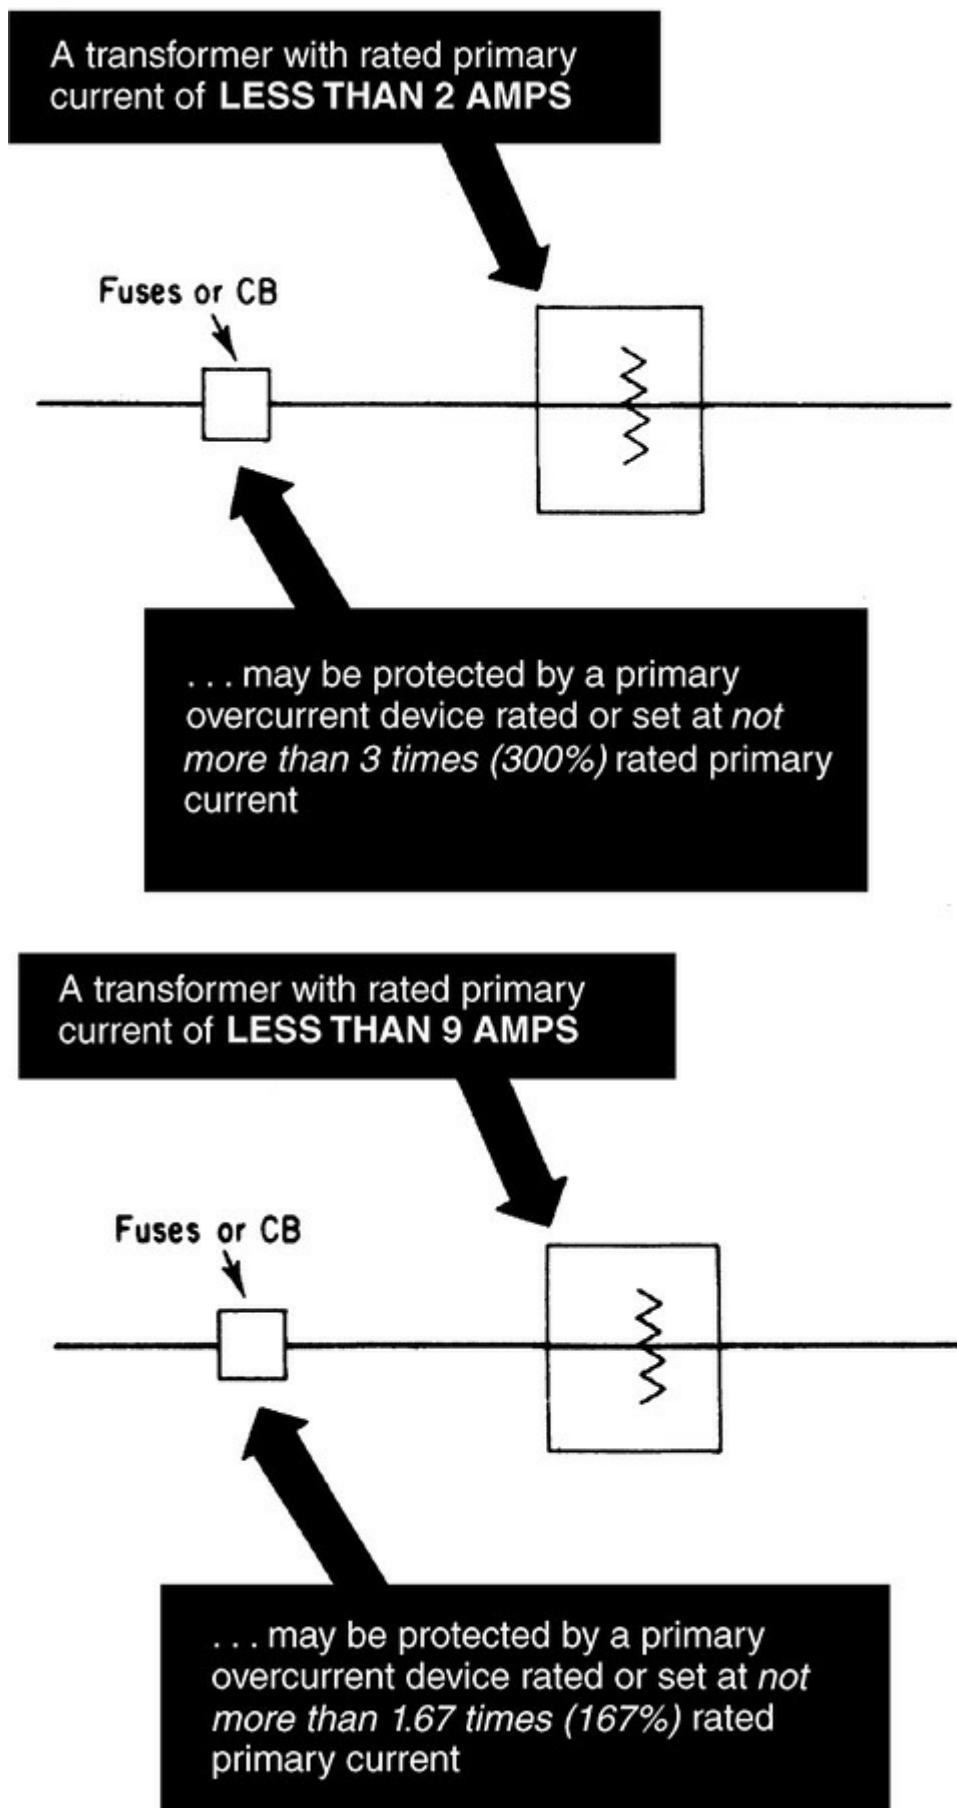

Fig. 450-6. Higher-percent protection is permitted for smaller transformers. (Table 450.3.)

When the rules of Table 450.3(B) are observed, the transformer itself is properly protected and the primary feeder conductors, if sized to correspond, may be provided with the protection required by 240.4. But all considerations on the secondary side of the transformer then have to be separately

and independently evaluated. When a transformer is provided with primary-side overcurrent protection, a whole range of design and installation possibilities are available for secondary arrangement that satisfies the Code. The basic approach is to provide required overcurrent protection for the secondary circuit conductors right at the transformer—such as by a fused switch or CB attached to the transformer enclosure, as shown in Fig. 450-7. Or 10- or 25-ft (3.0- or 7.5-m) taps may be made, as covered in 240.21.

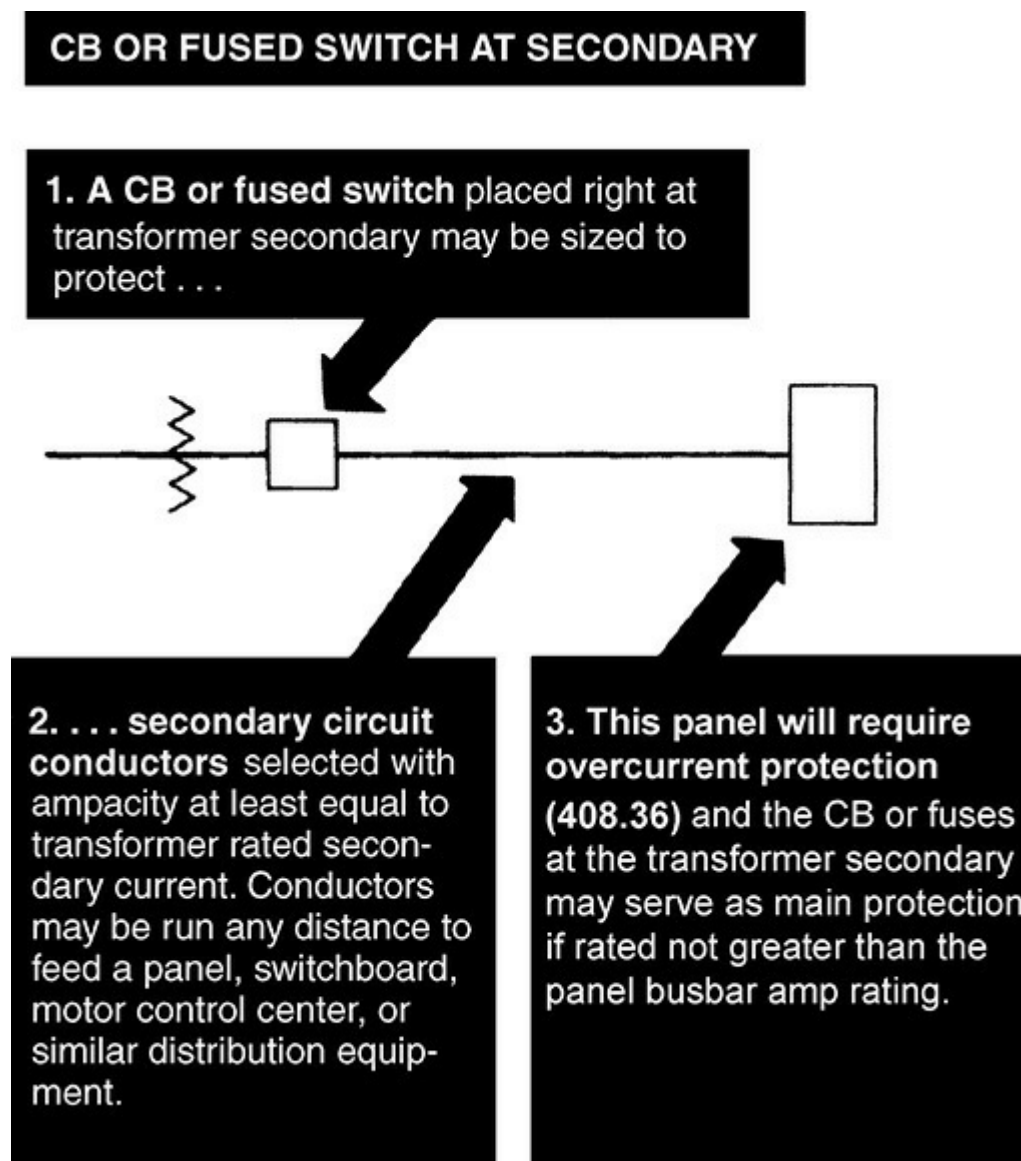

Fig. 450-7. Protection of secondary circuit must be independent of primary-side transformer protection. (Sec. 450.3.)

Transformers operating 1000 V and less, with primary side protection only

There is another acceptable way to protect a 1000-V transformer, described in Table 450.3(B). In this method, the transformer primary may be fed from a circuit which has overcurrent protection (and circuit conductors) rated up to 250 percent (next higher standard size permitted) of rated primary current (instead of 125 percent, as previously)—*but*, in such cases, there must be a protective device on the secondary side of the transformer, and that device must be rated or set at not more than 125 percent of the transformer's rated secondary current (Fig. 450-8). This secondary protective device must be located right at the transformer secondary terminals or not more than the length of a 10- or 25-ft (3.0- or 7.5-m) tap away from the transformer, and the rules of 240.21 on tap conductors must

be fully satisfied.

Fig. 450-8. Secondary protection permits higher-rated primary protective device. (Table 450.3.)

The secondary protective device covered by Table 450.3(B) may readily be incorporated as part of other required provisions on the secondary side of the transformer, such as protection for a secondary feeder from the transformer to a panel or switchboard or motor control center fed from the switchboard. And a single secondary protective device rated not over 125 percent of secondary current may serve as a required panelboard main as well as the required transformer secondary protection, as shown at the bottom of [Fig. 450-9](#).

Fuses or CB, right at transformer secondary, rated not over 125% of rated secondary current satisfies Table 450.3(B) as transformer protection, and the same fuse or CB may serve as protection for secondary feeder conductors and also as main protection that might be required for a lighting panel fed from the transformer.

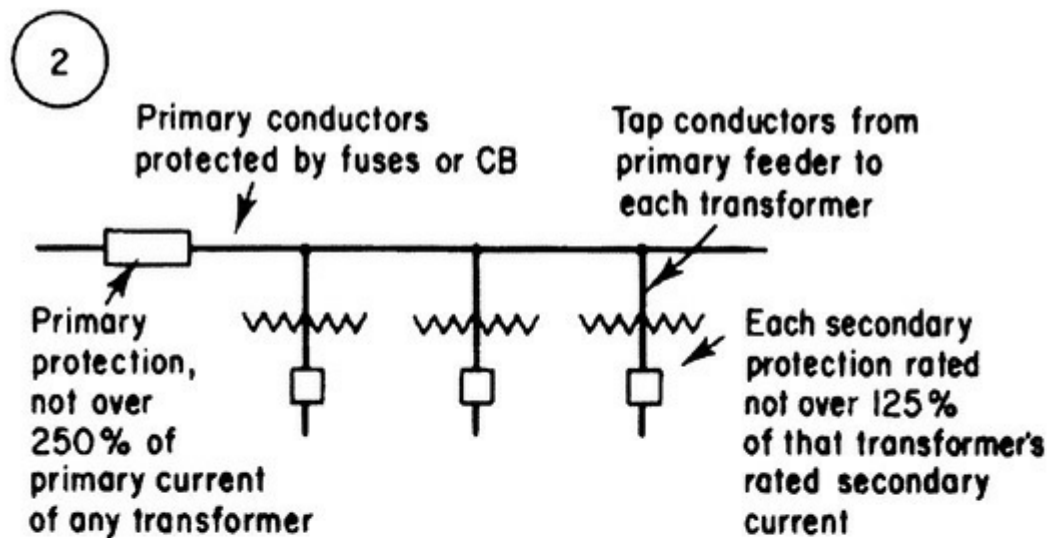

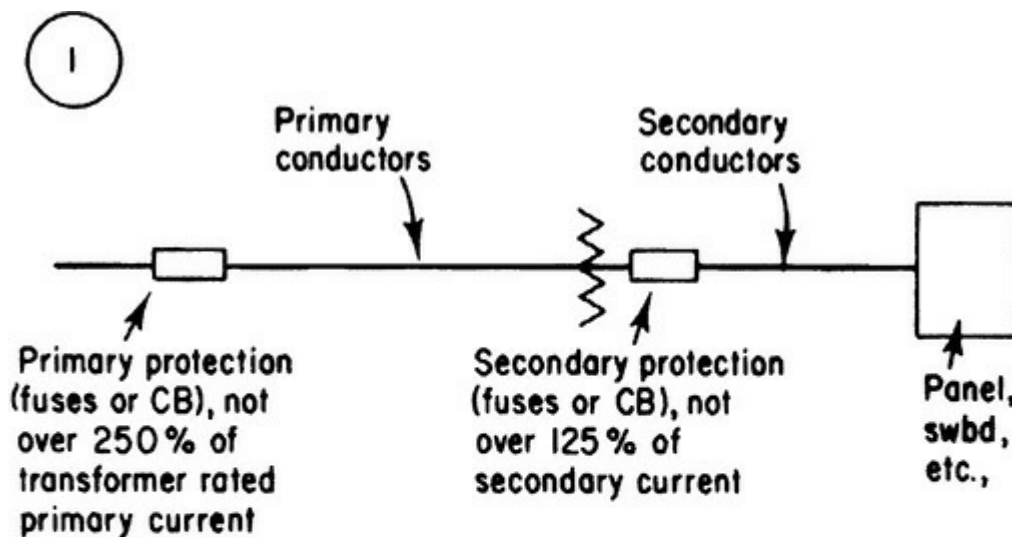

This may be an individual CB or fused switch or may be a panel or switchboard main protection.

NOTE: In both cases, primary and secondary feeder conductors must be sized to be properly protected by the fuses or CB in both the primary and secondary circuit, which will give them more than adequate ampacity for the transformer full-load current.

Fig. 450-9. With 250 percent primary protection, secondary protection may be located like this. (Table 450.3.)

The use of a transformer circuit with primary protection rated up to 250 percent of rated primary

current offers an opportunity to avoid situations where a particular set of primary fuses or CB rated at only 125 percent would cause nuisance tripping or opening of the circuit on transformer inrush current. But the use of a 250 percent rated primary protection has a more common and widely applicable advantage in making it possible to feed two or more transformers from the same primary feeder. The number of transformers that might be used in any case would depend on the amount of continuous load on all the transformers. But in all such cases, the primary protection must be rated not more than 250 percent of any one transformer, if they are all the same size, or 250 percent of the smallest transformer, if they are of different sizes. And for each transformer fed, there must be a set of fuses or CB on the secondary side rated at not more than 125 percent of rated secondary current, as shown in [Fig. 450-10](#).

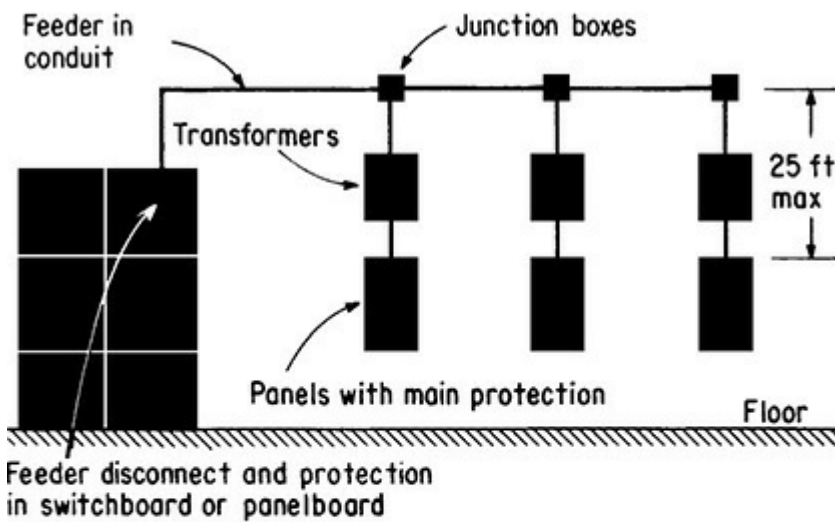

NOTE: Each set of conductors from primary feeder to each transformer may be same size as primary feeder conductors **OR** may be smaller than primary conductors if sized in accordance with 240.21(B)(3)—which permits a 25-ft tap from a primary feeder to be made up of both primary and secondary tap conductors. The 25-ft tap may have any part of its length on the primary or secondary but must be longer than 25-ft and must terminate in a single CB or set of fuses.

Fig. 450-10. With primary 250 percent protection, primary circuit may vary. (Sec. 450.3.)

Figure 450-11 shows an example of application of 250 percent primary protection to a feeder supplying three transformers (such as at the bottom of Fig. 450-10). The example shows how the rules of Table 450.3(B) must be carefully related to 240.21 and other Code rules:

THIS LAYOUT —

— IS HOOKED UP LIKE THIS:

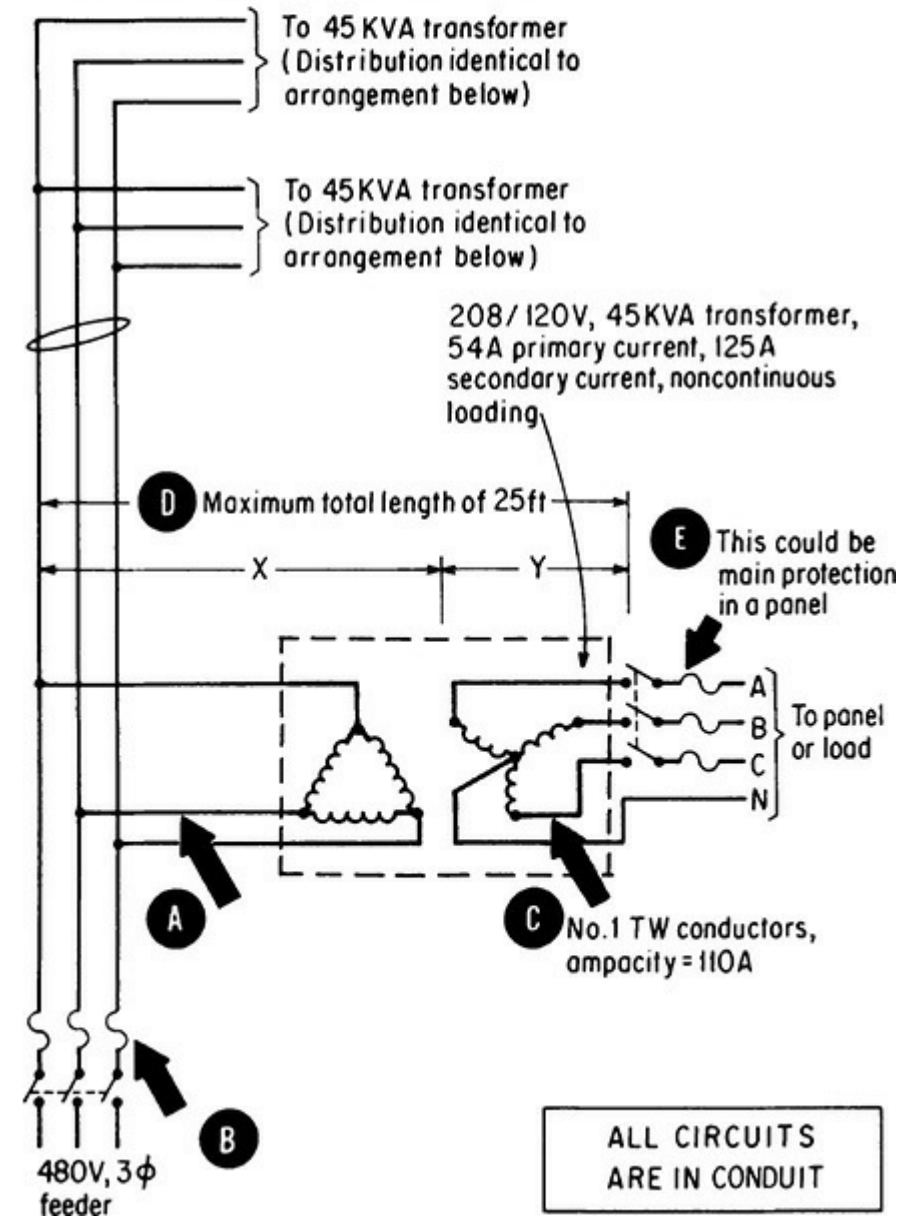

Fig. 450-11. Code rules must be tied together. (Sec. 450.3.)

Part **(B)(3)** of 240.21 of the **NEC** is a rule that covers use of a 25-ft (7.5-m) *unprotected* tap from

feeder conductors, with a transformer inserted in the 25-ft (7.5-m) tap. This rule does not eliminate the need for secondary protection—it makes a special condition for placement of the secondary protective device. It is a restatement of part **(B)(3)** as applied to a tap containing a transformer and applies to both single-phase and 3-phase transformer feeder taps.

Figure 450-11 shows a feeder supplying three 45-kVA transformers, each transformer being fed as part of a 25-ft (7.5-m) feeder tap that conforms to part (B)(3) of 240.21.

Although each transformer has a rated primary current of 54 A at full load, the demand load on each transformer primary was calculated to be 41 A, based on secondary loading. No. 1 THW copper feeder conductors were considered adequate for the total noncontinuous demand load of 3×41 A, or 123 A. A step-by-step analysis of this system follows. Refer to circled letters in the figure:

- A. The primary circuit conductors are No. 6 TW rated at 55 A, which gives them “an ampacity at least $\frac{1}{3}$ that of the *overcurrent protection* from which they are tapped ...,” because these conductors are tapped from the feeder conductors protected at 125 A. No. 6 TW is okay for the 41-A primary current.
- B. The 125-A fuses in the feeder switch properly protect the No. 1 THW feeder conductors, which are rated at 130 A.
- C. The conductors supplied by the transformer secondary must have “an ampacity that, when multiplied by the ratio of the secondary-to-primary voltage, is at least $\frac{1}{3}$ the ampacity of the conductors *or* overcurrent protection from which the primary conductors are tapped ...” The ratio of secondary-to-primary voltage of the transformer is

$$\frac{208 \text{ V}}{480 \text{ V}} = 0.433$$

Note that phase-to-phase voltage must be used to determine this ratio.

Then, for the secondary conductors, 240.21(B)(3)b says that

$$\text{Minimum conductor ampacity} \times 0.433 = \frac{1}{3} \times 125 \text{ A}$$

$$\frac{1}{3} \times 125 = 41.67$$

Then, minimum conductor ampacity equals

$$\frac{41.67}{0.433} = 96 \text{ A}$$

The No. 1 TW secondary conductors, rated at 110 A, are above the 96-A minimum and are, therefore, satisfactory.

- D. The total length of the unprotected 25-ft (7.5-m) tap—that is, the primary conductor length *plus* the secondary conductor length ($x + y$) for any circuit leg—must not be greater than 25 ft (7.5 m).

E. The secondary tap conductors from the transformer must terminate in a single CB or set of fuses that will limit the load on those conductors to their rated ampacity from Table 310.15(B)(16). Note that there is no exception given to that requirement and the “next higher standard device rating” may not be used if the conductor ampacity does not correspond to the rating of a standard device.

The overcurrent protection required at E, at the load end of the 25-ft (7.5-m) tap conductors, must not be rated more than the ampacity of the No. 1 TW conductors.

Max. rating of fuses or CB at E = 110 A

But a 100-A main would satisfy the 96-A secondary load. (*Note: The overcurrent protective device required at E could be the main protective device required for a panel fed from the transformer.*)

Watch Out for This Trap!

Although the foregoing calculation shows how unprotected taps may be made from feeder conductors by satisfying the rules of 240.21(B)(3), the rules of 240.21 are all concerned with PROTECTION OF CONDUCTORS ONLY. Consideration must now be made of *transformer* protection, as follows:

1. Note 240.21(B)(3) makes no reference to *transformer* protection. [240.21(C) is followed by an informational note that references 450.3.] But 450.3 calls for protection of transformers, and there is no exception made for the conditions of part **(B)(3)** to 240.21.
2. It is clear from 450.3(B) and Table 450.3(B) that the transformer shown in [Fig. 450-11](#) is *not* protected by a primary-side overcurrent device rated not more than 125 percent of primary current (54 A), because $1.25 \times 54 \text{ A} = 68 \text{ A}$, maximum.
3. But 450.3(B)(2) does offer a way to provide required protection. The 110-A protection at E *is* secondary protection *rated not over* 125 percent of rated secondary current ($1.25 \times 125 \text{ A}$ secondary current = 156 A). With that secondary protection, a primary feeder overcurrent device rated not more than 250 percent of rated primary current will satisfy 450.3(B)(2). That would call for fuses in the feeder switch (or a CB) (at B in the diagram) rated not over

$250 \text{ percent} \times 54 \text{ A primary current} = 135 \text{ A}$

But, the fuses in the feeder switch are rated at 125 A—which are not in excess of 250 percent of transformer primary current and, therefore, satisfy Table 450.3(B).

In addition to the two basic methods for protecting transformers previously described, Note 3 to Table 450.3(B) also provides for protection with a built-in thermal overload protection, as shown in [Fig. 450-12](#).

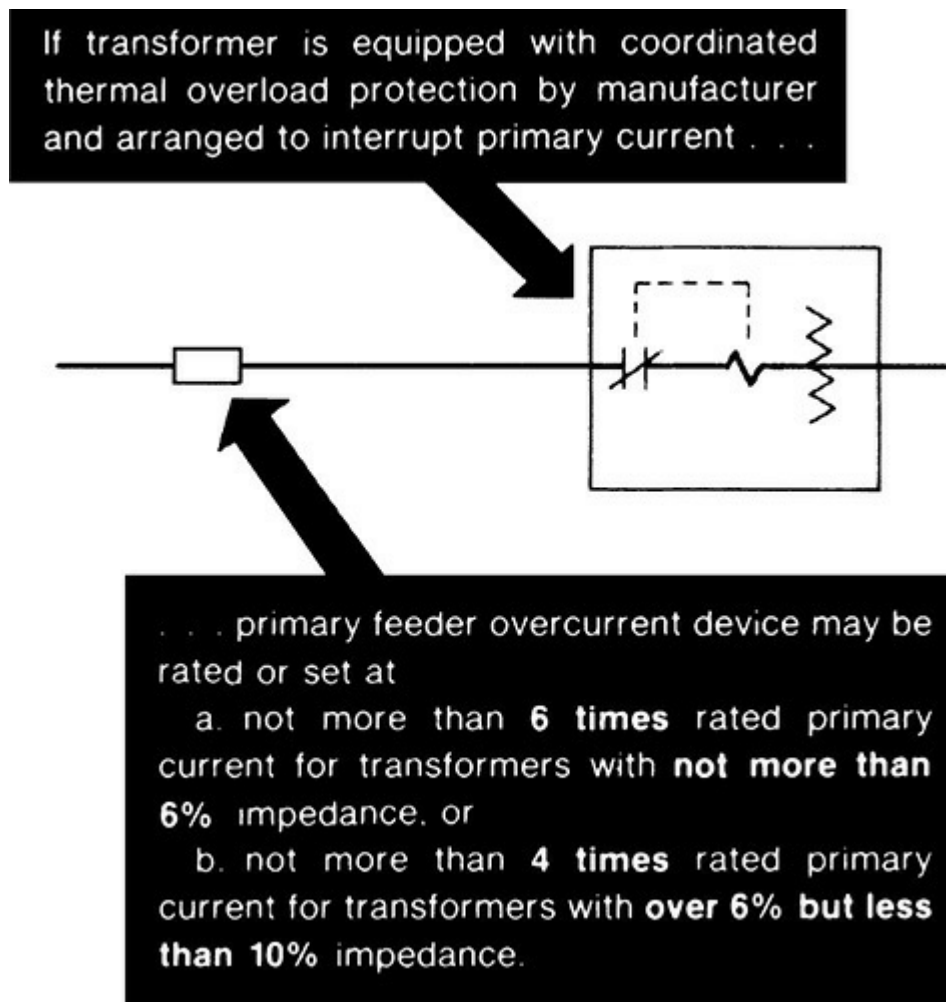

Fig. 450-12. Built-in protection is another technique for transformers. [Note 3 to Table 450.3(B).]

450.4. Autotransformers 1000 V, Nominal, or Less. This section sets the rules for the permitted connections to and the required overcurrent protection for autotransformers. It is important to place these rules in the context of provisions in 210.9 and 215.11 that limit their use in some circumstances. In general, a branch circuit or a feeder may be supplied through an autotransformer only if the system supplied has a grounded conductor that is electrically connected to a grounded conductor of the system supplying the autotransformer, with the following exceptions:

1. An autotransformer can be used to extend or add a branch circuit for an equipment load without the connection to a similar grounded conductor when transforming from a nominal 208-V to a nominal 240-V supply or similarly from 240 to 208 V.
2. In industrial occupancies, where conditions of maintenance and supervision ensure that only qualified persons will service the installation, autotransformers can be used to supply nominal 600-V loads from nominal 480-V systems, and 480-V loads from nominal 600-V systems, without the connection to a similar grounded conductor.

This transformation is commonly employed to connect 480-V equipment in a factory with a 600-V distribution, or vice versa. A 480 to 120-V, two-winding transformer is connected with its windings in series so it functions as an autotransformer, as shown in [Fig. 450-13](#). There is an easy way to determine how to size the two-winding transformer that will be connected in this way. If C = transformation capacity as an autotransformer; X = rated transformation capacity as a two-winding transformer; and R = the voltage ratio of the two windings, then

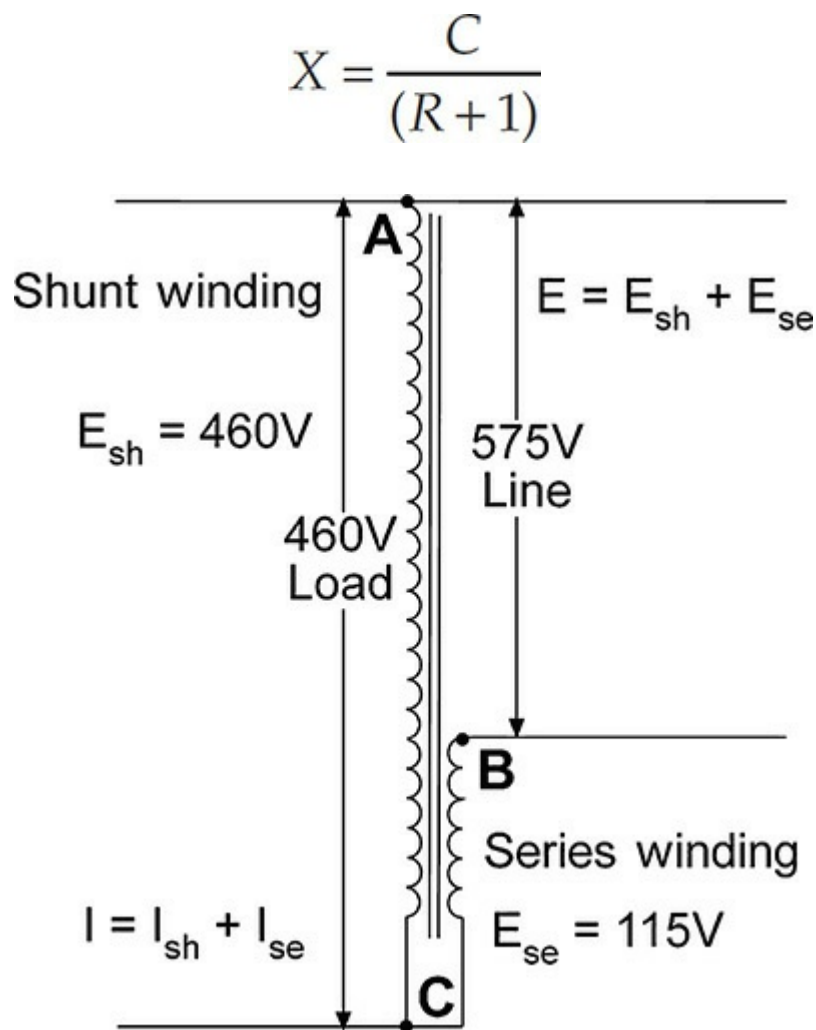

Fig. 450-13. A 480- to 120-V transformer connected as an autotransformer to run 460-V equipment on a 575-V system. (Sec. 450.4.)

example Suppose a 50-hp and a 3-hp motor, both rated 460 V, will be connected to a 575-V, 3-phase system. If two 480 V/120 V two-winding transformers will be connected in open delta to service the loads, what sized transformers should be purchased?

The full-load ratings of the motors must be evaluated using the **NEC** Table 430.250. The 50-hp motor draws 65 A and the 3-hp motor 4.8 A. Converting to kilovolt-amperes, $65 \text{ A} \times 460\sqrt{3}/(1000) = 52 \text{ kVA}$ and $4.8 \text{ A} \times 460\sqrt{3}/(1000) = 4 \text{ kVA}$.

Add 13 kVA (25 percent of the largest motor) to get 69 kVA total.

In the formula, R will be $480 \text{ V} \div 120 \text{ V} = 4$, and C will be 69 kVA.

Then the capacity required will be $69 \text{ kVA} \div 5$ or 14 kVA.

Remember that the capacity of an open delta transformer bank is not the sum of the two transformers; instead, the capacity is that of the two transformers multiplied by half the square root of three. Two 10-kVA two-winding transformers would be a good choice in this case. The final capacity would be $(10 \text{ kVA} + 10 \text{ kVA})(\frac{1}{2}\sqrt{3}) = 17 \text{ kVA}$.

Note that this 480-V transformer (120-V secondary) will be connected to a 600-V supply voltage. The **NEC** requires that field-connected autotransformers be identified for use at the elevated voltage because the dielectric withstand test is often done at a lower level for windings rated 250 V or less, and in this case the 120-V winding must be tested as though it were a 600-V winding. Transformer manufacturers are very familiar with this application and appropriate products are readily available.

The **NEC** requires autotransformers rated 1000 V, nominal, or less be protected by an individual overcurrent device in series with each ungrounded conductor, rated or set at not more than 125 percent of the rated full-load input current of the autotransformer. If this calculation does not correspond to a standard rating and the rated input current is 9 A or more, the next higher standard device is permitted. No overcurrent device is permitted to be placed in series with the shunt winding.

Referring to Fig. 450-13, no overcurrent device should be placed between points “A” and “C.” If the overcurrent device opened and the load impedance were low, the input 575 V would return to the autotransformer at some voltage approaching 575 V across the series winding (between “B” and “C” in Fig. 450-13). Given the 1:4 winding ratio, that could result in a voltage on the 460 V side of the

autotransformer exceeding 2000 V.

As an example of an overcurrent protective device sizing calculation, the two 10-kVA transformers used in the Sec. 5.117 analysis can supply 17.3 kVA of load transformation. In the formula, rearrange the terms to solve for C: $C = X(R + 1)$, or in this case $17.3 \text{ kVA} (4 + 1) = 87 \text{ kVA}$; $87,000 \text{ VA} \div (575 \text{ V} \times \sqrt{3}) = 87 \text{ A}$. This arrangement of autotransformers must be protected at not more than 125 percent of this number, or 108 A, with the next higher standard size protective device (110 A) permitted.

450.5. Grounding Autotransformers. An existing, ungrounded, 480-V system derived from a delta transformer hookup can be converted to grounded operation in two basic ways:

First, one of the three phase legs of the 480-V delta can be intentionally connected to a grounding electrode conductor that is then run to a suitable grounding electrode. Such grounding would give the two ungrounded phases (A and B) a voltage of 480 V to ground. The system would then operate as a grounded system, so that a ground fault (phase-to-conduit or other enclosure) on the secondary can cause fault-current flow that opens a circuit protective device to clear the faulted circuit.

But corner grounding of a delta system does not give the lowest possible phase-to-ground voltage. In fact, the voltage to ground of a corner-grounded delta system is the same as it is for an ungrounded delta system because voltage to ground for ungrounded circuits is defined as the greatest voltage between the given conductor and any other conductor of the circuit. Thus, the voltage to ground for an ungrounded delta system is the maximum voltage between any two conductors, on the assumption that an accidental ground on any one phase puts the other two phases at full line-to-line voltage aboveground.

In recognition of increasing emphasis on the safety of grounded systems over ungrounded systems, 450.5 covers the use of zig-zag grounding autotransformers to convert 3-phase, 3-wire, ungrounded delta systems to grounded wye systems. Such grounding of a 480-V delta system, therefore, lowers the voltage to ground from 480 V (when ungrounded) to 277 V (the phase-to-grounded-neutral voltage) when converted to a wye system (Fig. 450-14).

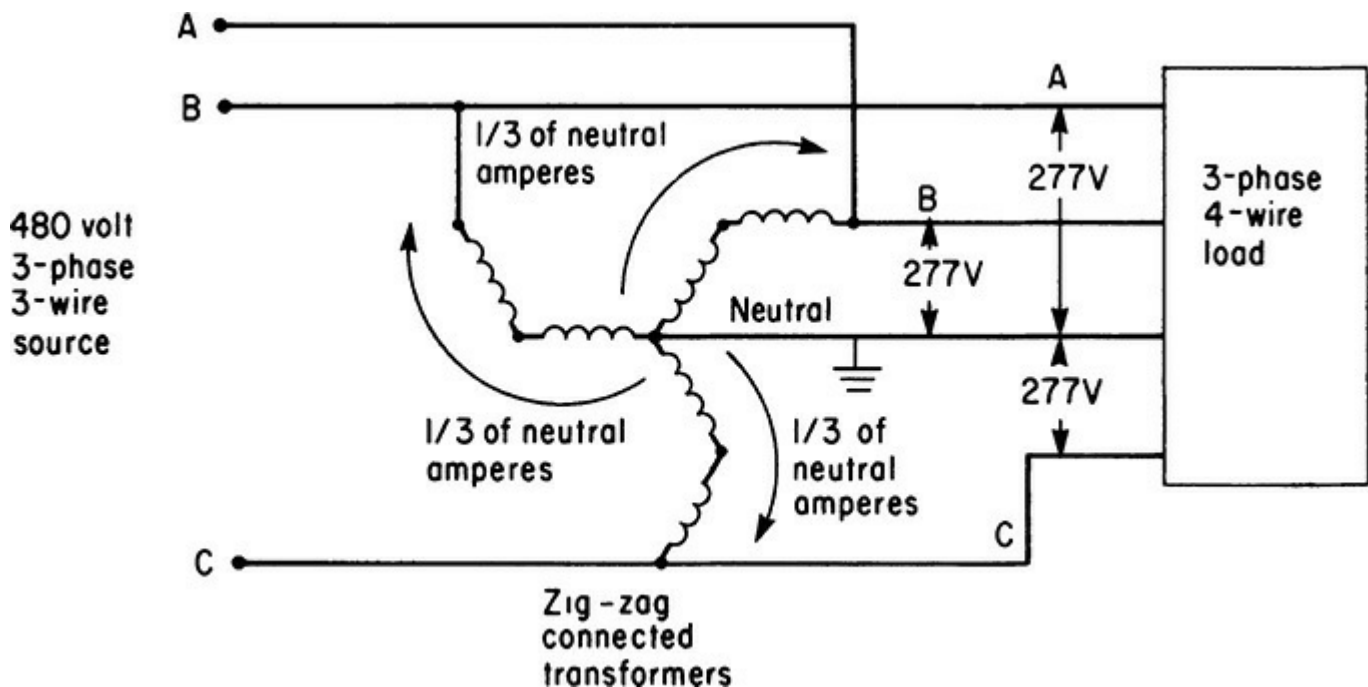

Fig. 450-14. Zig-zag transformer changes voltage to ground from 480 to 277 V. (Sec. 450.5.)

A zig-zag grounding autotransformer gets its name from the angular phase differences among the six windings that are divided among the three legs of the transformer's laminated magnetic core assembly. The actual hookup of the six windings is an interconnection of two wye configurations,

with specific polarities and locations for each winding. Just as a wye or delta transformer hookup has a graphic representation that looks like the letter Y or the Greek letter Δ , so a zig-zag grounding autotransformer is represented as two wye hookups with pairs of windings in series but phase-displaced, as in Fig. 450-15.

Fig. 450-15. Windings of zig-zag transformer provide for flow of fault or neutral current. (Sec. 450.5.)

With no ground fault on any leg of the 3-phase system, current flow in the transformer windings is balanced, because equal impedances are connected across each pair of phase legs. The net impedance of the transformer under balanced conditions is very high, so that only a low level of magnetizing current flows through the windings. But when a ground fault develops on one leg of the 3-phase system, the transformer windings become a very low impedance in the fault path, permitting a large value of fault current to flow and operate the circuit protective device—just as it would on a conventional grounded-neutral wye system, as shown in Fig. 450-16.

Fig. 450-16. Zig-zag transformer converts ungrounded system to grounded operation. (Sec. 450.5.)

Because the kilovolt-ampere rating of a grounding autotransformer is based on short-time fault current, selection of such transformers is much different from sizing a conventional 2-winding transformer for supplying a load. Careful consultation with a manufacturer's sales engineer should precede any decisions about the use of these transformers.

Such transformers shall have a continuous per-phase current rating and a continuous neutral current rating. Zig-zag connected transformers must never be connected on the load side of system grounding connections, including those made in accordance with 250.24(B), 250.30(A)(1), or 250.32(B) Exception No. 1.

Part (A) of the section covers the use of these transformers when an actual 480Y/277V distribution system is being created. Zig-zag grounding autotransformers are comprised of two three-phase wye connections in series. Figure 450-17 shows most of the requirements as well as the angular displacements that give the transformation its name. The inner connections are a straightforward wye, and close inspection of the three outer segments of the pinwheel shows that they are also oriented in a wye configuration. In fact, at least one major transformer manufacturer now sells zig-zag customers three 2-winding transformers (thus, six windings) along with instructions as to how to connect them to achieve this result. (See also the right side of Fig. 450-15.) The simultaneous disconnection rule is crucial because if a single-pole overcurrent device were to open, the grounding transformer will no longer function as intended, including a strong likelihood of dangerous transient overvoltages on its load side. A grounding autotransformer used to create a 3-phase, 4-wire distribution system must comply with the following four requirements:

Fig. 450-17. Zig-zag connections must meet numerous **NEC** requirements. (Sec. 450.5.)

1. The transformer must be directly connected to the ungrounded phase conductors and never switched or provided with overcurrent protection that is independent of the main switch and common-trip overcurrent protection for the 3-phase, 4-wire system. A transformer used to limit transitory overvoltages must be of suitable rating and must be connected in accordance with this rule.
2. An overcurrent sensing device must be provided that will cause the main switch or common-trip overcurrent protection previously discussed to open if the load on the autotransformer reaches or exceeds 125 percent of the continuous current per-phase or neutral rating. Delayed tripping for temporary overcurrents sensed at the autotransformer overcurrent device is permitted for the purpose of allowing proper operation of branch or feeder protective devices on the 4-wire system.
3. A fault-sensing system that causes the opening of a main switch or common trip overcurrent device for the 3-phase, 4-wire system must be provided to guard against single phasing or internal faults. An explanatory note advises that this can be accomplished by the use of two subtractive-connected donut-type current transformers installed to sense and signal when an unbalance occurs in the line current to the autotransformer of 50 percent or more of rated current.
4. The autotransformer must have a continuous neutral-current rating that is sufficient to handle the maximum possible neutral unbalanced load current of the 4-wire system.

Note that there is now an express prohibition in the parent language regarding installing a zig-zag on the load side of any system grounding connection. These transformer hookups are never a substitute for running a neutral to a load, regardless of how remote. If the supply system is grounded at any point, then a parallel neutral return path will exist and this will desensitize the protective controls for the transformer.

This prohibition also follows from the fact that if a zig-zag grounding transformer is connected to a grounded system, and a ground fault occurs upstream, that fault current will share a ground-fault return path through both the supply (or system) main bonding jumper and also the derived neutral connection in the grounding transformer. If the upstream fault is large, such as a failure on a large capacity feeder, the current run through the grounding transformer can be enough to destroy it. In the past, zig-zag transformer hookups have been erroneously applied in instances where a remote location was served from a feeder that did not include a neutral, but it was later decided to change the local load profile to one that included line-to-neutral loads.

If a neutral is required on a remote point on a grounded system it must be brought to that point. If running the system neutral is truly onerous, another possibility is to install a fully-rated delta-wye transformer to create a separately derived 480Y/277V system at the desired location.

Part **(B)** covers grounding autotransformers that do not supply utilization loads, but instead merely provide a ground reference and a specified magnitude of ground-fault current for the operation of ground-responsive protective devices, typically so an ungrounded system can be grounded through an impedance. Refer to [Fig. 450-18](#), but insert the grounding impedance as indicated and eliminate all load connections to the neutral. There are three requirements:

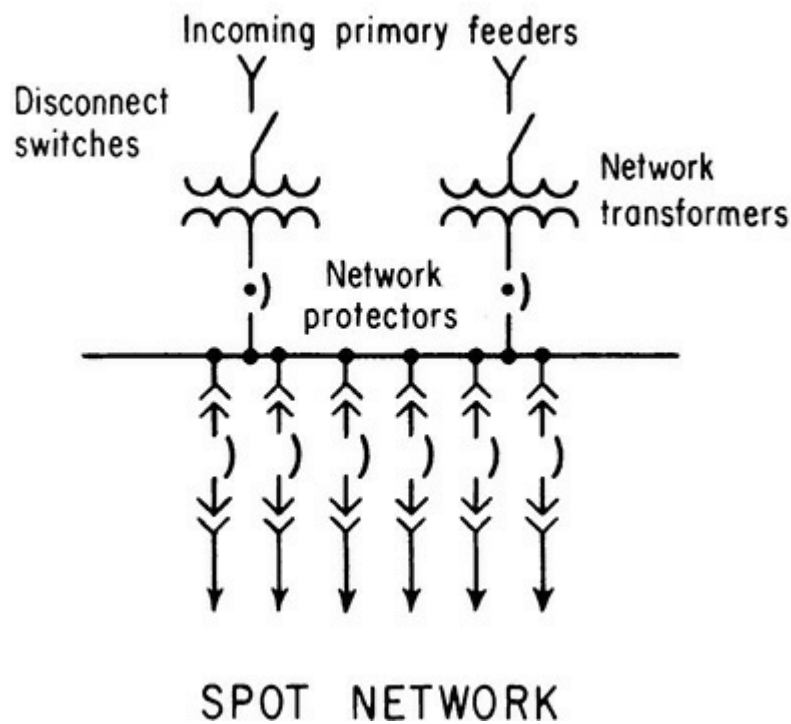

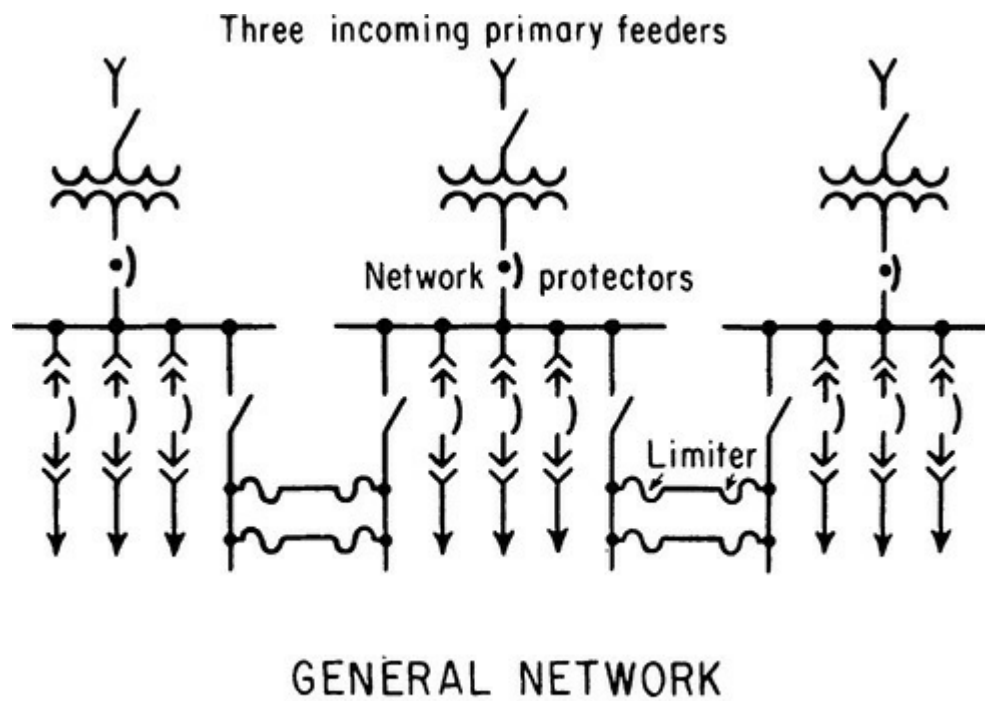

Fig. 450-18. These are the two basic types of network systems. (Sec. 450.6.)

1. The autotransformer must have a continuous neutral current rating sufficient for the specified ground-fault current.
2. An overcurrent device having an interrupting rating suitable for the fault current available at its supply terminals, and that will open simultaneously all ungrounded conductors when it operates, must be connected in the grounding autotransformer branch circuit.
3. This overcurrent protection must be rated or set at a current not exceeding 125 percent of the autotransformer continuous per-phase current rating or 42 percent of the continuous-current rating of any series-connected devices in the autotransformer neutral connection. Delayed

tripping for temporary overcurrents to permit the proper operation of ground-responsive tripping devices on the main system is permitted but must not exceed values that would be more than the short-time current rating of the grounding autotransformer or any series connected devices in the neutral connection.

The 42 percent rule reflects the fact that the current in each phase is 33 percent of the neutral return current, and 125 percent of this is about 42 percent. An exception follows for high-impedance grounded systems, for which the 125 percent rule is impracticable because the neutral current through the impedance is so low that 125 percent of this current does not come close to a conventional overcurrent device setting or rating.

For high-impedance grounded systems covered in 250.36, where the maximum ground-fault current is designed to be not more than 10 A, and where the grounding autotransformer and the grounding impedance are rated for continuous duty, an overcurrent device rated not more than 20 A that will simultaneously open all ungrounded conductors can be installed on the line side of the zig-zag.

450.6. Secondary Ties. In industrial plants having very heavy power loads it is usually economical to install a number of large transformers at various locations within each building, the transformers being supplied by primary feeders operating at voltages up to 13,800 V. One of the secondary systems that may be used in such cases is the network system.

The term *network system* as commonly used is applied to any secondary distribution system in which the secondaries of two or more transformers at different locations are connected together by secondary ties. Two network layouts of unit subs are shown in [Fig. 450-18](#). In the spot network, two or three transformers in one location or “spot” are connected to a common secondary bus and divide the load. Upon primary or transformer fault, the secondary is isolated from the faulted section by automatic operation of the network protector, providing a high order of supply continuity in the event of faults. The general form of the network system is similar, except that widely separated individual substations are used with associated network protectors, and tie circuits run between the secondary bus sections. The system provides for interchange of power to accommodate unequal loading on the transformers. Limiters protect the ties. The purpose of the system is to equalize the loading of the transformers, to reduce voltage drop, and to ensure continuity of service. The use of this system introduces certain complications, and, to ensure successful operation, the system must be designed by an experienced electrical engineer.

The provisions of 450.3 govern the protection in the primary. Refer to [Fig. 450-18](#). The network protector consists of a CB and a reverse-power relay. The protector is necessary because without this device, if a fault develops in the transformer, or, in some cases, in the primary feeder, power will be fed back to the fault from the other transformers through the secondary ties. The relay is set to trip the breaker on a reverse-power current not greater than the rated secondary current of the transformer. This breaker is not arranged to be tripped by an overload on the secondary of the transformer.

450.6(A)(3) provides that:

1. Where two or more conductors are installed in parallel, an individual protective device is provided at each end of each conductor.
2. The protective device (fusible link or CB) does not provide overload protection, but provides short-circuit protection only.

In the case of a short circuit, the protective device must open the circuit before the conductor reaches a temperature that would injure its insulation. The principles involved are that the entire system is so designed that the tie conductors will never be continuously overloaded in normal

operation—hence protection against overloads of less severity than short circuits is not necessary—and that the protective devices should not open the circuit and thus cause an interruption of service on load peaks of such short duration that the conductors do not become overheated.

A limiter is a special type of fuse having a very high interrupting capacity. Figure 450-19 is a cross-sectional view of one type of limiter. The cable lug, the fusible section, and the extension for connection to the bus are all made in one piece from a length of copper tubing, and the enclosing case is also copper. A typical device of this type is rated to interrupt a current of 50,000 A without perceptible noise and without the escape of flame or gases from the case.

Fig. 450-19. A *limiter* is a cable connection device containing a fusible element. (Sec. 450.6.)

Figure 450-20 is a single-line diagram of a simple 3-phase industrial-plant network system. The primary feeders may operate at any standard voltage up to 13,800 V, and the secondary voltage would commonly be 480 V. The rating of the transformers used in such a system would usually be within the range of 300 to 1000 kVA. The diagram shows two primary feeders, both of which are carried to each transformer, so that by means of a double-throw switch each transformer can be connected to either feeder. Each feeder would be large enough to carry the entire load. It is assumed that the feeders are protected in accordance with 450.3(A) so that no primary overcurrent devices are required at the transformers. The secondary ties consist of two conductors in multiple per phase and it will be noted that these conductors form a closed loop. Switches are provided so that any section of the loop, including the limiters protecting that section, can be isolated in case repairs or replacements should be necessary.

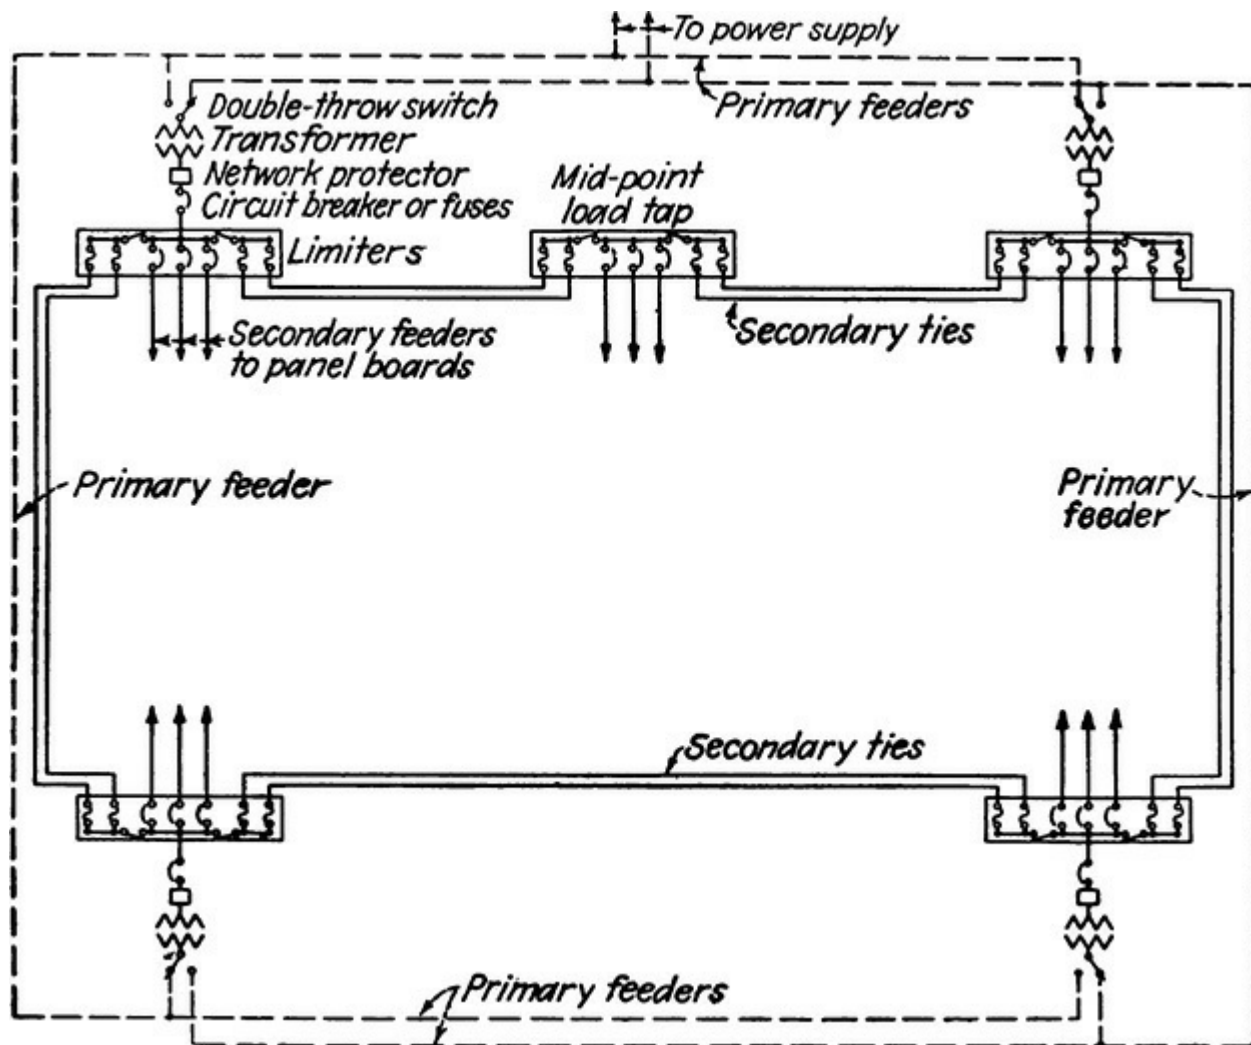

Fig. 450-20. A typical industrial-plant network distribution system. (Sec. 450.6.)

450.7. Parallel Operation. To operate satisfactorily in parallel, transformers should have the same percentage impedance and the same ratio of reactance to resistance. Information on these characteristics should be obtained from the manufacturer of the transformers.

450.8. Guarding. Figure 450-21 summarizes these rules. Refer to 110.27 on guarding of live parts. Safety to personnel is always important, particularly where a transformer is to operate with live parts. To protect against accidental contact with such components, isolate the unit or units in a room or place accessible only to qualified personnel and guard live parts, such as with a railing. When elevation is used for safeguarding live parts, consult 110.34(E) and 110.27.

1. Transformers must be protected against physical damage.
2. Exposed live parts must be protected against accidental contact by putting the transformer in a room or place accessible only to qualified personnel or by keeping live parts above the floor in accordance with Table 110.34(E).

ISOLATION

ELEVATION - OUTDOORS

3. Signs or other visible markings must be used on equipment or structure to indicate the operating voltage of exposed live parts

WARNING FOR HIGH VOLTAGE

Fig. 450-21. Transformer installations must be effectively guarded. (Sec. 450.8.)

As noted in part (C), switches and other equipment operating at up to 1000 V and serving only circuits within a transformer enclosure may be installed within the enclosure *if* it is accessible to qualified persons only. This is intended to be part of the requirement that exposed, energized parts must be properly guarded. Part (D) requires that the operating voltage of exposed live parts be posted on the equipment or support structures.

450.9. Ventilation. As noted in the last paragraph, ventilation grilles or slots in the sides or back of transformer enclosures must have adequate clearance from walls and objects to ensure free and substantial airflow through the case. Further, the required clearance must be "clearly marked" on the transformer. Because of the tight quarters in today's electrical rooms and the tendency to give as little space as possible to electrical equipment, this is a critically important installation requirement to ensure safety and trouble-free operation of enclosed transformers. The substantiation for this proposal stated the following:

Today's widespread use of dry type power transformers indoors has resulted in the common practice of their being installed directly up against walls completely blocking the rear vents. As inspectors, we frequently wind up trying to find out if the transformer installation instructions are anywhere around so we can see what clearances the manufacturer has specified.

Clearly, this is not the best system. Furnaces, for example, commonly have required clearances marked on the nameplate. This

proposal will let people know that clearances are required. Secondly, it will let us know what these clearances are.

450.10. Grounding. The 2014 **NEC** has completely reworked this section to address field problems involved with making equipment grounding connections in dry transformer connection enclosures. If the transformer makes its circuit connections using terminals and wired equipment grounding conductor or supply-side bonding conductors or both are used, then a terminal bar must be installed to receive the grounding connections. The paint must be scraped away to ensure a sound connection, and the bar must not land on or over any vented part of the enclosure. If the transformer uses leads instead of terminals, then any connection method compliant with 250.8 and bonded to the enclosure (if metallic) is sufficient.

450.11. Marking. This section appears in a list format as of the 2014 **NEC**, with a separate part (B) covering wiring the normal secondary side of a transformer as a primary; for example, taking a normal step-down transformer and wiring it to step-up the voltage. This is only permitted if the manufacturer has recognized the reverse transformation in the installation instructions. Such transformers are frequently marked “bidirectional.” Note that higher than usual inrush currents may result from these connections, and some modifications may be necessary with respect to the time-delay characteristics of the primary side overcurrent protective devices.

(See [Fig. 450-22](#), top.)

Fig. 450-22. Basic rule calls for every transformer to have adequate ventilation and ready, easy, direct access for inspection or maintenance. (Secs. 450.9 and 450.13.)

450.13. Accessibility. Accessibility is an important location feature of transformer installation. The **NEC** generally requires a transformer (whether liquid-filled or dry-type) to be readily accessible to qualified personnel for inspection and maintenance ([Fig. 450-22](#)). That is, it must be capable of being reached quickly for operation, repair, or inspection without requiring use of a portable ladder to get at it, and it must not be necessary to climb over or remove obstacles to reach it. A transformer may be mounted on a platform or balcony, but there must generally be fixed stairs or a fixed ladder for access to the transformer ([Fig. 450-23](#)). However, there are some alternatives in subparts (A) and (B):

Fig. 450-23. Transformers must be “readily accessible” without need for portable ladder to reach them. (Sec. 450.13.)

Part (A) permits dry-type transformers rated 1000 V or less to be located “in the *open* on walls, columns, or structures”—without the need to be readily accessible. This allowance does not apply to a liquid-cooled transformer. A transformer suspended from the ceiling or hung on a wall—in which cases a ladder would be required to reach them because they are over 6½ ft (1.98 m) above the floor—would be okay, as shown in [Fig. 450-24](#). There is no kilovolt-ampere limit on this provision, as opposed to the next paragraph. Part (B) permits dry-type transformers up to 1000 V, 50 kVA, to be installed in fire-resistant hollow spaces of buildings not permanently closed in by structure, provided the transformer is designed to have adequate ventilation for such installation. (See [Fig. 450-25](#).)

Fig. 450-24. Transformer mounted on wall (or suspended from ceiling) would be considered not readily accessible because a ladder would be needed to reach it. But, because it is “in the open,” such use conforms to 450.13(A). (Sec. 450.13.)

Fig. 450-25. Recessed mounting of dry-type transformers is permitted within hollow spaces of buildings, generally including spaces above suspended ceilings but not limited to those areas as this figure illustrates. (Sec. 450.13.)

Note in part (A) that a transformer *may* be *not* readily accessible only if it is located in the *open*. The words “in the open” do not readily and surely relate to such words as “concealed” or “exposed.” But it is reasonable to conclude that “in the open” would be difficult to equate with “above a suspended ceiling.” The latter location is in a generally smaller, confined space in which the transformers must be readily accessible; part (A) must be taken as a condition in which a transformer does *not* have to be readily accessible—that is, that it may be mounted up high where a portable ladder would be needed to get at it. And, the wording of part (B) specifically recognizes installation of transformers rated 50 kVA or less to be installed in “hollow spaces” such as hung ceilings (Fig. 450-26).

Fig. 450-26. Watch out for transformers above suspended ceilings. (Sec. 450.13.)

450.14. Disconnecting Means. Except for Class 2 or Class 3 control transformers, there is now (as of the 2011 **NEC**) a requirement for a disconnecting means for transformers for the first time. The disconnect need not be in sight of the transformer, but if it is remote, then it must be capable of being locked open, and the transformer must be field-marked to indicate the location of the remote disconnect.

450.21. Dry-Type Transformers Installed Indoors. This rule differentiates between dry-type transformers based on kilovolt-ampere rating. All dry-type transformers rated at $112\frac{1}{2}$ kVA or less, at up to 35 kV, must be installed so that a minimum clearance of 12 in. (305 mm) is provided between the transformer and any combustible material, or a fire barrier must be provided.

The last sentence in 450.21(A) recognizes the use of fire-resistant heat-insulating barriers instead of space separation for transformers rated not over $112\frac{1}{2}$ kVA. *But* be aware that clearances required to ensure proper ventilation of the transformer *must* be provided to satisfy 450.9. That is, the minimum clearance called for by the manufacturer to ensure proper airflow for cooling must be provided between the insulating barrier and the transformer's ventilation openings.

The exception permits those transformers rated 1000 V or less that are completely enclosed to be installed closer than the 12-in. (300-mm) minimum, but consideration must always be given to the requirements of 450.9 for those enclosed transformers with ventilation openings, as indicated in the previous paragraph.

For units rated over $112\frac{1}{2}$ kVA, part (B) of the rule basically calls for such transformers to be installed in vaults, with two exceptions for high-temperature insulation systems provided. [Figure 450-27](#) shows the rules of this section. Related application recommendations are as follows:

TRANSFORMERS RATED 112½ KVA OR LESS

TRANSFORMERS RATED OVER 112½ KVA

Completely enclosed and ventilated unit with Class 155 or higher insulation...

... may be installed in any room or area (need not be fire-resistant)

Clearances from combustible materials in any room or area (not fire-resistant)

Dry-type transformer with Class 155 or higher insulation but not enclosed and ventilated

Room of fire-resistant construction to house transformer

Dry transformer with less than Class 155 insulation

Dry transformer rated over 35 KV...

... must be in *NE Code* constructed transformer vault (Part III, Art.450)

Fig. 450-27. Construction of dry-type transformer affects indoor installation rules. (Sec. 450.21.)

- Select a place that has the driest and cleanest air possible for installation of open-ventilated

units. Avoid exposure to dripping or splashing water or other wet conditions. Outdoor application requires a suitable housing. Try to find locations where transformers will not be damaged by floodwater in case of a storm, a plugged drain, or a backed-up sewer.

- Temperature in the installation area must be normal, or the transformer may have to be derated. Modern standard, ventilated, dry-type transformers are designed to provide rated kilovolt-ampere output at rated voltage when the maximum ambient temperature of the cooling air is 40°C and the average ambient temperature of the cooling air over any 24-h period does not exceed 30°C. At higher or lower ambients, transformer loading can be adjusted by the following relationships:

1. For each degree Celsius that average ambient temperature exceeds 30°C, the maximum load on the transformer must be reduced by 1 percent of rated kilovolt-amperes.
2. For each degree Celsius that average ambient temperature is less than 30°C, the maximum load on the transformer may be increased by 0.67 percent of rated kilovolt-amperes.

Depending on the type of insulation used, transformer insulation life will be cut approximately in half for every 10°C that the ambient temperature exceeds the normal rated value—or doubled for every 10°C below rated levels. Estimates assume continuous operation at full load. With modern insulations this rule is actually conservative for ambient temperature below normal operating temperatures and optimistic above it.

For proper cooling, dry-type transformers depend on circulation of clean air—free from dust, dirt, or corrosive elements. Filtered air is preferable and may be mandatory in some cases of extreme air pollution. In any case, it can reduce maintenance.

In restricted spaces—small basement mechanical rooms and the like—ventilation must be carefully checked to ensure proper transformer operating temperature. The usual requirement is for 100 cfm of air movement for each kilowatt of transformer loss. Areas of inlet and outlet vent openings should be at least 1 net sq ft per 100 kVA of rated transformer capacity.

Height of vault, location of openings, and transformer loading affect ventilation. One manufacturer calls for the areas of the inlet and outlet openings to be not less than 60 sq ft per 1000 kVA when the transformer is operating under full load and is located in a restricted space. And a distance of 1 ft should be provided on all sides of dry-type transformers as well as between adjacent units.

Freestanding, floor-mounted units with metal grilles at the bottom must be set up off the floor a sufficient distance to provide the intended ventilation draft up through their housings.

The installation location must not expose the transformer housing to damage by normal movement of persons, trucks, or equipment. Ventilation openings should not be exposed to vandalism or accidental or mischievous poking of rubbish, sticks, or rods into the windings. Adequate protection must be provided against possible entry of small birds or animals.

450.22. Dry-Type Transformers Installed Outdoors. A transformer that sustains an internal fault that causes arcing and/or fire presents the same hazard to adjacent combustible material whether it is installed indoors or outdoors. For that reason, a clearance of at least 12 in. (300 mm) is required between any dry-type transformer rated over 112½ kVA and combustible materials of buildings where installed outdoors.

As an alternative, the clearance of 12 in. (300 mm) from combustible building materials is *not* required for outdoor dry-type transformers that have a Class 155 insulation system and are completely enclosed, except for ventilation openings. The same consideration given for an 80°C-rise

(Class 155) transformer is made outdoors as it is indoors, in Exception No. 2 in 450.21(B).

450.23. Less-Flammable Liquid-Insulated Transformers. 450.23 covers the liquid-filled transformers that have essentially replaced askarel-insulated transformers. Because oil-filled transformers used indoors require a transformer vault, the *less-flammable* (also called *high-fire-point*) insulated transformer offers an alternative to the oil-filled transformers, without the need for a vault. This Code section permits installation of these high-fire-point liquid-insulated transformers indoors or outdoors. Over 35 kV indoors, such a transformer must be in a vault.

The rules of this section recognize that these various high-fire-point liquid-insulated dielectrics are less flammable than the mineral oil used in oil-filled transformers but not as fire-resistant as askarel. Because these askarel substitutes will burn to some degree, Code rules are aimed at minimizing any fire hazards:

1. Less-flammable liquid dielectrics used in transformers must, first of all, be listed—that is, tested and certified by a testing laboratory or organization and shown in a published listing as suitable for application. *Less-flammable* liquids for transformer insulation are defined as having “a fire point of not less than 300°C.”
2. Transformers containing the high-fire-point dielectrics may be used *without a vault* but only within buildings of noncombustible construction or limited combustibility (brick, concrete, etc.) and then only in rooms or areas that do not contain combustible materials. A Type I or Type II building is a building of noncombustible construction or limited combustibility, as described in the informational note and also in the Informative Annex E at the end of the Code book, and there must be no combustible materials stored in the area where the transformer is installed.
3. The entire installation must satisfy all conditions of use, as described in the listing of the liquid. There are two major testing laboratories with listing programs for these transformers (FM and UL) and there are very substantial differences between their procedures. Make certain to carefully explore the requirements that are imposed by the particular listing agency. The 2017 **NEC** added identical informational notes on this topic, one following 450.23(A)(1)d and one following 450.23(B)(1), which provide context allowing some advance understanding of the sort of conditions that one might expect as part of listing restrictions on the liquid. These could include the maximum tank pressure, whether pressure-relief valves must be provided, appropriate fuse characteristics, and how overcurrent protection is sized, among other possibilities.

Be careful: The wording in 450.23(A) has been incorrectly formatted due major software issues involved in the processing of the 2017 edition, and it has become completely unusable as a result. **NFPA** has refused to classify this as an erratum, so it will stand until it is corrected with a TIA. The overview is that the mandatory provisions of the rule are supposed to be unchanged from the 2014 edition. Indoor installations are supposed to be permissible provided you comply with one of three approaches, (1), (2), or (3). The first approach should have four conditions, set up as a list of four lettered items (a., b., c., and d.). Then follows, correctly and new for the 2017 edition, is the informational note described in the prior paragraph, and directly addressing item d (hence its location.) Following this are supposed to come the other two approaches, which should have been numbered (2) (on sprinklers and containment) and (3) (on compliance with flammable liquid rules). Instead, the software caused these provisions to print as items e and f, making them additional factors in the first option, and removing them as

options in their own right. Until this is corrected, you will need to work with the inspector on this.

4. A liquid-confinement area must be provided around such transformers that are not in a vault, because tests indicate these liquids are not completely nonpropagating—that is, if they are ignited, the flame will be propagated along the liquid. A propagating liquid must be confined to a given area to confine the flame of its burning (Fig. 450-28). The liquid-confinement area (a curb or dike around the transformer) must be of sufficient dimensions to contain the entire volume of liquid in the transformer.

Fig. 450-28. Transformers containing askarel-substitute liquids must satisfy specific installation requirements. (Sec. 450.23.) This drawing shows the way the **NEC** is intended to read by the Code-making panel, and not the way it has been printed. See text.

A less-flammable liquid-insulated transformer installed in such a way that all of conditions 2 and 3 are not satisfied must be *either*

1. Provided with an automatic fire extinguishing system and a liquid-confinement area, or
2. Installed in a Code-specified transformer vault (Part III of Art. 450), without need for a liquid-confinement area

Less-flammable liquid-insulated transformers rated over 35 kV and installed indoors must be

enclosed in a Code-constructed transformer vault. All less-flammable liquid-insulated transformers installed outdoors may be attached to or adjacent to or on the roof of Type I or Type II buildings. Such installation at other than Type I or Type II buildings, where adjacent to combustible material, fire escapes, or door or window openings, must be guarded by fire barriers, space separation, and compliance with instructions for using the particular liquid.

Because these rules are general in nature and lend themselves to a variety of interpretations, application of these requirements may depend heavily on consultation with inspection authorities.

Although askarel-filled transformers up to 35 kV were used for many years for indoor applications because they do not require a transformer vault, there has been a sharp, abrupt discontinuance of their use over recent years. Growth in the ratings, characteristics, and availability of dry-type high-voltage transformers has accounted in major part for the reduction of askarel units. But another factor that has led to the rejection of askarel transformers in recent years is the environmental objections to the askarel liquid itself.

A major component of any askarel fluid is one or more polychlorinated biphenyls (PCBs), a family of chemical compounds designated as harmful environmental pollutants because they are nonbiodegradable and cannot be readily disposed of. Thus, although the askarels are excellent coolants where freedom from flammability is important, environmental objections to the sale, use, and disposal of PCBs have eliminated new applications of askarel transformers and stimulated a search for a nontoxic, environmentally acceptable substitute.

Proper handling and disposal of askarel is important for units still in use. A regulation of the EPA (Environmental Protection Agency), No. 311, required that all PCB spills of 1 lb (454 g) or more must be reported. Failure to report a spill is a criminal offense punishable by a \$10,000 fine and/or 1-year imprisonment. Both the EPA and OSHA have objected to the use of askarels. A manufacturer of askarel has established a program for disposal of spent or contaminated PCB fluid using an incinerator that completely destroys the fluid by burning it at over 2000°F.

Non-PCB dielectric coolant fluids for use in small- and medium-sized power transformers as a safe alternate to askarels are available, and transformers using these new high-fire-point dielectric coolants have been widely used.

Extensive data from tests on available askarel substitutes show that they provide a high degree of safety. Such fluids do have **NEC** and OSHA recognition. Responsibility for proper clearances with insurance underwriters, government regulating agencies, and local code authorities rests with the user or purchaser of the fluid in new or refilled transformers. Underwriters Laboratories does not test or list liquid-filled equipment. Both UL and Factory Mutual Research Laboratory have been involved in providing a classification service of flammability. The EPA has commented favorably on such high-fire-point fluids.

Few physical changes to transformers are necessary when using the new fluid dielectrics. However, load ratings on existing units may be reduced about 10 percent because of the difference in fluid viscosity and heat conductivity compared with askarel. The high-fire-point fluids cost about twice as much as askarel. Purchase price of a new transformer filled with the fluid (such as a typical 1000-kVA loadcenter unit) is about 10 to 15 percent more than an askarel-filled unit. But the economics vary for different fluids and must be carefully evaluated.

High-fire-point liquid-insulated transformers require no special maintenance procedures. The liquids exhibit good dielectric properties over a wide range of temperatures and voltage stress levels, and they have acceptable arc-quenching capabilities. They have a high degree of thermal

stability and a high resistance to thermal oxidation that enables them to maintain their insulating and other functional properties for extended periods of time at high temperatures.

Because silicone liquids will ignite at 750°F (350°C), they are not classed as fire-resistant. However, if the heat source is removed or fluid temperature drops below 750°F, burning will stop. The silicone fluids are thus self-extinguishing.

450.24. Nonflammable Fluid-Insulated Transformers. This section permits indoor and outdoor use of transformers that utilize a noncombustible fluid dielectric, which is one that does not have a flash point or fire point and is not flammable in air (Fig. 450-29). As an alternative to askarel-insulated transformers, these transformers offer high BIL ratings and other features of operation similar to high-fire-point dielectric-insulated transformers—without concern for flammability. Such transformers do not, therefore, have the restrictions that are set down in 450.23 for the high-fire-point-liquid transformers.

Relative Flammability Scale	Ether	100
	Mineral Oil	20-30
	Silicone	4-5
	Askarel	1-2
	R-113	0
	Water	0

THIS IS THE LIQUID DIELECTRIC FOR TRANSFORMERS NOW COVERED BY 450.24.

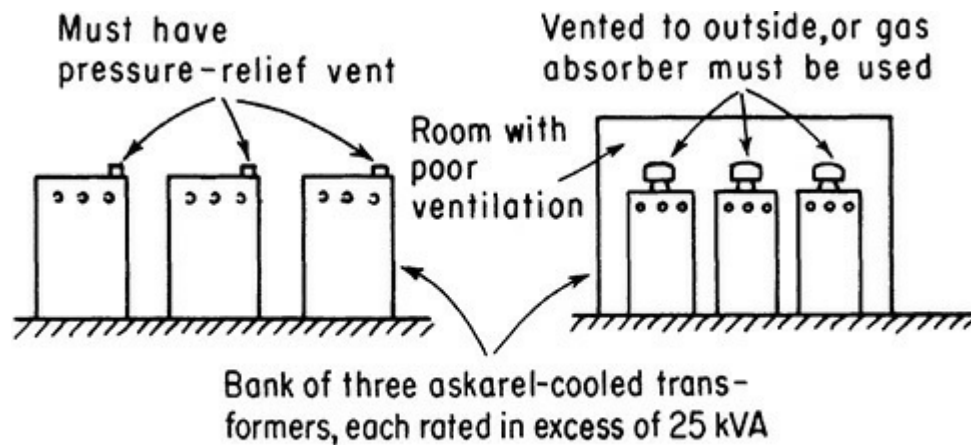

Chart is based on a UL-defined flammability scale as tested by ASTM.

Fig. 450-29. Comparison of the relative flammabilities of liquid dielectrics compared with ether. (Sec. 450.24.)

Nonflammable fluid-insulated transformers installed indoors must have a liquid-confinement area and a pressure-relief vent. In addition, such transformers must be equipped to absorb gases generated by arcing inside the tank, or the pressure-relief vent must be connected to a flue or duct to carry the gases to “an environmentally safe area.” Units rated over 35 kV must be installed in a vault when used indoors.

450.25. Askarel-Insulated Transformers Installed Indoors. Although askarel transformers are being phased out, the Code rule says such transformers installed indoors must conform to the following:

1. Units rated over 25 kVA must be equipped with a pressure-relief vent.
2. Where installed in a poorly ventilated place, they must be furnished with a means for absorbing any gases generated by arcing inside the case, or the pressure-relief vent must be connected to a chimney or flue, which will carry such gases outside the building (Fig. 450-30).

UNITS RATED OVER 35,000 VOLTS MUST BE USED IN A VAULT

Fig. 450-30. Code rules still cover askarel transformers. (Sec. 450.25.)

3. Units rated over 35,000 V must be installed in a vault.

450.26. Oil-Insulated Transformers Installed Indoors. The basic rule is illustrated in Fig. 450-31. Oil-insulated transformers installed indoors must be installed in a vault constructed according to Code specs, but the exceptions note general and specific conditions under which a vault is not necessary. The most commonly applied exceptions are as follows:

Fig. 450-31. Oil-filled transformers generally require installation in a vault. (Sec. 450.26.)

1. A hookup of one or more units rated not over 112½ kVA may be used in a vault constructed of reinforced concrete not less than 4 in. thick.
2. Units installed in detached buildings used only for providing electric service do not require a Code-constructed vault if no fire hazard is created and the interior is accessible only to qualified persons.

450.27. Oil-Insulated Transformers Installed Outdoors. Figure 450-32 shows how physical locations of building openings must be evaluated with respect to potential fire hazards from leaking transformer oil.

Fig. 450-32. Precautions must be taken for outdoor oil transformers. (Sec. 450.27.)

The outdoor locations need to be considered in light of the access requirement in 450.13. Some locations that comply with this section may be judged insufficiently accessible. The informational note following 450.27 points out that additional information can be found in the *National Electrical Safety Code* (not the **NEC**). That code covers use of such transformers as shown in [Fig. 450-33](#). But, because this note is only informational and presents no rule, the requirements of 450.13 must be observed.

Fig. 450-33. High mounting of oil-filled transformers would require use of a portable ladder for access to the units. But 450.27 covers such units installed on poles or structures. (Sec. 450.27.)

450.28. Modification of Transformers. Askarel transformers that are drained and refilled with another liquid dielectric must be identified as such and must satisfy all rules of their retrofilled status. This rule is intended to maintain safety in all cases where askarel transformers are modified to eliminate PCB hazards. Marking must show the new condition of the unit and must not create Code violations. For instance, an indoor askarel transformer that is drained and refilled with oil may require construction of a vault, which is required for oil-filled transformers as specified in 450.26.

450.41. Location. Ideally, a transformer vault should have direct ventilating openings (grilles or louvers through the walls) to outdoor space. Use of ducts or flues for ventilating is not necessarily a Code violation, but should be avoided wherever possible.

450.42. Walls, Roof, and Floor. Basic mandatory construction details are established for an

NEC-type transformer vault, as required for oil-filled transformers and for all transformers operating at over 35,000 V. The purpose of a transformer vault is to isolate the transformers and other apparatus. It is important that the door as well as the remainder of the enclosure be of proper construction and that a substantial lock be provided. Details required for any vault are shown in Fig. 450-34 and include the following:

Fig. 450-34. Transformer vault must assure containment of possible fire. (Sec. 450.42.)

1. Walls and roofs of vaults shall be constructed of reinforced concrete, brick, load-bearing tile, concrete block, or other fire-resistive constructions with adequate strength and a fire resistance of 3 h according to ASTM Standard E119-99. “Stud and wall board construction” may not be used for walls, roof, or other surfaces of a transformer vault. Although the rule here does *not* flatly mandate concrete or masonry construction, that is essentially the objective of the wording. The substantiation for this rule said the following:

The only guidance provided in Sec. 450.42 as to the type of material to be used in vault construction is in an informational note which states that “six-in. (152-mm) thick reinforced concrete is a typical 3-h construction.” This, of course, is only advisory. Sheetrock can be so installed as to have a 3-h fire rating, however, it should not be considered as being suitable for this type of installation. It would not have adequate structural strength in case of oil fire. It is not too difficult to break through such a wall, either intentionally or unintentionally. This is why the **NEC** specifically disallows it.

Your attention is also called to Sec. 230.6(3), which states that conductors installed in a transformer vault shall be considered outside of a building. The major thrust of 230.6 has been that the conductors are to be masonry-encased.

2. A vault must have a concrete floor not less than 4 in. (100 mm) thick when in contact with the earth. When the vault is constructed with space below it, the floor must have adequate structural strength and a minimum fire resistance of 3 h. Six in. (150 mm) thick reinforced concrete is a typical 3-h-rated construction.
3. Building walls and floors that meet the preceding requirements may serve for the floor, roof, and/or walls of the vault.

An exception to the basic regulations establishing the construction standards for transformer

fireproof vaults notes that the transformer-vault fire rating may be reduced where the transformers are protected with automatic sprinkler, water spray, or carbon dioxide. The usual construction standards for transformer vaults (such as 6 in. [150 mm] thick reinforced concrete) provide a minimum fire-resistance rating of 3 h. Where automatic sprinkler, water spray, or carbon dioxide is used, a construction rating of only 1 h will be permitted.

450.43. Doorways. Each doorway must be of 3-h fire rating as defined in the *Standard for the Installation of Fire Doors and Windows* (NFPA No. 80-1999). The Code-enforcing authority may also require such a door for doorways leading from the vault to the outdoors, in addition to any doorways into adjoining space in the building.

As required in part (C), vault doors must swing *out* and must be equipped with "listed panic hardware."

This is intended to provide the greater safety of a push-open rather than a rotating-knob type of door release. As noted in the substantiation:

Conventional rotating door knob hardware is used on transformer vault doors due to lack of specific wording in the paragraph as presently written. The *National Electrical Safety Code* is believed to be very specific, or has been formally interpreted to be, requiring "panic type" door hardware. In an electrical flash or arc an electrical worker may lose the use of hands for twisting a conventional door knob.

In accordance with the concept of providing greater protection for personnel within the vault, other Code rules have also adopted similar wording. See 110.26(C)(3).

450.45. Ventilation Openings. This rule sets the size and arrangement of vent openings in a vault where such ventilation is required by ANSI C57.12.00-1993—"General Requirements for Liquid-Immersed Distribution, Power, and Regulating Transformers," as noted in 450.9. [Figure 450-35](#) shows the openings as regulated by part (C) of this section. One or more openings may be used, but if a single vent opening is used, it must be in or near the roof of the vault—and not near the floor.

Fig. 450-35. Vault vent opening(s) may be in or near the roof—or near floor level also, if one is at or near roof level. (Sec. 450.45.)

450.47. Water Pipes and Accessories. This section addresses a crucial topic in electrical work. Sprinklers belong in transformer vaults and they are absolutely not to be considered as foreign to the electrical installation. For many electricians, the idea of providing water-based sprinkler protection for electrical equipment is anathema. "Water and electricity don't mix" goes the argument. However, it has been conclusively demonstrated that the loss experience associated with an electrical fire is far lower when that fire is controlled with an automatic sprinkler.

The express permission to use water-based sprinkler protection has been in this part of the **NEC** for about 65 years. A major challenge to this concept occurred during the 1987 **NEC** cycle, when the panel advanced a proposal requiring outdoor rated transformers in vaults that had sprinkler protection. Everyone understood that the cost differential in providing this rating would be a serious impediment to providing the protection. The initial panel action drew a large number of extremely negative comments, and when the panel reconvened to act on the comments it unanimously rejected the concept.

ARTICLE 455. PHASE CONVERTERS

Refer to [Fig. 455-1](#), which shows details of the rules given in 455.2, 455.4, 455.6, 455.7, and 455.8.

A wide range of Code rules cover single- to 3-phase converters for motors and other 3-phase loads in new Art. 455.

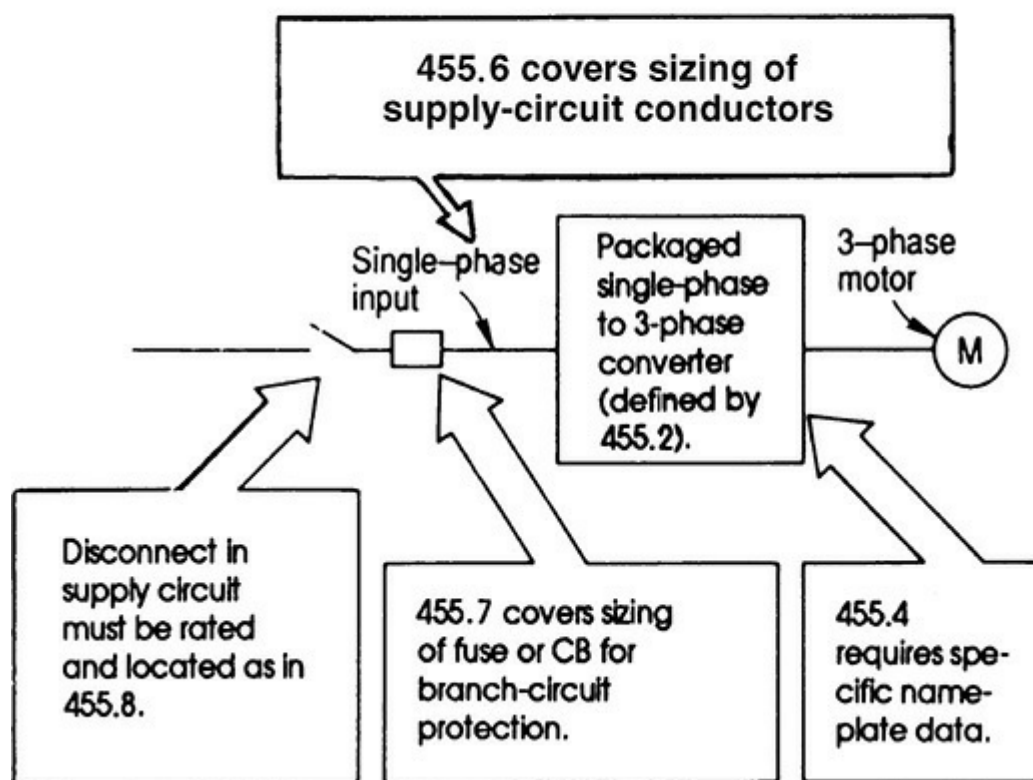

Fig. 455-1. Code rules on phase converters cover these considerations. (Art. 455.)

455.2. Definitions. A phase converter is a static or a rotary device that converts single-phase power to 3-phase power. The informational note calls attention to the fact that phase converters, which do not produce perfect 3-phase power, alter the starting torque and locked-rotor current of motors connected to them.

455.6. Conductors. Part (A)(1) addresses the general case and requires that conductors supplying a phase converter must have an ampacity at least equal to 125 percent of the “phase converter nameplate single-phase input full-load amperes.” Part (A)(2) covers instances where a specific load will be supplied, in which case the supply conductor ampacity must be at least 250 percent of the connected load. Currents are multiplied by the output-to-input voltage ratio as

applicable if there is a voltage transformation involved. An informational note suggests 3 percent as a voltage drop allowance not to be exceeded in the single-phase portion of the circuit in order to promote proper starting and operation of the three-phase load.

Part **(B)** requires the manufactured phase conductor, which is the one originated by the converter and not connected to the line, to have a distinctive marking at all accessible locations and in a consistent manner throughout the system. The method of identification is not specified, but the color yellow appears to be the generally preferable choice. Section 455.9 prohibits connecting single-phase load to the manufactured phase, so it is essential to know which wire to avoid when making a single-phase load connection.

455.7. Overcurrent Protection. The rating of the overcurrent protective device protecting the phase converter supply conductors follows the same percentage rules (except stating the result as a maximum) as given for determining conductor ampacity, with an allowance for the next higher standard sized overcurrent device. The overcurrent protection cannot exceed 125 percent of the rated full-load input current.

There are no rules in this article for overcurrent protection on the load side of the converter. Presumably these conductors are a form of a tap and are subject to the rules in Secs. 240.4 and 240.21. Applying the 10-ft tap rule in 240.21(B) would clearly comply with Code rules.

455.8. Disconnecting Means. A readily accessible disconnecting means that opens the single-phase ungrounded supply conductors simultaneously must be located in sight of the phase converter. The disconnecting means must be a circuit breaker or molded-case switch, or a switch rated in horsepower. Nonmotor loads may use a switch rated in amperes. For general purposes, the disconnecting means must have a rating equal to 115 percent of the “phase converter nameplate single-phase input full-load amperes.” If specific loads are supplied then the required rating depends on the type of disconnecting means used: Note that, in 455.20, the single-phase disconnecting means for a static phase converter supplying a single load may also serve as the disconnecting means for that load, provided it is in sight.

A circuit breaker or molded-case switch is to be based on at least 250 percent of the 3-phase full-load amperes, adjusted for voltage as required. The procedure for these disconnects parallels that for sizing overcurrent protection.

A horsepower-rated switch is to be based on 200 percent of the equivalent horsepower of the 3-phase load. The horsepower-rated switch rule uses a summation of up to three numbers to obtain a lock-rotor ampere rating: the nonmotor loads; the 3-phase locked rotor current of the largest motor, as given in Table 430.251(B); and the full-load currents of all other motors operating at the same time. The sum of these numbers is then multiplied by the output-to-input voltage ratio if necessary, and then taken back into Table 430.151(B) for reversion into horsepower.

455.21. Start-Up. A rotary converter must be started before the 3-phase load is energized. If a rotary phase converter is started under load, the output phase angles will not usually allow the 3-phase motor to start properly, risking burnout of components and fire. The next section requires that rotary converter installations be arranged so that if power to the converter fails, the loads cannot be reenergized (until the converter has successfully restarted, per Sec. 455.21). An informational note advises that magnetic contactors, etc., with manual or time-delay restarting will comply with this rule.

455.23. Capacitors. Capacitors installed for a motor load (and not as an integral part of the phase conversion system) must be installed on the line side of the motor running overload protection.

This avoids the necessity to apply 460.9 to correct for improved power factor in sizing running overload protection if capacitors are on the load side of that protection. As implied in the informational note following the phase converter definition in 455.2, that power factor may be difficult to accurately predict.

ARTICLE 460. CAPACITORS

460.1. Scope. The sections in this article apply chiefly to capacitors used for the power-factor correction of electric-power installations in industrial plants and for correcting the power factors of individual motors (Fig. 460-1). These provisions apply only to capacitors used for surge protection where such capacitors are not component parts of other apparatus.

Fig. 460-1. A typical power-factor correction capacitor bank is this 300-kvar bank of twelve 25-kvar, 480-V capacitor units installed in a steel enclosure in an outdoor industrial substation. (Sec. 460.1.)

In an industrial plant using induction motors, the power factor may be considerably less than 100 percent, particularly when all or part of the motors operate most of the time at much less than their full load. The lagging current can be counteracted and the power factor improved by installing capacitors across the line. By raising the power factor, for the same actual power delivered the current is decreased in the generator, transformers, and lines, up to the point where the capacitor is connected.

Figure 460-2 shows a capacitor assembly connection to the main power circuit of a small

industrial plant, consisting of capacitors connected in a 3-phase hookup and rated at 90 kVA for a 460-V system. An externally operable switch mounted on the wall is used as the disconnecting means, and the discharge device required by 460.6 consists of two high-impedance coils inside the switch enclosure, which consume only a small amount of power but, having a comparatively low dc resistance, permit the charge to drain off rapidly after the capacitor assembly has been disconnected from the line.

Fig. 460-2. Six internally delta-connected capacitors form a 3-phase capacitor bank. (Sec. 460.1.)

460.6. Discharge of Stored Energy. If no means were provided for draining off the charge stored in a capacitor after it is disconnected from the line, a severe shock might be received by a person servicing the equipment, or the equipment might be damaged by a short circuit. If a capacitor is permanently connected to the windings of a motor, as in [Fig 460-3](#), the stored charge will drain off rapidly through the windings when the circuit is opened. Reactors or resistors used as discharge devices either must be permanently connected across the terminals of the capacitor (such as within the capacitor housing) or a device must be provided that will automatically connect the discharge devices when the capacitor is disconnected from the source of supply. Most available types of capacitors have discharge resistors built into their cases. When capacitors are not equipped with discharge resistors, a discharge circuit must be provided.

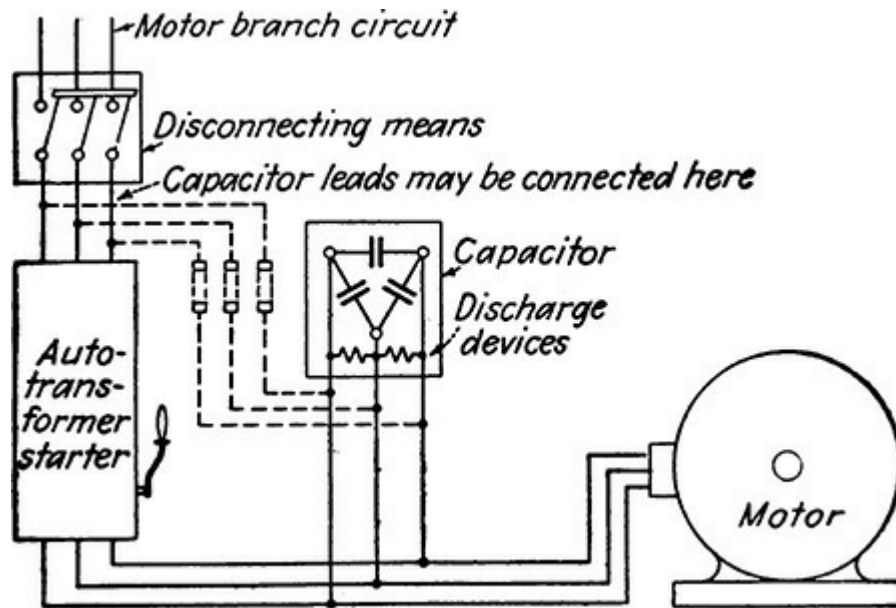

Fig. 460-3. Capacitor voltage must be discharged when circuit is opened. (Sec. 460.6.)

Figure 460-3 shows a capacitor used to correct the power factor of a single motor. The capacitor may be connected to the motor circuit between the starter and the motor or may be connected between the disconnecting means and the starter, as indicated by the dotted lines in the diagram. If connected as shown by the dotted lines, an overcurrent device must be provided in these leads, as required by 460.8(B). The capacitor is shown as having discharge devices consisting of resistors.

Power capacitors, in most applications, are installed to raise the system power factor, which results in increased circuit or system current-carrying capacity, reduced power losses, and lower reactive power charges (most utility companies include a power-factor penalty clause in their industrial billing). Also, additional benefits derived as a result of a power capacitor installation are reduced voltage drop and increased voltage stability. [Figure 460-4](#) presents basic data on calculating size of capacitors for power-factor correction. However, manufacturers provide tables and graphs to help select the capacitor for a given motor load.

Power-factor capacitors can be connected across electric lines to neutralize the effect of lagging power-factor loads, thereby reducing the current drawn for a given kilowatt load. In a distribution system, small capacitor units may be connected at the individual loads or the total capacitor kilovolt-amperes may be grouped at one point and connected to the main. Although the total kvar of capacitors is the same, the use of small capacitors at the individual loads reduces current all the way from the loads back to the source and thereby has greater PF corrective effect than the one big unit on the main, which reduces current only from its point of installation back to the source.

Calculating Size of Capacitor:

Assume it is desired to improve the power factor a given amount by the addition of capacitors to the circuit.

Then $kvar_R = kw \times (\tan \theta_1 - \tan \theta_2)$

- where $kvar_R$ = rating of required capacitor
- $kvar_1$ = reactive kilovolt-amperes at original PF
- $kvar_2$ = reactive kilovolt-amperes at improved PF
- θ_1 = original phase angle
- θ_2 = phase angle at improved PF
- kw = load at which original PF was determined.

NOTE: The phase angles θ_1 and θ_2 can be determined from a table of trigonometric functions using the following relationships:

- θ_1 = The angle which has its cosine equal to the decimal value of the original power factor (e.g., 0.70 for 70% PF; 0.65 for 65%; etc.)
- θ_2 = The angle which has its cosine equal to the decimal value of the improved power factor.

Fig. 460-4. Capacitors reduce circuit current by supplying the magnetizing current to motors. (Sec. 460.6.)

In the past, the Code limited power-factor correction to unity (100 percent, or 1.0) when there is no load on the motor. That will result in a power factor of 95 percent or better when the motor is fully loaded. The old rule recognized the use of capacitors sized *either* for the value that will produce 100 percent power factor of the circuit when the motor is running at no load *or* for a value equal to 50 percent of the kilovolt-ampere rating of the motor input for motors up to 50 hp, 1000 V.

That provision was removed as of the 1984 **NEC** based on an important and detailed proposal from NEMA. The proposal pointed out that the prescriptive limits then 460.7 were design considerations that were of chiefly economic impact, and did not address hazards to personnel. The proposal also described the impact of increasing motor efficiencies that would likely result in inadvertent “premature motor failure as the result of overvoltage and potential transient torques and

currents as compared to previous designs.” The substantiation also pointed out that the 50-hp parameter was no magic number. A 50-hp or a 1000-hp motor was subject to the same issues because the electromagnetic principle for both were identical. However, losing a 50-hp motor was far less costly than a larger motor, so in essence the Code was capping the risk of over-excitation at a point where the economic impact was judged acceptable. Taken as a whole the issue needed to come out of the electrical safety standard and remain with the owners and their engineers. The panel unanimously agreed.

Nevertheless, the entire commentary as well as three drawings illustrating its application have been retained in all subsequent editions of this book. After over 25 years, motor efficiencies have further increased and variable-speed drive technology has advanced and proliferated, which also impacts power factor in ways never considered in the 1970s. In addition, increased harmonic loading that comes in part from these developments creates new challenges to installing capacitors, because they can place an electrical system into resonance, creating overvoltages and overcurrents. These issues require careful engineering study and in some cases the installation of line reactors to remove the resonant condition.

The previously retained material in this location did not explain any topic now subject to **NEC** regulation, nor did it address these more contemporary topics. We have decided to remove this material as dated and likely counterproductive in some cases.

460.8. Conductors. Part (A) of this section covers sizing of circuit conductors. The current corresponding to the kilovolt-ampere rating of a capacitor is computed in the same manner as for a motor or other load having the same rating in kilovolt-amperes. If a capacitor assembly used at 460 V has a rating of 90 kVA, the current rating is $90,000 \text{ VA} / (480 \text{ V} \times \sqrt{3}) = 90,000 \text{ VA} / (277 \text{ V} \times \sqrt{3} \times \sqrt{3}) = 90,000 \text{ VA} / 831 \text{ V} = 108 \text{ A}$. The minimum required ampacity of the conductors would be $1.35 \times 108 \text{ A}$, or 146 A.

The manufacturing standards for capacitors for power-factor correction call for a rating tolerance of “0, + 15 percent,” meaning that the actual rating in kilovolt-amperes is never below the nominal rating and may be as much as 15 percent higher. Thus, a capacitor having a nameplate rating of 100 kVA might actually draw a current corresponding to 115 kVA. The current drawn by a capacitor varies directly with the line voltage, so that, if the line voltage is higher than the rated voltage, the current will be correspondingly increased. Also, any variation of the line voltage from a pure sine wave form will cause a capacitor to draw an increased current. It is for these reasons that the conductors leading to a capacitor are required to have an ampacity not less than 135 percent of the rated current of the capacitor.

example Given the kvar rating of capacitors to be installed for a motor, determining the correct capacitor conductor size is relatively simple. The rule here requires that the ampacity of the capacitor conductors be not less than one-third the ampacity of the motor circuit conductors and not less than 135 percent of the capacitor rated current. The capacitor nameplate will give rated kvar, voltage, and current. It is then a simple matter of multiplying rated current by 1.35 to obtain the ampacity value of the conductor to be installed and selecting the size of conductor required to carry that value of current, from Table 310.15(B)(16). Then check that the ampacity is not less than one-third the ampacity of the motor circuit conductors.

For a motor rated 100 hp, 460 V, 121 A full-load current, a 25-kvar capacitor would correct power factor to between 0.95 and 0.98 at full load. The nameplate on the capacitor indicates that the capacitor is rated 460 V, 31 A. Then $31 \times 1.35 = 42 \text{ A}$. From Code Table 310.15(B)(16), a No. 6 TW conductor rated to carry 55 A might appear to do the job. (No. 8 THW rated at 50 A would most likely be

considered not acceptable because UL and the **NEC** generally call for use of 60°C wires in circuits up to 100 A.) The motor circuit conductors are found to be 2/0 THW [based on Table 430.250 (124A) increased by 25 percent to 155A], with an ampacity of 175 A. Because $\frac{1}{3} \times 175 = 58$ A, the No. 6 THW, with an ampacity of 65 A, should be used.

If these conductors are connected to the load terminals of the motor controller, the overload protection heaters may have to be changed (or if the OL is adjustable, its setting may have to be reduced), because the capacitor will cause a reduction in line current and adjustment of relay setting is required by 460.9.

Although part **(B)** of the rule requires overcurrent protection (fuses or a CB) in each ungrounded conductor connecting a capacitor assembly to a circuit, the exception considers the motor-running overload relay in a starter to be adequate protection for the conductors when they are connected to the motor circuit on the load side of the starter. Where separate overcurrent protection is provided, as required for line-side connection, the device must simply be rated “as low as practicable.” When a capacitor is thrown on the line, it may momentarily draw an excess current. A rating or setting of 250 percent of the capacitor current rating will provide short-circuit protection. Being a fixed load, a capacitor does not need overload protection such as is necessary for a motor.

Most power capacitors are factory equipped with fuses that provide protection in case of an internal short circuit. These fuses are usually rated from 165 to 250 percent of the rated kilovar current to allow for maximum operating conditions and momentary current surges. When installed on the load side of a motor starter, as noted previously, capacitors do not require additional fusing. However, for bank installations, separate fuses are required.

Part **(C)** of the rule requires a disconnecting means for all the ungrounded conductors connecting a capacitor assembly to the circuit—but a disconnect is not needed when the capacitor is connected on the load side of a starter with overload protection. The disconnect must be rated at least equal to 1.35 times the rated current of the capacitor.

Note that part **(C)(1)** requires a multipole switching device for the disconnect. This rule was originally adopted because of the inherent danger of single-pole switching of low-voltage capacitors. Normal switching or closing on faults may cause arcs or splattering of molten metal.

Two accepted methods of wiring capacitors are illustrated in [Fig. 460-5](#). Diagram *A* shows the method of connection at a central location, such as at a power center or on a busway feeder. In such an installation, the Code rule requires an overcurrent device in each ungrounded conductor, a separate disconnecting means, and a discharge resistor (usually furnished with capacitors). The current rating of both the capacitor disconnect switch and the conductors supplying the capacitor must be not less than 135 percent of the rated current of the capacitor. In *B*, the capacitor is connected directly to motor terminals. Installation on the load side of the motor starter eliminates the need for separate overcurrent protection and separate disconnecting means. However, motor-running overcurrent protection must take into account the lower running current of the motor, as required by 460.6.

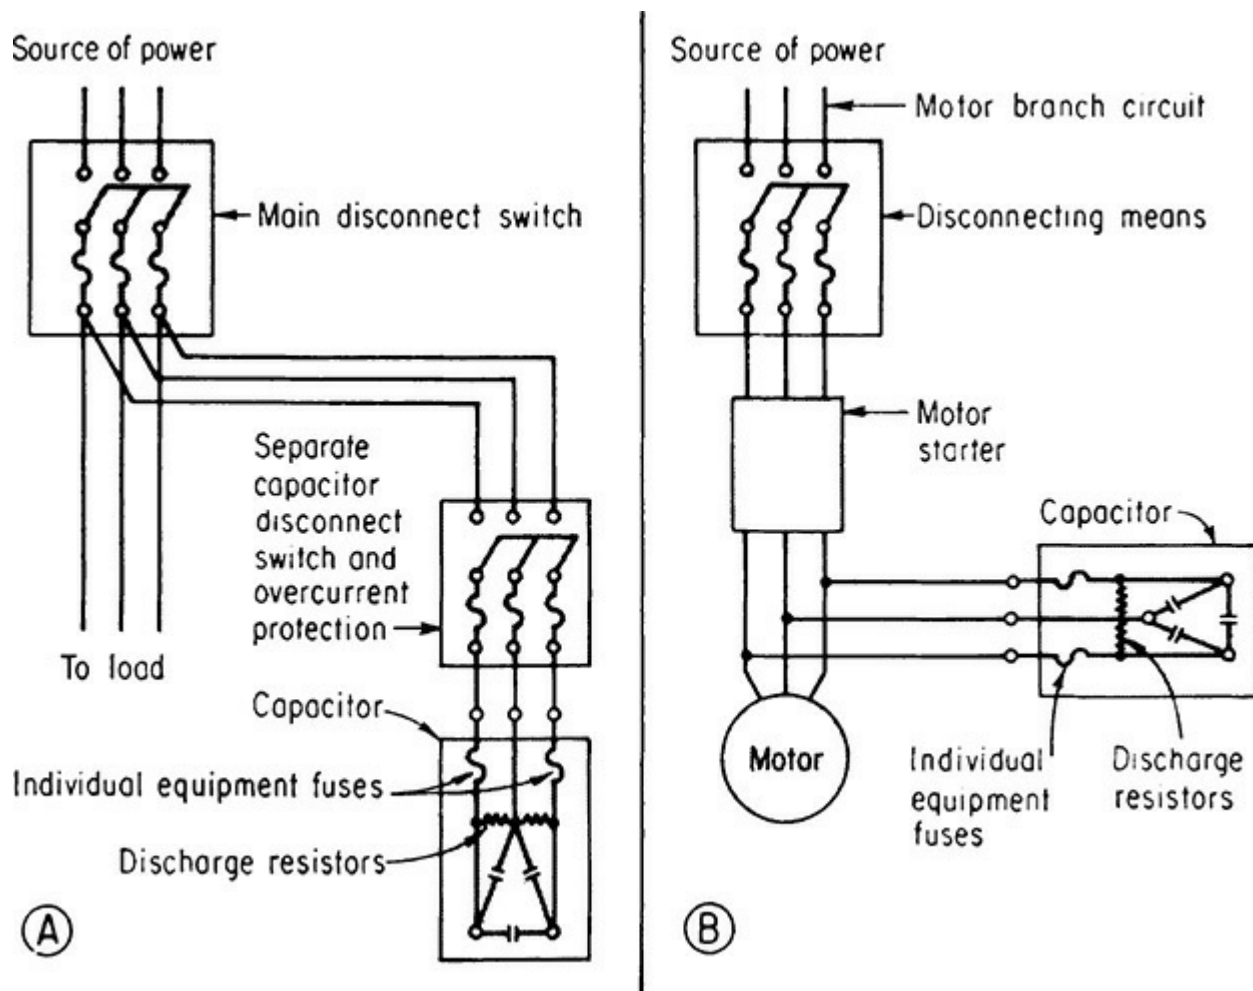

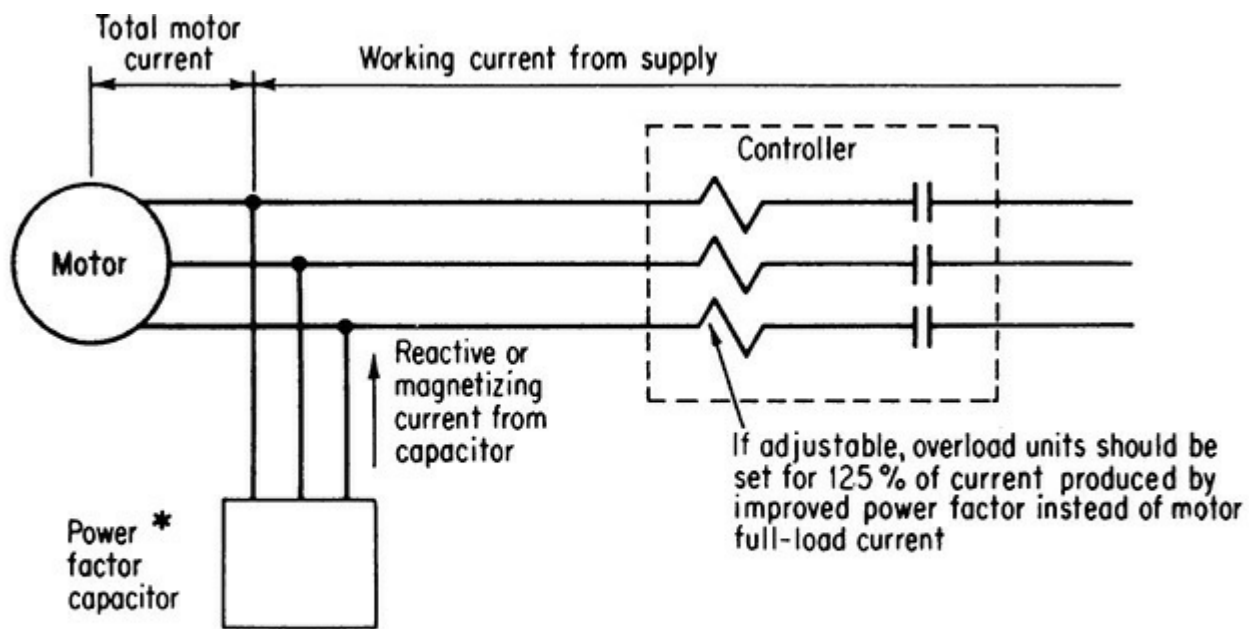

Fig. 460-5. PF capacitor assembly may be connected on the line or load side of a starter. (Sec. 460.8.) Note that the discharge resistors are not required in drawing "B" because the charge will dissipate through the motor windings.

460.9. Rating or Setting of Motor Overload Device. When a power-factor capacitor is connected to a motor circuit at the motor—that is, on the load or motor side of the motor controller—the reactive current drawn by the motor is provided by the capacitor, and, as a result, the total current flowing in the motor circuit up to the capacitor is reduced to a value below the normal full-load current of the motor. With that hookup, the total motor full-load current flows only over the conductors from the capacitor connection to the motor, and the entire motor circuit up to that connection carries only the so-called working current or resistive current. That is shown in the top part of [Fig. 460-6](#).

TOTAL MOTOR CURRENT = VECTOR SUM OF REACTIVE AND WORKING CURRENTS

EXAMPLE: Motor with 70% power factor has full-load current of 143 amps. Capacitor corrects to 100% PF.

$$\cos \theta = 0.70$$

I_{xL} = Magnetizing current

I_w = Working current

I_{xC} = Capacitor current

I_{xC} cancels I_{xL} leaving only working current to be supplied from circuit. Working current = $143 \times \cos \theta = 143 \times 0.70 = 100$

OVERLOAD RELAYS SHOULD BE SET FOR 125% OF 100 AMPS

* The rating of such capacitors should not exceed the value required to raise the no-load power factor of the motor to unity. Capacitors of these maximum ratings usually result in a full-load power factor of 95 to 98 percent.

Fig. 460-6. Motor overload protection must be sized for the current at improved PF. (Sec. 460.9.)

Under the conditions shown, it is obvious that setting the overload relay in the starter for 125 percent of the motor nameplate full-load current (as required by 430.32) would actually be an excessive setting for real protection of the motor, because considerably less than full-load current is flowing through the starter. The rule of this section clearly requires that the rating of a motor overload protective device connected on the line side of a power-factor correction capacitor must be based on 125 percent (or other percentage from 430.32) times the circuit current produced by the improved power factor—rather than the motor full-load current (see Fig. 460-6).

The 25-kvar capacitor used on the 100-hp, 460-V motor in the example in 460.8 will reduce the

motor line current by about 9 percent. Section 430.32(A) (also 430.34 and 460.9) requires that the running overload protection be sized not more than 125 percent of motor full-load current produced with the capacitor. If the OL protection heaters were originally sized at 125 percent of the motor full-load current (1.25×121), they would have been sized at 151 A. With the motor current reduced by 9 percent (0.09×121 , or 11 A), the motor full-load current with the capacitor installed would be 121 - 11, or 110 A. Because 125 percent of 110 A is 137.5 A, the heaters must be changed to a size not larger than 137.5 A.

If the capacitor conductors could be connected on the line side of the heaters, the heaters would not have to be reduced in size, since the reduction of line current occurs only from the source back to the point of the capacitor connection. Conductor connections at this location are extremely difficult to make because of the lack of space and the large size of the connecting lugs. Controller load terminals are furnished with connectors that will accept an additional conductor, or they can be easily modified to permit a dependable connection.

460.10. Grounding. The metal case of a capacitor is suitably grounded by lock-nut and bushing connections of grounded metal nipples or raceways carrying the conductors connecting the capacitor into a motor circuit or feeder.

ARTICLE 470. RESISTORS AND REACTORS

470.1. Scope. Except when installed in connection with switchboards or control panels that are so located that they are suitably guarded from physical damage and accidental contact with live parts, resistors should always be completely enclosed in properly ventilated metal boxes.

Large reactors are commonly connected in series with the main leads of large generators or the supply conductors from high-capacity network systems to assist in limiting the current delivered on short circuit. Small reactors are used with lightning arresters, the object here being to offer a high impedance to the passage of a high-frequency lightning discharge and so to aid in directing the discharge to ground. Another type of reactor, having an iron core and closely resembling a transformer, is used as a remote-control dimmer for stage lighting. Reactors, like resistors, are sources of heat and should therefore be mounted in the same manner as resistors. Reactors are also commonly installed in conjunction with variable-speed drives to improve power quality and performance.

ARTICLE 480. STORAGE BATTERIES

480.1. Scope. “Stationary installations of storage batteries” provide an independent source of power for emergency lighting, switchgear control, engine-generator set starting, signal and communications systems, laboratory power, and similar applications. They are an essential component of UPS systems. This Code article does not cover batteries used to supply the motive power for electric vehicles.

480.2. Definitions. Nominal voltage (battery or cell) The value assigned to a cell or battery for the purpose of having a convenient designation; the actual operating voltage may vary on either side of this number. It is now a generic definition, that applies to any storage battery technology. This definition replaced a definition that specified particular voltages.

Sealed cell or battery These have no provision for routine addition of water or electrolyte, or for external measurements of electrolyte specific gravity. They may contain a pressure relief venting

arrangement. These batteries can have water or electrolyte added if necessary with a syringe-type tool, although this would not be routine maintenance.

Storage battery A battery with rechargeable cells.

Storage cells are of two general types: the so-called lead-acid type, in which the positive plates consist of lead grids having openings filled with a semisolid component, commonly lead peroxide, and the negative plates are covered with sponge lead, the plates being immersed in dilute sulfuric acid; and the alkali type, in which the active materials are nickel peroxide for the positive plate and iron oxide for the negative plate, and the electrolyte is chiefly potassium hydroxide (Fig. 480-1).

Fig. 480-1. Article 480 applies only to “stationary installations of storage batteries”—whether they are used for supply to lighting, generator cranking, switchgear control, or in UPS (uninterruptible power supply) systems. (Sec. 480.1.)

The most commonly used battery is the lead-acid type—either lead-antimony or lead-calcium. Nickel-cadmium batteries offer a variety of special features that, in many instances, offset their higher initial cost. Other types include silver-zinc, silver-cadmium, and mercury batteries.

The *lead-antimony battery* is readily available at a moderate price, has a high efficiency (85 to 90 percent), is comparatively small, and has a relatively long life if operated and maintained properly under normal conditions. Voltage output is about 2 V per cell; ratings range to about 1000 A-h (based on an 8-h discharge rate).

Lead-calcium batteries offer features similar to the lead-antimony type, and they require less maintenance. They do not require an “equalizing” charge (application of an overvoltage for a period

of time to ensure that all cells in a battery bank will produce the same voltage). For this reason, they are often selected for use in UPS systems.

This type of cell can usually be operated for a year or more without needing water, depending on the frequency and degree of discharge. Sealed or maintenance-free batteries of this type never need water. Voltage output is 2 V per cell, with ratings up to about 200 A-h (8-h rate).

Nickel-cadmium batteries are particularly useful for application in temperature extremes. They are reputed to have been successfully operated at temperatures from -40°F to 163°F (-40°C to 73°C). They have a very high short-time current capability and are well suited to such applications as engine starting and UPS operation. Initial cost is higher than lead-acid types; however, they offer long life (25 to 30 years), reliability, and small size per unit. Voltage is about 1.2 V per cell.

480.3. Equipment. Other than lead-acid batteries, storage batteries and the equipment to manage their state of charge, etc., must be listed.

480.4. Battery and Cell Terminations. This section is new as of the 2014 **NEC**. Part (A) requires the use of an antioxidant compound where dissimilar metals are in contact at a battery terminal, provided the battery manufacturer recommends it. Part (B) requires that the conductors joining cell to cell and also tiers and shelves of a given battery rack (“intercell” and “intertier” connectors) to have a cross-sectional area sufficient to ensure that even during maximum load the conductors will not heat to the point of threatening the integrity of their insulation or supports. An informational note observes that customary voltage drop allowances based, in effect, on 215.2(A)(1) Informational Note No. 2 (here 3 percent maximum load; 5 percent to the most remote connection point) may not be appropriate for these systems and cites an IEEE publication for guidance. Part (C) requires that wiring connections to the battery terminals be arranged so as to prevent mechanical strain on the terminals. It also requires the use of terminal plates if practicable. An informational note suggests preforming conductor bends, or using finely stranded cables, or both, and consulting the manufacturer’s literature.

480.5. Wiring and Equipment Supplied from Batteries. As indicated in [Fig. 480-2](#), whatever kinds of circuits and loads a battery bank serves, all rules of the **NEC** covering operation at that voltage must be applied to the wiring and equipment.

Fig. 480-2. Applicable Code rules must be observed for load circuits fed by batteries. (Sec. 480.4.)

480.7. DC Disconnect Methods. Part (A) requires a disconnecting means to be provided for

any ungrounded conductor supplied by a stationary battery bank operating over 60 V. It must be readily accessible and located within sight of the battery system. This rule correlates with the new 240.21(H) that specifies a comparable location for overcurrent protection for such conductors.

Part (B), new in the 2014 **NEC**, requires some background information in terms of context from its substantiating submittal to be comprehensible.

DC busway is common in large UPS installations in which there are multiple strings of batteries. Each cell in a string is connected in series to create the necessary dc voltage and each string has a disconnecting means and/or overcurrent protective device. The strings are connected in parallel to a common dc bus which may also have a disconnecting means. The individual string disconnects allow manual disconnecting so that maintenance can be performed on a redundant battery string while the remaining battery strings support the load. It also functions as an OCPD to prevent the energy from other strings from feeding into a faulted cell in one string. The disconnect on a dc busway system can allow for a single point of shutdown for the entire dc supply.

The disconnecting means for an individual or a group of batteries in a large system may be managed remotely, and in such cases it must be capable of being locked open and it must bear a label describing the location of the remote controls.

Part (C) allows a busway switch to control the dc bus it supplies and thereby qualify as the system disconnect. Part (D) includes a label reminiscent of the one required for services in 110.24 that includes the nominal voltage and the maximum short-circuit current available from the battery system, along with a calculation date.

480.9. Battery Support Systems. This section now includes, in the second paragraph, a readily accessible requirement for battery terminals to allow for cleaning, inspection, and test readings. If a battery has a transparent container, then at least one side must be readily accessible for inspection of internal components.

480.10. Battery Locations. Although specific “battery rooms” or enclosures are no longer required for installation of any batteries, part (A) does require ventilation at battery locations. A specific battery room was previously required for open-tank or open-jar batteries, but such units are no longer made or in use.

This section has also received major attention in the 2014 **NEC**. Part (C) now includes rules for spacing battery racks such that a minimum of 1 in. separates a cell container and any wall or structure on a side not requiring maintenance access. The workspace rule (110.26 clearances) remains in effect and applies from the edge of a battery cabinet, rack, or tray. A battery stand can contact an adjacent structure, including for support, provided not over 10 percent of its length is not obstructed from air circulation. An informational note advises that greater space is often required to accommodate hoisting equipment and for other tasks. Part (D) requires that top-terminal batteries have open vertical spacings above them for maintenance in accordance with the manufacturer’s recommendations. Part (E) applies the panic hardware rule in 110.26(C)(3) to egress doors from dedicated battery rooms. Part (F) prohibits gas piping in dedicated battery rooms. Part (G) incorporates the lighting requirement of 110.26(D), with the additional requirement that the luminaires be located so as to not expose those maintaining them to energized battery components, or where a failure in the luminaire would create a problem for the batteries.

ARTICLE 490. EQUIPMENT OVER 1000 VOLTS, NOMINAL

490.1. Scope. The requirements previously given in Art. 710 for equipment rated over 1000 V

nominal are now covered in Art. 490. As defined in 490.2, the term *high voltage* applies to *any* equipment rated at more than 1000 V nominal. The systems customarily utilized as premises wiring and therefore subject to the **NEC** are usually not over 69 kV and therefore the technically correct terminology is “medium voltage,” which is the usual term used in this book.

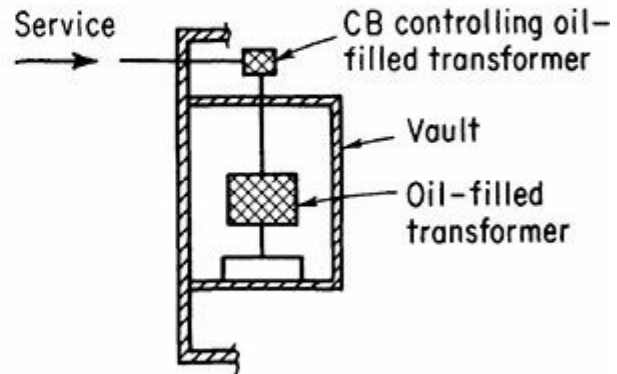

490.21. Circuit-Interrupting Devices. Medium-voltage power CBs provide load switching, short-circuit protection, electrical operation, adjustable time delays of trip characteristics for selectively coordinated protection schemes, quick reclosing after tripping, and various protective hookups such as differential relay protection of transformers. There are oil-type, oilless (or air-magnetic), and vacuum-break CBs. The air-magnetic CB is the common type for indoor applications in systems up to 15 kV and higher. Oil CBs are sometimes used for indoor and outdoor medium-voltage service equipment, where they provide economical disconnect and protection on the primary of a transformer.

Modern medium-voltage CB equipment meets all the needs of control and protection for electrical systems, from the simplest to the most complex and sophisticated. In particular, its use for selectively coordinated protection of services, feeders, and branch circuits is unique. In current ratings up to 3000 A, CB gear has the very high interrupting ratings required for today’s high-capacity systems. Available in *metal-clad* assemblies, all live parts are completely enclosed within grounded metal enclosures for maximum safety. For applications exposed to lightning strikes or other transient overcurrents, CB equipment offers quick reclosing after operation. Drawout construction of the CB units provides ease of maintenance and ready testing of breakers. CB gear offers unlimited arrangements of source and load circuits and is suited to a variety of ac or dc control power sources. Accessory devices are available for special functions.

Figure 490-1 covers the basic rules of this section on use of CBs. [Figure 490-2](#) shows an oil CB, with the line-side isolating switch required by 230.204(A).

- A. Indoor installations of circuit breakers must consist of metal-enclosed units or fire-resistant, cell-mounted units, except that open-mounted CBs may be used in places accessible to qualified persons only.
- B. All CBs must be rated for short-circuit duty at point of application.

C. Circuit breakers controlling oil-filled transformers *must* either be located outside the transformer vault or be capable of being operated from outside the vault.

- D. Oil CBs must be arranged or located so that adjacent readily combustible structures or materials are safeguarded in an approved manner. Adequate space separation, fire-resistant barriers or enclosures, trenches containing sufficient coarse crushed stone, and properly drained oil enclosures such as dikes or basins are recognized as suitable safeguards.

Fig. 490-1. Detailed rules regulate use of medium-voltage circuit breakers. (Sec. 490.21.)

Fig. 490-2. Oil circuit breaker for medium-voltage application has a disconnecting switch on its supply side to isolate the line terminals of the breaker. (Sec. 490.21.)

Part **(B)** covers power fuses, which are available in current-limiting and noncurrent-limiting types. (See [Fig. 490-3](#) for an example of the uses to which power fuses may be put.) The current-limiting types offer reduction of thermal and magnetic stresses on fault by reducing the energy let-through. They are constructed with a silver-sand internal element, similar to 600-V current-limiting fuses. Such fuses generally have higher interrupting ratings at some voltages, but their continuous current-carrying ratings are limited.

Fig. 490-3. Typical power fuses are used in load-interrupter switchgear, which is an alternative to circuit-breaker gear for control and protection in indoor medium-voltage systems. (Sec. 490.21.)

Noncurrent-limiting types of power fuses are made in two types of operating characteristics: expulsion type and nonexpulsion type. The expulsion fuse gets its name from the fact that it expels hot gases when it operates. Such fuses should not be used indoors without a “snuffer” or other protector to contain the exhaust, because there is a hazard presented by the expelled gases. At the end of part **(B)(1)**, the rule says that vented expulsion-type power fuses used indoors, underground, or in metal enclosures must be “identified for the use.” Vented power fuses are not safe for operation in confined space—unless specifically tested and *identified* for such use. Part **(B)(5)** of this section requires that fuses expelling flame in operation must be designed or arranged to prevent hazard to persons or property. The boric-acid fuse with a condenser or other protection against arcing and gas expulsion is a typical nonexpulsion, noncurrent-limiting fuse (Fig. 490-4).

Fig. 490-4. Boric-acid fuse uses a device to protect against flame expulsion. (Sec. 490.21.)

Parts **(B)(6)** and **(B)(7)** cover very important safeguards for the use of fuses and fuseholders. The 2014 **NEC** relocated a substation requirement formerly at 225.70(A)(3) to **(B)(6)** requiring a warning label advising the need to disconnect the circuit before replacing a fuse. There are other considerations regarding the use of fuses:

In coordinating power fuses, care must be taken to account for ambient temperature adjustment factors, because time-current curves are based on an ambient of 25°C. Adjustment also must be made for preheating of fuses due to load current to ensure effective coordination of fuses with each other and/or with CBs. Manufacturer's curves of adjustment factors for ambient temperature and fuse preloading are available.

Figure 490-5 shows the time-current characteristic for an R-rated, current-limiting (silver-sand) fuse designed for 2400- and 4800-V motor applications. Such fuses must be selected to coordinate with the motor controller overload protection, with the controller clearing overloads up to 10 times motor current and the fuse taking over for faster opening of higher currents up to the interrupting rating of the fuse. The amp rating of R-rated fuses is given in values such as 2R or 12R or 24R. If the number preceding the R is multiplied by 100, the value obtained is the ampere level at which the fuse will blow in 20 s. Thus, the rating designation is *not* continuous current but is based on the operating characteristics of the R-rated fuse. Continuous current rating of such fuses is given by the manufacturer at some value of ambient temperature.

Fig. 490-5. R-rated fuses are used in motor starters for 2400- and 4800-V motors. (Sec. 490.21.)

Fused cutouts for medium-voltage circuits, as shown in [Fig. 490-6](#), are available for outdoor applications only, as regulated by part (C) of this section in general, and (C)(1) in particular, which flatly prohibits this equipment from being used indoors. Pull-type fuse cutouts are used outdoors on pole-line crossarms where the ionized gas expelled during operation is unlikely to cause a flashover in a confined space, or damage someone's hearing due to the loudness of the report. The use indoors in electric rooms where accessible only to qualified persons, as shown in [Fig. 490-7](#), appears to be a violation of this rule. Such fused cutouts, if "designed for the purpose," are acceptable for use as an isolating switch, as permitted by 490.22.

Fig. 490-6. Expanded rules cover use of distribution cutouts. (Sec. 490.21.)

Fig. 490-7. Distribution cutouts are single-pole, fused, protective, and disconnect devices that are hook-stick-operable. Note voltage and current rating on case of each cutout (arrow), as required by part (C)(5) of 490.21. (Sec. 490.21.) The location appears to be indoors, and if so, would be controversial in light of the prohibition in 490.21(C)(1).

Part (D) of this section covers oil-filled cutouts. In addition to air CBs, oil CBs, and fused load-interrupter switches, another device frequently used for control of medium-voltage circuits is the oil-filled cutout. Compared to breakers and fused switchgear, oil-filled cutouts are inexpensive devices that provide economical switching and, where desired, overload and short-circuit protection for primary voltage circuits.

The oil-filled cutout is a completely enclosed, single-pole assembly with a fusible or nonfusible element immersed in the oil-filled tank that makes up the major part of the unit, and with two terminals on the outside of the housing. Figure 490-8 shows the basic construction of a typical cutout with a listing of available entrance fittings for the terminals to suit them to various cable and job requirements. The circuit is broken or closed safely and rapidly by the internal switching mechanism. The switch mechanism is made up of a rotating element that, in the closed position, bridges two internal contacts—each contact connecting to one of the outside terminals. The rotating element is completely insulated from the external case and from the external handle that operates the element. The rotating element may be simply a shorting blade when the cutout is used as an unfused switch. When the cutout is to be used as a fused switching unit, the rotating bridging element is fitted with a fuse. Operation of an oil-filled cutout is controlled at the top end of the shaft extending out through the top of the housing.

Fig. 490-8. Oil-filled cutout is a fused or unfused, single-pole disconnect device. (Sec. 490.21.)

As a single-pole switching device, the oil-filled cutout is not polarized—that is, either terminal may be a line or load terminal. This is a result of the symmetrical construction of the switching

element and suits the device to use in circuit sectionalizing or as a tie device in layouts involving two or more primary supply circuits. Note that these Code rules on oil-filled cutouts are different from those in part (C) on distribution cutouts.

With an oil-filled cutout, the switching of load current or the breaking of fault current is confined within a sturdy metal housing. Operation is made safe and quiet by confining arcs and current rupture forces within the enclosure. This operating characteristic of the cutouts especially suits them to use where there are explosive gases or flammable dusts, where complete submersion is possible, where severe atmospheric conditions exist, or where exposure of live electrical parts might be hazardous.

Oil-filled (sometimes called *oil-fuse*) cutouts are made in three sizes based on continuous current—100, 200, and 300 A, up to 15 kV. In one line there are three basic types. *Pole-type cutouts* are equipped with rubber-covered leads from the terminals for use in open wiring. *Pothead-type cutouts* have a cable lead from one terminal for open wiring and a sleeve on the other for connecting a lead or rubber-covered cable from an underground circuit. *Subway-type cutouts* are for underground vaults and manholes, particularly where submersion might occur, and are equipped with a sleeve on each terminal for rubber- or lead-sheathed cable. [Figure 490-9](#) lists the various types of terminal connections that are available on oil-filled cutouts.

Application	Cable cover	No. of conduits	Entrance type	Method of sealing
Indoor	Rubber or neoprene	Single	Porcelain	Tape Always tape this connection!
		Multiple	Stud bushing	
Indoor or outdoor	Rubber, lead or neoprene	Single	Stuffing box	Compression fittings
	Polyethylene	Single		Compression fittings and tube seal
	Lead	Single	Wiping sleeve	Solder wipe

Fig. 490-9. Terminals on oil-filled cutouts must be matched to application and cable type. (Sec. 490.21.)

For multiphase circuits, two or three single-phase cutout units can be group-mounted with a gang-operating mechanism for simultaneous operation. [Figure 490-10](#) shows three-gang assemblies. For pole mounting, linkage and a long handle are available for operating cutouts from the ground. Or cutouts can be flange-mounted on a terminal box, as shown in [Fig. 490-11](#), where the three-gang assembly was added to a medium-voltage switchgear on a modernization job.

Fig. 490-10. Oil-filled cutouts can be assembled as a 3-pole device for 3-phase circuits. (Sec. 490.21.)

Fig. 490-11. Gang-operated 3-pole assembly of oil-filled cutouts provided addition of a new medium-voltage circuit on a modernization project, but location of the units was questioned because part **(D)(7)** imposes a 5-ft (1.5 m) maximum mounting height. (Sec. 490.21.)

Because oil-filled cutouts provide load-break capability and overcurrent protection, they may be used for industrial and commercial service equipment, for switching outdoor lighting of sports fields and shopping centers, for transformer loadcenters, for primary-voltage motor circuits, or for use in vaults and manholes of underground systems.

In 100- and 200-A ratings, oil-filled cutouts are available in combination with current-limiting power fuses in double-compartment indoor or outdoor enclosures. These fused oil interrupter switches provide moderate load-break and high fault-current interrupting capability in an economical package.

Part **(E)** of this section recognizes the use of so-called load-interrupter switches used in medium-voltage systems. In parts **(1)** to **(6)**, a wealth of specific data provides guidance to design engineers, electrical installers, and electrical inspectors on the proper installation, operation, and maintenance

of medium-voltage interrupter switches—with particular emphasis on safety to operators and maintenance personnel.

Switching for modern medium-voltage electrical systems can be provided by a number of different equipment installations. For any particular case, the best arrangement depends on several factors: the point of application—either for outside or inside distribution or as service equipment; the voltage; the type of distribution system—radial, loop, selective, network; conditions—accessibility, type of actual layout of the equipment; job atmosphere; use; future system expansion; and economic considerations.

Types of switches used in medium-voltage applications include:

1. Enclosed air-break load-interrupter switchgear with or without power fuses
2. Oil-filled cutouts (fused or unfused)
3. Oil-immersed-type disconnect switches

Modern load-interrupter switchgear in metal safety enclosures finds wide application in medium-voltage distribution systems, in combination with modern power fuses (Fig. 490-12). 230.208 of the **NEC** covers use of air load-interrupter switches, with fuses, for disconnect and overcurrent protection of medium-voltage service-entrance conductors, and refers the reader to Part **II** of Art. 490. Part **(E)** of 490.21 also covers use of fused air load-interrupter switches for medium-voltage feeder in distribution systems, as well as at service equipment.

Fig. 490-12. Load-interrupter switchgear is generally used with fuses to provide protection as well as load-break switching for medium-voltage circuits. The fuses must be rated to provide complete protection for the load interrupter on closing, carrying, or interrupting current—up to the assigned maximum short-circuit rating. (Sec. 490.21.)

Metal-enclosed fused load interrupters offer a fully effective alternative to use of power CBs, with substantial economies, in 5- and 15-kV distribution systems for commercial, institutional, and industrial buildings. Typical applications for such switchgear parallel to those of power CBs include the following:

1. *In switching centers*—Switchgear is set up for control and protection of individual primary feeders to transformer loadcenters.
2. *In substation primaries*—Load-interrupter switchgear is used for transformer switching and protection in the primary sides of substations.
3. *In substation secondaries*—Here the switchgear is used as a switching center closely coupled to a medium-voltage transformer secondary.
4. *In service entrances*—This is a single-unit application of a switchgear bay for service-entrance disconnect and protection in a primary supply line.

Fused load-interrupter switchgear, typically rated up to 1200 A, can match the ratings and required performance capabilities of power CBs for a large percentage of applications in which either might be used.

Fuse-interrupter switches for medium-voltage circuits are available with manual or power operation—including types with spring-powered, over-center mechanisms for manual operation or motor-driven, stored-energy operators. Available in indoor and outdoor housings, assemblies can be equipped with a variety of accessory devices, including key-interlocks for coordinating switch operation with remote devices such as transformer secondary breakers.

Vacuum switchgear, with its contacts operating in a vacuum “bottle” that is enclosed in a compact cylindrical assembly, has gained wide acceptance as load interrupters for medium-voltage switching and sectionalizing. Available in 200- and 600-A ratings for use at 15.5, 27, and 38 kV, this switching equipment is suited to full-load interruption and is rated for 15,000- or 20,000-A short-circuit current under momentary and make-and-latch operations. BIL ratings are 95, 125, or 150 kV.

Vacuum switch assemblies, with a variety of accessories, including stored-energy operators and electric motor operators for remote control, are suited to all indoor and outdoor switching operations—including submersible operation for underground systems. The units offer fireproof and explosionproof operation, with virtually maintenance-free life for their rated 5000 load interruptions. Units are available in standard 2-, 3-, and 4-way configurations, along with automatic transfer options. Accessory CTs and relays can be used with stored-energy operators to apply vacuum switches for fault-interrupting duty.

490.22. Isolating Means. Air-break or oil-immersed switches of any type may be used to provide the isolating functions described in this section. Distribution cutouts or oil-filled cutouts are also used as isolating switches.

Oil-immersed disconnect switches are used for load control and for sectionalizing of primary-voltage underground-distribution systems for large commercial and industrial layouts (Fig. 490-13). Designed for high-power handling—such as 400 A up to 34 kV—this type of switch can be located at transformer loadcenter primaries or at other strategic points in medium-voltage circuits to provide a wide variety of sectionalizing arrangements to provide alternate feeds for essential load circuits.

Fig. 490-13. Oil switches are commonly used for isolating equipment and circuits for sectionalizing and for transfer from preferred to emergency supply. (Sec. 490.22.)

Oil-immersed disconnect switches are available for as many as five switch positions and ground positions to ground the feeder or test-ground positions for grounding or testing. Ground positions are used in such switches to connect circuits to ground while they are being worked on to assure safety to personnel.

Oil switches for load-break applications up to 15 kV are available for either manual or electrically powered switching for all types of circuits. When electrical operation is used, the switch functions as a medium-voltage magnetic contactor.

Switches intended only for isolating duty must be interlocked with other devices to prevent opening of the isolating switch under load, or the isolating switch must be provided with an obvious sign warning against opening the switch under load.

490.24. Minimum Space Separation. For field fabricated installations, these are the distances that have to be met in terms of clearances between uninsulated live parts and from such parts to ground. If equipment has been formally manufactured and evaluated in accordance with recognized standards, then the dimensions in this table no longer apply.

490.25. Backfeed. This section was relocated from one of the substation provisions formerly in 225.70(A)(4) and also by borrowing appropriate prescriptive language regarding the required warning from 404.6(C) Exception. In this location it applies generally. A single-line diagram is

required that identifies the connections to high voltage.

III. EQUIPMENT—METAL-ENCLOSED POWER SWITCHGEAR AND INDUSTRIAL CONTROL ASSEMBLIES

490.30. General. Where the previous sections presented regulations on the individual switching and protective devices, this section covers enclosure and interconnection of such unit devices into overall assemblies. Basically, the rules of this section are aimed at the manufacturers and assemblers of such equipment.

Use of all medium-voltage switching and control equipment must be carefully checked against information given with certification of the equipment by a test laboratory—such as data given by UL in its Guide Card information [see discussion at 110.3(B) for details]. Typical data are as follows:

Unit substations listed by UL have the secondary neutral bonded to the enclosure and have provision on the neutral for connection of a grounding conductor. A terminal is also provided on the enclosure near the line terminals for use with an equipment grounding conductor run from the enclosure of primary equipment feeding the unit sub to the enclosure of the unit sub. Connection of such an equipment grounding conductor provides proper bonding together of equipment enclosures where the primary feed to the unit sub is directly buried underground or is run in nonmetallic conduit without a metal conduit connection in the primary feed (Fig. 490-14).

Fig. 490-14. NEC rules on equipment construction are supported by UL data. (Sec. 490.24.)

The rule of 490.44 is particularly aimed at the designers and installers of equipment, rather than at manufacturers. Part (B) emphasizes that careful layout and application of switching components of all types are important. Figure 490-15 shows the kind of condition that can be extremely hazardous in

medium-voltage layouts where there is the chance of a secondary to primary feedback—such as the intentional one shown to provide emergency power to essential circuits in Building 2. Under emergency conditions, the main fused interrupter is opened and the secondary CB for the generator is closed, feeding power to the 480-V switchboard in Building 1 and then feeding through two transformers to supply power to the 480-V circuits in Building 2. This hookup makes the load side of the main interrupter switch live, presenting the hazard of electrocution to any personnel who might go into the switch thinking that it is dead because it is open. A second switch can eliminate this difficulty, if applied with interlocks.

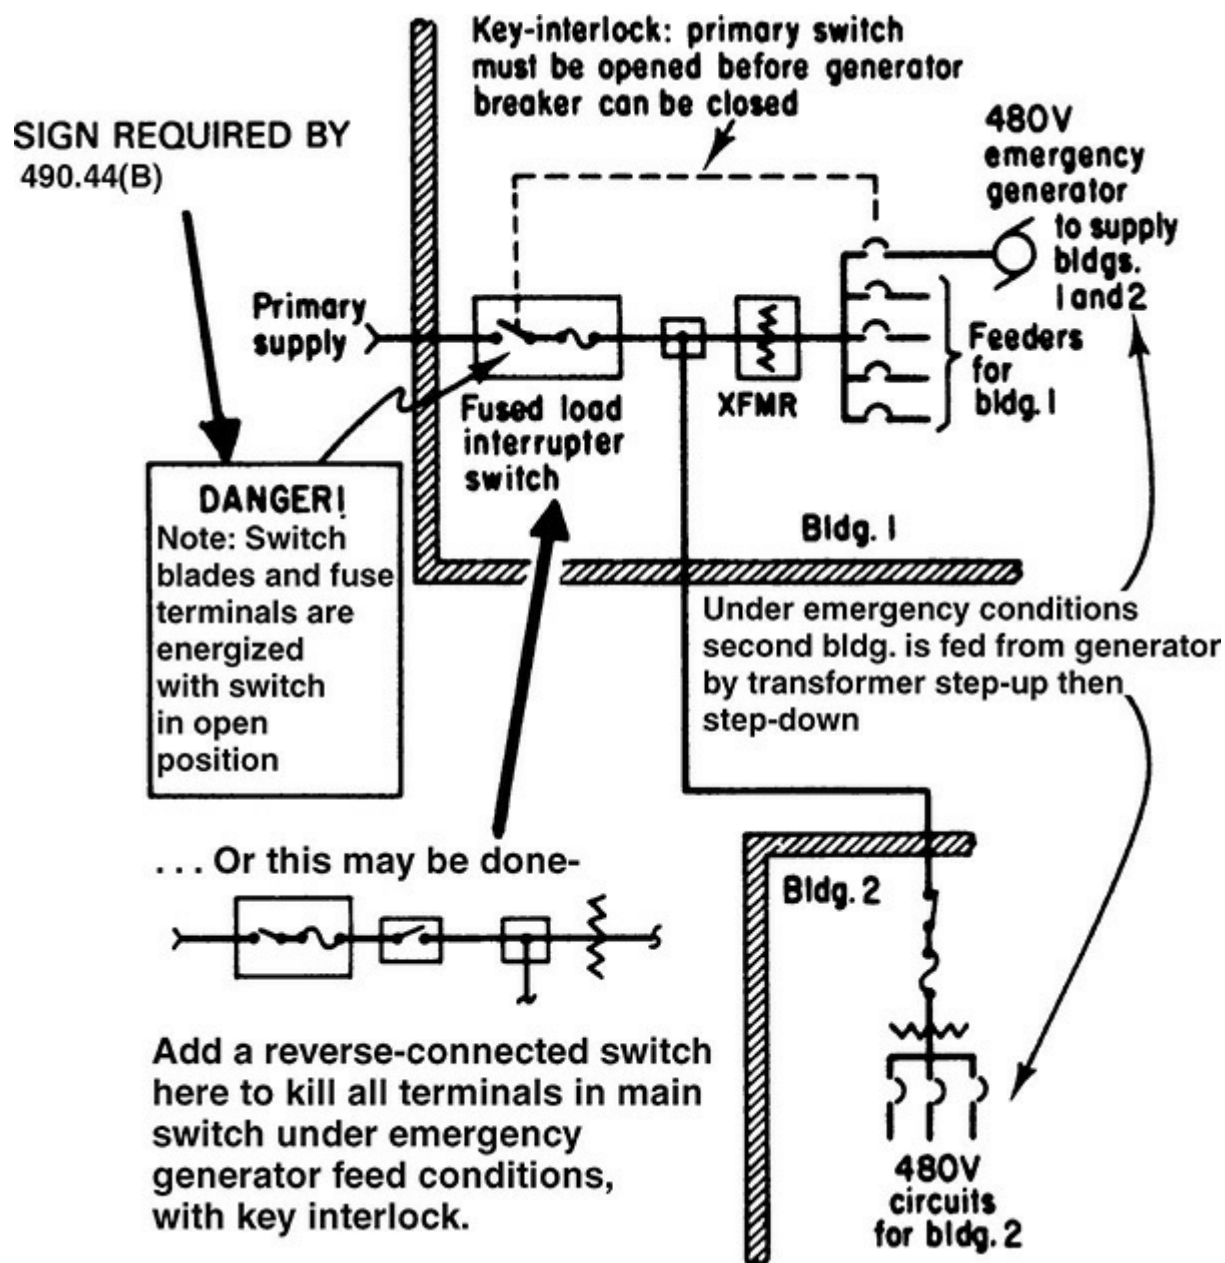

Fig. 490-15. Feedback in medium-voltage hookups can be hazardous. (Sec. 490.24.)

490.35. Accessibility of Energized Parts. Equipment operating at 1000 V and below must be excluded from medium-voltage enclosures with exposed live parts [part (A)] unless access under hazardous conditions is eliminated due to interlocks or other procedures. However, space heaters, and also medium-voltage instrument or control transformers [part (C)] are permitted in such spaces without any access limitations beyond the locked doors required in part (A). The 2014 NEC

relocated a warning sign requirement from its former home [225.70(A)(5)(b)] addressing substations and made it generally applicable at these voltages by improving its editorial content and placing at the end of this section.

490.41. Location of Industrial Control Equipment. Operating handles for control and instrument transfer switches or pushbuttons must be readily accessible, and not over 2.0 m (78 in.) high. Operating handles requiring more than 23 kg (50 lb) of force to move must not be over 1.7 m (66 in.) high. Part (B), however, waives this requirement for “infrequently operated devices” and sets out a list by way of explaining by example the intended application of the word “infrequently.” The section was reorganized in the 2011 cycle to clarify its terms.

490.46. Circuit Breaker Locking. This is the medium-voltage version of the locking-mechanism-to-remain-in-place rule, addressing drawout gear, etc.

490.47. Metal-Enclosed and Metal-Clad Service Equipment. This rule requires medium-voltage service equipment manufacturers to provide a grounding busbar that extends into the compartment where the service conductors will terminate. The busbar will provide a termination point for cable shielding connections to earth, as well as an appropriate point to attach safety grounds for the protection of personnel who may need to work on the equipment. The 2014 **NEC** has added a marking requirement [relocated from former 225.70(A)(5)(c)] to the connection compartment addressed here and subject to the warning sign required by the new language in 490.35(A). The access door or panel must advise that access is limited to the serving utility or permitted only following their authorization.

490.48. Substation Design, Documentation, and Required Diagram. The 2014 **NEC** has addressed substation designs involving medium-voltage sections in a major way. Part (B) of this section covering the required one-line diagram is not new, having moved (with editorial improvements) from its former location in 225.70(A)(5)(a). As previously, a simple unit substation with only one set of high-voltage switching devices is exempt. Part (A) is entirely new to the **NEC**, having been suggested by a high-voltage task group, but significantly modified in the process of being incorporated into Art. 490. It places substation design into the hands of a licensed professional engineer and requires the design documentation to be available to the inspector. However, to the extent the substation has been the subject of an overall listing process, such as is frequently the case for unit substations, the underlying documentation falls within the parameters of 90.7 and is not required to be made available to fulfill this requirement.

Chapter Five

ARTICLE 500. HAZARDOUS (CLASSIFIED) LOCATIONS, CLASSES I, II, AND III, DIVISIONS 1 AND 2

The informational note provided before the main body of text informs the reader that certain rules within the scope of Arts. 500 through 504 contain references to rules in other **NFPA** standards, with slight editorial modifications. For more information regarding those rules, consult the specified portion and related rules within that standard.

500.1. Scope—Articles 500 Through 504. In the heading of this article, the word *classified* makes clear that hazardous locations are those which have been classified as hazardous by the inspection authority. Hazardous locations in plants and other industrial complexes are involved with a wide variety of flammable gases and vapors and ignitable dusts—all of which have widely different flash points, ignition temperatures, and flammable limits. These explosive or flammable substances are processed and handled under a wide range of operating conditions. In such places, fire or explosion could result in loss of lives, facilities, and/or production.

Effective with the 2017 **NEC**, the definitions formerly covered in this location have been moved to Art. 100. Refer to Table 100-1 at the end of Article 100 coverage in this book for a listing of definitions related to hazardous (classified) locations that are now in that location, including all the definitions formerly within Art. 500. This book will continue to comment on the requirements in these articles, and do so entirely within the coverage of these articles. There will be no commentary on hazardous (classified) location terminology within the coverage this book otherwise provides in Article 100.

500.4. General. This basic requirement of part (A) calls for documentation of all hazardous (classified) locations. The nature of the document may vary from jurisdiction to jurisdiction, but some paperwork must be produced to identify those areas that are hazardous (classified) locations within any facility. This paperwork should properly and clearly indicate those portions of the facility that are designated as classified locations and the specific classification affixed to that area, including the class/division or zone designation. Such documentation must be made available to design and maintenance personnel.

Part (B) contains a number of informational notes that identify other **NFPA** standards that bear on specifics related to various types of combustible materials. These documents provide standards and guidelines for the safe handling, processing, storage, and so on, of the combustible material in question. The 2017 **NEC** adds a sixth note here regarding the use of self-contained power supplies within hazardous (classified) locations.

500.5. Classifications of Locations. Part (A) addresses the classification of various explosive

environments. Classification of hazardous areas must be approached very carefully, based on experience and a detailed understanding of electrical usage in the various kinds of locations. After study and analysis—and consultation with inspection authorities or other experts in such work—hazardous areas may be identified and delineated diagrammatically by defining the limits and degree of the hazards involved. In all cases, classification must be carefully based on the type of gas involved, whether the vapors are heavier or lighter than air, and similar factors peculiar to the particular hazardous substance.

Locations used for pyrophoric materials, which ignite spontaneously on contact with air, are exempted from designation as Class I hazardous locations. The status of adjacent electrical components has no bearing on whether these materials will ignite, and therefore any enhanced wiring precautions, including those in this chapter of the **NEC**, would be irrelevant to the likelihood of fire or explosion associated with their use. Therefore electrical equipment approved for classified locations is not needed for places where pyrophoric materials are handled. As an example, sodium metal is pyrophoric, and is usually stored under oil to prevent contact with air for this reason.

The **NEC** uses three basic classes to indicate the type of hazard involved, and those classes (I, II, and III) are in two cases (I and II) further subdivided into lettered groupings to specify the exact type of hazard. Additionally, each of the three classes is divided into two divisions to indicate the prevalence of hazard. Area classifications are seldom performed by an electrical inspector; they are done by qualified engineers subject to review. The reviewer may be the chief of the fire department or some other official.

Classification takes into account that all sources of hazards—gas, vapor, dust, fibers—have different ignition temperatures and produce different pressures when exploding. Electrical equipment must, therefore, be constructed and installed in such a way as to be safe when used in the presence of particular explosive mixtures. The source of hazard must be evaluated in terms of those characteristics that are involved with explosion or fire, and the following discussion regarding the classification of diesel fuel is a good example.

Diesel Oil and Heating Oil

Questions often arise about the need for hazardous location wiring for electrical equipment installed in areas containing diesel fuel oil or heating oil. The National Fire Code (NFC) classifies diesel fuel oil as a Class II liquid having a flash point at or above 100°F (37.8°C) and below 140°F (60°C). The same NFC standard on bulk plants states in part that in areas where Class II or Class III liquids are stored or handled, the electrical equipment *may* be installed in accordance with the provisions of the **NEC** for ordinary (i.e., nonhazardous) locations. Diesel fuel oil is classified as a Class II liquid and does not come under requirements for hazardous (classified) locations. With this type of liquid, explosionproof wiring methods *are not* required and the wiring methods listed in [Chaps. 1 through 4](#) of the **NEC** may be used. The NFC does, however, caution that, if any Class II flammable liquid is heated, it may be necessary that Class I Group D wiring methods be used. In some geographic areas with hot climates, local regulations do require diesel fuel areas to be treated as hazardous areas because of high ambient temperatures. Temperatures in the Southwest often exceed 115°F (46°C), especially in closed, nonventilated areas.

The *flash point* of a liquid is the minimum temperature at which the liquid will give off sufficient vapor to form an ignitable mixture with air near the surface of the liquid or within the vessel used.

(This characteristic is not applicable to gases.)

The *autoignition temperature* of a substance is the lowest temperature that will initiate explosion or cause self-sustained combustion of the substance.

Explosive limits: When flammable gases or vapors mix with air or oxygen, there is a minimum concentration of the gas or vapor below which propagation of flame does not occur upon contact with a source of ignition. There is also a maximum concentration above which propagation does not occur. These boundary-line mixtures are known as the lower and upper explosive (or flammable) limits and usually are expressed in terms of the percentage of gas or vapor in air, by volume.

Vapor density is the weight of a volume of pure vapor or gas (with no air present) compared to the weight of an equal volume of dry air at the same temperature and pressure.

A note in 500.5(A) indicates that maximum effort should be made to keep as much electrical equipment as possible out of the hazardous areas—particularly minimizing installation of arcing, sparking, and high-temperature devices in hazardous locations. It is generally economically and operationally better to keep certain electrical equipment out of hazardous areas. [Figure 500-1](#) shows an example in which the drive shaft of the motor is extended through a packing gland in one of the enclosing walls. To prevent the accumulation of flammable vapors or gas within the motor room, it should be ventilated effectively by clean air or kept under a slight positive air pressure. A gas detector giving a visual and/or audible alarm would be an additional desirable safety feature.

Fig. 500-1. Keeping electrical equipment in nonhazardous area eliminates costly hazardous types. (Sec. 500.5.)

The separate paragraph at this point covering rooms used for ammonia refrigeration systems has been revised for the 2017 **NEC**, and now provides specific, threshold parameters relative to acceptable ammonia concentrations. Specifically, if they are ventilated to prevent an ammonia concentration above 150 ppm, they can be unclassified. There are many vendors that sell gas detection systems capable of monitoring the area and initiating ventilation as required. Ammonia is an inexpensive refrigerant with wide industrial usage, and is often used for commercial activities as well, such as large commercial refrigeration activities including skating rinks. Note that there are other large-scale applications for ammonia beyond refrigeration. For just one, ammonia is used in many municipal water plants to help purify the water, and they face comparable area classification issues. It may be advisable in a future Code cycle to make this paragraph more generally worded.

Positive-pressure ventilation is also cited as a means of reducing the level of hazard in areas where explosive or flammable substances are or might be present. Air-pressurized building interiors can provide safe operation without explosionproof equipment. When explosionproof equipment is not

justified financially, pressurized building interiors can alter the need. For example, if a motor control center is to be located in a building in a Class I hazardous location, the entire room may be pressurized. But construction must comply with certain specific requirements:

1. The building area or room must be kept as airtight as possible.
2. The interior space must be kept under slight overpressure by adequate positive-pressure ventilation from a source of clean air.
3. The pressurizing fans should be connected to an emergency supply circuit.
4. Ventilating louvers must be located near ground level to achieve effective airflow within the pressurized room.
5. Safeguards against ventilation failure must be provided.

The first part of this section concludes with important information regarding the use of ammonia for refrigeration. Ammonia normally presents a Class I explosion hazard, however, the lower explosive limit is relatively high, and far beyond the limits of toleration for human exposure. To correlate with an ASHRAE document governing refrigeration machinery, if gas detection equipment is in place that will initiate ventilation in the event the ammonia concentration reaches or exceeds 150 ppm, then the area can be considered unclassified. The current **NEC** limits this permission to refrigeration areas. Ammonia has many other uses, including water purification, that could, and probably should, benefit from inclusion in this allowance going forward. It might be a fruitful topic of a 90.4 (equivalent hazard) conversation with the inspector where it applies.

Part **(B)** of 500.5 describes Class I locations. In each of the three classes of hazardous locations discussed in parts **(B)**, **(C)**, and **(D)** of 500.5, the Code recognizes varying degrees of hazard; hence, under each class, two divisions are defined. In the installation rules that follow, the requirements for Division 1 of each class are more rigid than the requirements for Division 2.

The hazards in the three classes of locations are due to the following causes, and then divided into divisions (1 or 2) based on the prevalence of the combustible agent, as follows:

Class I locations, as covered in **(B)**, are those “in which flammable gases, flammable liquid-produced vapors, or combustible liquid-produced vapors are present or may be present in the air in quantities sufficient to produce explosive or ignitable mixtures.” Class I, Division 1 locations are those in which hazardous concentrations of gas (1) exist continuously or intermittently under normal operations, (2) exist frequently because of maintenance or leakage, or (3) might exist because of breakdowns or faulty operation that might also result in simultaneous failure of electric equipment in such a way as to cause the electrical equipment to become an ignition source. Examples are paint-spraying areas, systems that process or transfer hazardous gases or liquids, portions of some cleaning and dyeing plants, and hospital operating rooms in countries that still use ethers and related flammable anesthetic agents. These anesthetizing materials are no longer used in the United States, but they are still used in some countries.

Class I, Division 2 locations are locations (1) in which flammable gases or volatile flammable liquids are normally confined within containers or closed systems from which they can escape only in case of breakdown, rupture, or abnormal operation; (2) in which the hazardous concentrations are prevented by mechanical ventilation from entering but which might become hazardous upon failure of the ventilation; or (3) that are adjacent to a Class I, Division 1 location and might occasionally become hazardous unless prevented by positive-pressure ventilation from a source of clean air by a ventilation system that has effective safeguards against failure. Examples are storage in sealed

containers and piping without valves.

Class II locations, as covered in (C), are those having combustible dust.

Class II, Division 1 locations are those in which combustible dust is or may be in suspension in the air in sufficient quantity to produce an explosive or ignitable mixture (1) continuously or intermittently during normal operation, (2) as a result of failure or abnormal operation that might also provide a source of ignition by simultaneous failure of electric equipment, or (3) in which combustible dust that is electrically conductive may be present. Examples are grain elevators, grain-processing plants, powdered-milk plants, coal-pulverizing plants, and magnesium-dust-producing areas.

Class II, Division 2 locations are those in which combustible dust is not normally in suspension in the air and is not likely to be under normal operations in sufficient quantity to produce an explosive or ignitable mixture but in which accumulations of dust (1) might prevent safe dissipations of heat from electric equipment, or (2) might be ignited by arcs, sparks, or burning material escaping from electric equipment. Examples are closed bins and systems using closed conveyors and spouts.

Class III locations are those in which there are easily ignitable fibers or flyings, such as lint, but in which the fibers or flyings are not in suspension in the air in sufficient quantity to produce an ignitable mixture. Class III, Division 1 locations are those in which easily ignitable fibers or materials that produce combustible flyings are manufactured, used, or otherwise handled, such as textile mills, cotton gins, and woodworking plants. Class III, Division 2 locations are those in which such fibers are stored, such as a warehouse for baled cotton, yarn, and so forth.

A frequent question arises as to whether a Class III location should be actually classified as Class II or the reverse. **NFPA 499** includes a useful, objective definition on this point. A combustible finely divided dust that is comprised of particles no larger than 420 μm (0.017 in.) in diameter, thereby capable of passing through a U.S. No. 40 standard sieve, is a Class II exposure. This definition, extracted from **NFPA 499**, now appears in 500.2, so it is no longer necessary to search the source document for it. Larger fibers and flyings, such as in textile operations, are Class III. Most sawdust is neither, but some woodworking operations with very fine powder from some sanding operations do fall into a Class II classification.

The classifications are easily understood, and, if a given location is to be classed as hazardous, it should not be difficult to determine in which of the three classes it belongs. Each of the classifications in this section includes extensive informational notes that are very well written and of great assistance in clarifying the conditions that produce a given area classification. However, it is obviously impossible to make rules that will in every case determine positively whether the location is or is not hazardous. Considerable common sense and good judgment must be exercised in determining whether the location under consideration should be considered as hazardous or likely to become hazardous because of a change in the processes carried on, and if so, what portion of the premises should be classed as coming under Division 1 and what part may safely be considered as being in Division 2.

500.6. Material Groups. Informational note No. 2 in part (A) explains the basic reason for the subdivisions. Equipment for use in Class I locations is divided into Groups A, B, C, and D; for Class II into Groups E, F, and G. Each group is for a specific hazardous material, which you can determine by consulting your copy of the **NEC**. All equipment for hazardous locations must be marked to show the class and the group for which it is approved; some equipment is suitable for more than one group

and is so marked. Note that for Group E, which encompasses the electrically conductive metallic dusts, there are no Division 2 locations. These dusts are so hazardous that if they are present in any quantities, no matter how infrequently, the location must be wired to Class II, Division 1 standards, using equipment evaluated for Group E exposure.

The exception to 500.6, correlated with language in 500.8(C)(3) on required markings, allows an evaluation based on a specific substance (gas, vapor, dust, or fiber/flying) in lieu of a group classification. This is probably not practical for fiber/flying applications, but occasionally is used in other cases.

500.7. Protection Techniques. This section indicates those methods that provide protection against accidental ignition of a combustible atmosphere.

Purging of electrical raceways and enclosures is a strategy that can be used to reduce the degree of hazard (Fig. 500-2). But that requires both the manufacturer and the user of purged equipment to ensure the integrity of the system. Prepackaged purge controls for both Division 1 and Division 2 locations are in the market.

Fig. 500-2. A seal fitting (upper arrow) is used for equipment enclosure. But nitrogen purging of the conduit system was also applied at this installation at a space-rocket launch-pad. Equipment was specified to be listed for Class I, Division 1, Group B where exposed to hydrogen and for Group D where the equipment was in a rocket-fuel atmosphere. Where motors, panelboards, enclosures, etc., were not available in the proper group rating, nitrogen purging and pressurization were used in addition to sealing, to add another measure of safety. The valve (lower arrow) was used in the cover of each conduit body to provide continuous bleedoff of the nitrogen to maintain a pressure (2 in. of water) within the conduit, enabling the steady flow of nitrogen to keep the conduit free of any

explosive mixture. (Sec. 500.7.)

This technique is called “purged and pressurized” in the **NEC**. This equipment must be connected to a source of clean air under constant pressure. It must be arranged with automatic means to disconnect power if the air supply fails, and it must be equipped with a time-delay function so that its interior can purge prior to the restoration of power. There are three levels of purged and pressurized enclosures. Type X purging reduces a Division 1 environment to unclassified, Type Y purging reduces from Division 1 to Division 2, and Type Z purging goes from Division 2 to unclassified.

The purging medium—for example, inert gas, such as nitrogen, or clean air—must be essentially free from dust and liquids. The normal ambient air of an industrial interior is usually not satisfactory. And because the purge supply can contain only trace amounts of flammable vapors or gases, the compressor intake must be in a nonhazardous area. The compressor intake line should not pass through a hazardous atmosphere. If it does, it must be made of a noncombustible material, must be protected from damage and corrosion, and must prevent hazardous vapors from being drawn into the compressor.

Another widely used method involves the use of “intrinsically safe” equipment in hazardous locations and exempts such equipment from the rules of Arts. 500 through 517 where such areas of the various occupancies and locations covered by these articles are identified as “hazardous (classified) locations.” Intrinsic safety is obtained by restricting the energy available in an electrical system to much less than that required for the ignition of specified flammable atmospheres such as gases and vapors that may exist in a particular processing area. If the energy level can be assured to be sufficiently low, any failure in the wiring system won’t be ignition capable. These energy levels are very low. For example, an energy level of just $\frac{1}{4}$ milliwatt-second will ignite methane, and levels one-tenth of that will ignite unsaturated hydrocarbons such as ethylene. These circuits use Zener diodes in their supplies, arranged so that even a direct short circuit with its associated potential arcing and heating would not be ignition capable. These circuits can be used with ordinary wiring methods in hazardous (classified) locations for which they are rated. But such equipment must be “approved,” which requires careful attention by the AHJ and the installer to any applicable UL listing and application data from the Hazardous Location Equipment Directory of UL.

Any applications of “intrinsically safe apparatus” in Class I, II, or III, or Class I, Zones 0, 1, and 2, or Zone 20, 21, and 22 locations must satisfy the rules of Art. 504 covering such apparatus. In this section, the reference to Art. 504 notes that the “provisions of Arts. 501 through 503 and 510 through 516 shall not be considered applicable” to intrinsically safe apparatus and wiring “except as required by Art. 504.”

Intrinsically safe circuits and equipment for use in Division 1 locations must be carefully applied. It is up to the designer and/or the installer to be sure that the energy level available in such equipment is below the level that could ignite the particular hazardous atmosphere. This must be ensured for both normal and abnormal conditions of the equipment. Testing of an intrinsically safe system by UL is based on a maximum distance of 5000 ft (1525 m) between the equipment installed in the nonhazardous, or Division 2, location and the equipment installed in the Division 1 location.

Nonincendive wiring is closely related to intrinsically safe wiring. Under all normal operating conditions it can’t produce ignition-capable energy, but under very unusual (but foreseeable) operating conditions, might produce such an effect. These circuits are allowed in ordinary wiring in Division 2 locations, but not Division 1. The principle here is that given two low-likelihood

probabilities, the probability of them occurring at the same moment is infinitesimal—the two low probabilities in this case being a Division 2 vapor release and a nonincendive circuit failing in a way that is ignition capable.

Wiring of intrinsically safe circuits must be run in separate raceways or otherwise separated from circuits for all other equipment to prevent imposing excessive current or voltage on the intrinsically safe circuits because of fault contact with the other circuits. In fact, no “fault” need occur; the adjacent circuits could cause a sufficient problem simply through induced voltages on the system believed to be intrinsically safe.

500.8. Equipment. Because of the inherently higher level of danger, design and installation of electrical circuits and systems in hazardous locations must be done in particularly strict compliance with the instructions given in product standards. Although **NEC 110.3(B)** requires all product applications to conform to the conditions and limitations specified in the directories issued by third-party testing labs (UL, Factory Mutual, ETL, etc.), the correlation of hazardous location electrical equipment is much more thoroughly dictated than that in nonhazardous areas.

In addition to the rules given in Arts. 500 through 504, an alternative method of classification is explained and permitted by Arts. 505 and 506. Application of the classifications indicated by Art. 505—that is, zone 0, 1, or 2, or 20, 21, and 22 (Art. 506)—is also permitted.

1. 500.8 requires that construction and installation of equipment in all hazardous areas “will ensure safe performance under conditions of proper use and maintenance.” A note urges designers, installers, inspectors, and maintenance personnel to “exercise more than ordinary care” for hazardous location work. Parts **(A)** and **(B)** identify what type of equipment may be used in the various groups of hazardous locations and stipulate the markings required for equipment used in each such location. Explanatory material describes the nature of various hazardous atmospheres.
2. Paragraph **(A)(1)** of this section requires that all equipment in hazardous locations be approved not only for the class of location (such as Class I, II, or III) but also for the particular type of hazardous atmosphere (such as Group A, B, C, or D for locations involving gases or vapors, or Group E, F, or G if the atmosphere involves combustible or flammable dusts). The Code section describes the specific atmospheres that correspond to these letter designations.

Part **(A)(2)** indicates that Division 1 equipment may be used in Division 2 locations provided such equipment is suitable for the same “class, group, and temperature class” as would be required for the Division 2 equipment. And installation must be as described in subparts **(A)** and **(B)**, of this section.

3. An important regulation is given in part **(B)(3)**, which permits use of “general-purpose equipment” or “equipment in general-purpose enclosures” in Division 2 conditions of Class I, II, or III locations. That rule permits equipment that is *not* listed for hazardous locations but is listed for general use—but such use is acceptable only where a Code rule specifically mentions such application. For instance, 501.10(B)4 does say that boxes and fittings in Class I, Division 2 locations do *not* have to be of the explosionproof type; in other words, sheet metal boxes could be used. But controversy arises over that third paragraph of 500.8(A)(3) because general-use enclosures are permitted only where the equipment does not pose a threat of ignition “under *normal* operating conditions.” Division 2 locations, however, *are* those where the hazardous atmosphere is not present under normal operating conditions.

This Code text is simply an editorial choice to restate that general principle. This is another

example of the larger principle discussed previously at nonincendive wiring, namely, that given two low-likelihood probabilities, the probability of them occurring at the same moment is infinitesimal—the two low probabilities in this case being a Division 2 vapor release and a wiring fault in the box. And this, in turn, is an application of the phrase in 90.1(B) that **NEC** adherence gives you an installation that is “essentially free from hazard”—not absolutely risk free, but essentially free from hazard.

4. In addition to being “approved” for the class and group of the hazardous area where it is installed, equipment is required by paragraph **(B)** of 500.8 to be “marked” with that data, along with its operating temperature at a 40°C ambient temperature, or at a higher ambient temperature if so rated and marked. Table 500.8(C) gives identification numbers that are used on heat-producing equipment nameplates to show the operating temperature for which the equipment is approved.

Non-heat-producing equipment does not require a temperature marking, nor does equipment that will not exceed 100°C. More than one temperature marking may appear based on differing operating environments. Part **(D)** requires, in the case of gases and vapors, that the applied temperature marking not exceed that of the autoignition temperature of the hazardous material. In the case of combustible dusts, the marked temperature must be less than the ignition temperature of the applicable dust. For organic dusts that may dehydrate or carbonize, the temperature rating must not exceed 165°C even if the rated ignition temperature is higher. As of the 2014 **NEC**, due to changes in other standards, the term “ignition temperature” is limited to combustible dusts, and the comparable temperature for gases and vapors is “autoignition temperature.”

Part **(E)** covers threads for conduit and other joints. In general all threaded joints must have at least five threads engaged, and also the joint must be made up wrenchtight whether or not a bonding jumper is installed. In this case the point is not simply to ensure equipment grounding continuity; it is also to ensure that the hot gases from an explosion inside a raceway only escape gradually and after they have cooled through the serpentine passage through the joint. There is an allowance for female threaded entries of listed equipment to only engage 4½ threads. The threads must use NPT specifications for taper of 1 in 16 (¾ in. taper per foot).

Metric-threaded equipment can be used, but the entries must be identified (probably means marked) as metric, or listed metric to NPT adapters must be provided. Note that there are cable fittings that use metric threads and that will mate with metric-threaded enclosures directly. Metric-threaded entries additionally require the engagement of eight threads for Group A (acetylene) and Group B (hydrogen) atmospheres. Metric entries also specify a minimum class of fit (6g/6H) which corresponds to a Class 2 (general use) fit in the NPT system. Not surprisingly unused openings must be plugged using metal plugs with comparable thread specifications.

Position of OSHA

With respect to equipment approval, great care must be taken to understand clearly the rules on hazardous locations equipment as covered in the electrical standards of the Occupational Safety and Health Administration (OSHA) of the U.S. Department of Labor. Those rules constitute federal law on this matter.

In the OSHA standard, Sec.1910.307, Hazardous (Classified) Locations, is listed as one of the

totally retroactive sections that apply to all electrical systems—both new ones and old ones—no matter when they were installed. On the matter of acceptability or approval of equipment used in hazardous locations, Sec. 1910.307(b) says:

Equipment, wiring methods, and installations of equipment in classified locations shall be intrinsically safe, approved for the hazardous (classified) location, or safe for the hazardous (classified) location. Requirements for each of these options are as follows:

(1) Intrinsically safe. Equipment and associated wiring approved as intrinsically safe shall be permitted in any hazardous (classified) location for which it is approved.

(2) Approved for the hazardous (classified) location.

[i] Equipment shall be approved not only for the class of location but also for the ignitable or combustible properties of the specific gas, vapor, dust, or fiber that will be present.

Note: NFPA 70[®], the National Electrical Code, lists or defines hazardous gases, vapors, and dusts by “Groups” characterized by their ignitable or combustible properties.

[ii] Equipment shall be marked to show the class, group, and operating temperature or temperature range, based on operation in 40°C ambient, for which it is approved. The temperature marking shall not exceed the ignition temperature of the specific gas or vapor to be encountered. However, the following provisions modify this marking requirement for specific equipment:

(A) Equipment of the non-heat-producing type, such as junction boxes, conduit, and fittings, and equipment of the heat-producing type having a maximum temperature not more than 100°C (212°F), need not have a marked operating temperature or temperature range.

(B) Fixed lighting fixtures marked for use in Class I, Division 2 locations only need not be marked to indicate the group.

(C) Fixed general-purpose equipment in Class I locations, other than lighting fixtures, which is acceptable for use in Class I, Division 2 locations need not be marked with the class, group, division, or operating temperatures.

(D) Fixed dusttight equipment, other than lighting fixtures, which is acceptable for use in Class II, Division 2 and Class III locations need not be marked with the class, group, division, or operating temperature.

(3) Safe for the hazardous (classified) location. Equipment which is safe for the location shall be of a type and design which the employer demonstrates will provide protection from the hazards arising from the combustibility and flammability of vapors, liquids, gases, dusts, or fibers.

Those regulations apply to *all* electrical installations in hazardous locations—both new and existing systems. Note that there are actually *three* alternative ways for equipment to be acceptable for use in hazardous locations. A piece of equipment is acceptable if it is “intrinsically safe” *or* “approved for the hazardous (classified) location” *or* “safe for the hazardous (classified) location.” A piece of equipment would have to satisfy only *one* of the three conditions described in the rule.

The three alternative conditions can be verified as follows:

Intrinsically safe equipment must be “approved” as such by UL, Factory Mutual Corporation, or some nationally recognized testing laboratory. In the *UL Hazardous Location Equipment Directory*, listings of various product categories indicate which equipment is intrinsically safe and the class and group of hazardous locations for which they are approved. Such equipment is evaluated and listed in accordance with Standard UL913, *Intrinsically Safe Apparatus and Associated Apparatus for Use in Class I, II, and III, Division 1, Hazardous Locations*. Another source of information on the subject is *Installation of Intrinsically Safe Instrument Systems in Class I Hazardous Locations (ANSI/ISA RP12.6-1987)*.

Approved for the hazardous (classified) location equipment is basically “listed” and “labeled” equipment certified by a nationally recognized testing laboratory—such as equipment covered in the *UL Hazardous Location Equipment Directory*.

Safe for the hazardous (classified) location equipment is a category that becomes much more difficult to identify by firm, specific criteria. Just how does an employer demonstrate that equipment

is safe for a hazardous location application? Although the OSHA rules themselves do not address that question anywhere, a note following Sec. 1910.307(b)(ii)(3) in the OSHA standard as published in the *Federal Register* does state that guidelines for making such a judgment are contained in [Chap. 5](#) of the current **National Electrical Code (NFPA 70)**. However, these guidelines are not the only means of complying with the standard. Any equipment or installation shown by the employer to provide protection from the hazards involved will be acceptable. This performance-oriented approach will allow the employer maximum flexibility in providing safety for employees. Obviously, that is very general and vague explanation that ultimately leaves determination of acceptability completely up to the OSHA compliance officer.

A clear effect of OSHA regulations is to require “listed,” “labeled,” “accepted,” and/or “certified” equipment to be used whenever available. If any electrical system component is of a kind that *any* nationally recognized testing lab “accepts, certifies, lists, labels, or determines to be safe,” then that component *must* be so designated in order to be acceptable for use under OSHA regulations. Every electrical designer and installer must exercise great care in evaluating any and all equipment and products used in hazardous electrical work to ensure compliance with OSHA rules requiring certification by a nationally recognized testing lab.

In UL’s Guide Card information [see discussion at 110.3(B) for details], limitations and application conditions are first set down for all equipment in general, as follows:

1. When equipment is listed and marked to show that it has been tested and is recognized for use in one or more of the Code-designated groups of hazardous locations, such marking indicates that such equipment is suitable for use in *either* a Division 1 or Division 2 location of the particular class of hazardous location, even though no reference is made to the division. Such equipment is, of course, also acceptable if used in a nonhazardous location. [Figure 500-3](#) shows a typical nameplate used on such equipment as required by parts (B) and (C) of 500.8, showing suitability as “explosionproof” (Class I) and “dusttight” (Class II).

Fig. 500-3. Typical UL part of equipment nameplate describes “Approval for Class and Properties.” (Sec. 500.5.)

2. *But* equipment that is marked “Division 2” or “Div. 2” is suitable for use in only such a division and may *not* be used in a Division 1 location. However, a piece of equipment may have other marking to indicate its acceptability for other specific uses. [Figure 500-4](#) shows a nameplate that is an addition to the nameplate in [Fig. 500-3](#), noting that the same fixture is “Suitable for Wet Locations.” 410.10(A) of the **NEC** requires such marking on “all fixtures installed in wet locations ...” Care must be taken to distinguish between different parts of nameplates to precisely determine what constitutes third-party certification.

Fig. 500-4. Additional data on a nameplate may show other acceptability—as for “wet locations.” (Sec. 500.5.)

3. Equipment that is listed and marked for “Class I” locations (explosionproof) may be used for “Class II” locations if it is dusttight to exclude combustible dusts and if its external operating temperature is not at or above the ignition level of the particular dust that might accumulate on it. Obviously, these characteristics must be carefully established before Class I equipment is used in a Class II location.

It is commonly, and completely erroneously believed that a Class I suitability involves more robust qualifications than for Class II locations and, therefore, anything that will work for Class I will work for Class II. This is incorrect. Combustible dusts settle on equipment and, through an inherent thermal blanketing effect, raise its internal temperature if heat is being generated inside it. Combustible metal dusts add electrical conductivity to the equation. Flammable gases through the natural process of convection do not have these problems, and frequently the autoignition temperature of those gases will be higher than that of the very dusts that are impacting the surface temperature of the same equipment. On the other hand Class I

chemicals can more easily reach the inside of an enclosure than Class II dusts. Class I and Class II threats are apples and oranges, and what works for one will not work for the other unless, by independent tests, it can be determined that the equipment under test is suitable for both locations.

4. Equipment listed for Class II, Group G (for flour, starch, or grain dust)—as used in a grain elevator—is also generally suitable for use in Class III locations, where combustible lint or flyings are present. The exception noted is for fan-cooled type motors, which might have their air passages choked or clogged by large amounts of the lint or flyings.
5. Because hazardous location equipment is critically dependent on proper operating temperature, a UL note warns that the ampere or wattage marking on power-consuming equipment is based on the equipment being supplied with voltage exactly equal to the rated voltage value. Voltage higher or lower than the rated value will produce other than rated amps or watts, with the possibility that the heating effect of the current within the equipment will be greater than normal. Higher-than-normal current will be produced by overvoltage to resistive loads and by undervoltage to induction motors. Because of this, the actual circuit voltage, rather than the nameplate value, must be used when calculating the required ampacity of branch-circuit conductors, rating or setting of overcurrent protection, rating of disconnect, and so on—all to ensure adequate sizing and avoid overheating.

Low-temperature ambient conditions pose challenges in this area as well. Although in some cases liquids will be below their flash points, low-temperature conditions can increase the force of explosions and reduce the ability of metals and seals to retain adequate strength.

6. Hazardous location equipment is tested and listed for use at normal atmospheric pressure in an ambient temperature not over 104°F (40°C), unless indicated otherwise. Use of equipment under higher-than-normal pressure, in oxygen-enriched atmospheres, or at higher ambient temperatures can be dangerous. Such abnormal conditions may increase the chance of igniting the hazardous atmosphere and may increase the pressure of explosion within equipment.
7. Openings or modifications must not be made in explosionproof or dust-ignitionproof equipment, because any such field alterations would void the integrity and tested safety of the equipment. Field alteration of listed products for nonhazardous application is also generally prohibited.
8. All bolts as well as all threaded parts of enclosures must be tightly made up.
9. Indoor hazardous location equipment that is exposed to severe corrosive conditions must be listed as suitable for those conditions as well as for the hazardous conditions.

The requirements of 500.8 and information in Code Table 500.8(C) provide the means of properly identifying and classifying equipment for use in hazardous locations. The identification numbers in Code Table 500.8(C) pertain to temperature-range classifications as used by Underwriters Laboratories in *UL Hazardous Location Standards*.

While the Code rules for Class I locations do not differ for different kinds of gas or vapor contained in the atmosphere, note that it is necessary to select equipment designed for use in the particular atmospheric group to be encountered. This is necessary because explosive mixtures of the different groups have different flash points and explosion pressures. It is also necessary because the autoignition temperatures vary with the groups of explosive mixtures.

Underwriters Laboratories lists fittings and equipment as suitable for use in all groups of Class I, although the listings for Groups A and B are not as complete as those for Groups C and D. In

addition, there is equipment that has its suitability for a particular group conditioned on seals being placed within a specified distance of the enclosure; if not, then the enclosure reverts to a different group with more challenging requirements.

In Class II locations, the Code, in a few cases, differentiates between the different kinds of dust—particularly dusts that are electrically conductive and those that are not conductive. Here again, as in Class I locations, care must be taken to determine that the equipment selected is suitable for use where a particular kind of dust is present.

In addition to taking more than ordinary care in selecting equipment for use in hazardous locations, special attention should be given to installation and maintenance details in order that the installations will be permanently free from electrical hazards. In making subsequent additions or changes, the high standards that were applied during the original installation must always be maintained.

For a more thorough knowledge of specific hazardous areas and equipment selection and location, it is essential to obtain copies of the various **NFPA** and ANSI standards referenced in Arts. 500 through 517.

ARTICLE 501. CLASS I LOCATIONS

501.1. Scope. In any Class I location, an explosive mixture of air and flammable gas or vapor may be present, which can be caused to explode by an arc or spark. To avoid the danger of explosions, all electrical apparatus that may create arcs or sparks should, if possible, be kept out of the rooms where the hazardous atmosphere exists, or, if this is not possible, such apparatus must be “of types approved for use in explosive atmospheres.”

All equipment such as switches, CBs, or motors must have some movable operating part projecting through the enclosing case, and any such part—for example, the operating lever of a switch or the shaft of a motor—must have sufficient clearance so that it will work freely; hence, the equipment cannot be hermetically sealed. Also, the necessity for subsequent opening of the enclosures for servicing makes hermetic sealing impracticable. Furthermore, the enclosure of the equipment must be entered by a run of conduit, and it is practically impossible to make conduit joints absolutely air- and gastight. Due to slight changes in temperature, the conduit system and the apparatus enclosures “breathe”; that is, any flammable gas in the room may gradually find its way inside the conduit and enclosures and form an explosive mixture with air. Under this condition, when an arc occurs inside the enclosure an explosion may take place.

It is crucial to recognize that Class I Division 1 wiring methods and equipment are not and never have been designed or intended to have their suitability for the environment based on the exclusion of the flammable agent from their internal parts. On the contrary, such methods, especially the explosionproof ones, assume that the flammable agent will enter the enclosure and eventually reach an explosive concentration and be ignited. The wiring and equipment is tested by UL to ensure that when the internal explosion occurs, and it is assumed to be inevitable, the explosion will be contained safely, as described in greater detail below, and without igniting the surrounding atmosphere.

Nevertheless, some misguided installers look at threaded joints and think about plumbing, even in some instances to applying Teflon tape or compounds to the conduit and enclosure threads. Not only does this impair the equipment grounding continuity, it can also result in over-tightened conduit due to the lubricating effects of the pipe dope. There have been hydrostatic testing failures of these joints

when they were made up in this way.

When the gas-and-air mixture explodes inside the enclosing case, the burning mixture must be confined entirely within the enclosure, so as to prevent the ignition of flammable gases in the room. In the first place, it is necessary that the enclosing case be so constructed that it will have sufficient strength to withstand the high pressure generated by an internal explosion. The pressure in pounds per square inch produced by the explosion of a given gas-and-air mixture has been quite definitely determined, and the enclosure can be designed accordingly.

Since the enclosures for apparatus cannot be made absolutely tight, when an internal explosion occurs, some of the burning gas will be forced out through any openings that exist. It has been found that the flame will not be carried out through an opening that is quite long in proportion to its width. This principle is applied in the design of so-called explosionproof enclosures for apparatus by providing a wide flange at the joint between the body and the cover of the enclosure and grinding these flanges to a definitely determined fit. In this case, the flanges are so ground that when the cover is in place the clearance between the two surfaces will at no point exceed 0.0015 in. (38.1 μm). Thus, if an explosion occurs within the enclosure, in order to escape from the enclosure the burning gas must travel a considerable distance through an opening not more than 0.0015 in. (38.1 μm) wide.

The basic construction characteristics of equipment for Class I hazardous locations are detailed in various sections of this article and in standards of testing laboratories. Application of the products hinges on understanding these details.

An explosionproof enclosure for Class I locations is capable of withstanding an explosion of a specified gas or vapor, which may occur within it, and of preventing the ignition of the specified gas or vapor surrounding the enclosure by sparks, flashes, or explosions of the gas or vapor within. Explosionproof equipment must provide three things: (1) strength, (2) joints which will not permit flame or hot gases to escape, and (3) cool operation, to prevent ignition of surrounding atmosphere.

UL requires that explosionproof enclosures must withstand a hydrostatic test of four times the maximum explosion pressure developed inside the enclosure. Explosionproof enclosures are not vapor- or gastight, and it is simply assumed that any hazardous gases in the ambient atmosphere will enter them either through normal breathing or when maintenance is performed on the enclosed equipment.

When an explosion occurs inside a rectangular explosionproof enclosure, the resulting force exerts pressure in all directions. The enclosure must be designed with sufficient strength to withstand these forces and avoid rupture ([Fig. 501-1](#)).

Fig. 501-1. An explosion creates strains and stresses in cross section of enclosure walls. (Sec. 501.1.)

The energy generated by an explosion within an enclosure must be permitted to dissipate through the joints of the enclosure under controlled conditions. There are two generally recognized joint designs intended to provide this control—threaded and flat:

1. Threaded construction of covers and other removable parts that have five full threads engaged ($4\frac{1}{2}$ threads if part of a listed product assembly) produces a safe, flame-arresting, pressure-relieving joint. When an explosion occurs within a threaded enclosure, the flame and hot gases create an internal pressure against the cover, thus locking the threads and forcing the gases out through the path between the threaded surfaces. When the gases reach the outside hazardous atmosphere, they have been cooled by the heat-sink effect of the mass of metal, to a point below the autoignition temperature of the outside atmosphere, as shown in [Fig. 501-2](#).

Fig. 501-2. Threaded joints cool the heated gas as it escapes from enclosure under pressure. (Sec. 501.1.)

2. A flat joint is constructed by accurate grinding or machining of the mating surfaces of the cover and the body. This flat joint works in a manner similar to the threaded joint. The two surfaces are bolted closely together, and as flame and hot gases are forced through the narrow opening, they are cooled by the mass of the metal enclosure, so that only cool gas enters the hazardous atmosphere. [Figure 501-3](#) shows the flat joint and a variation on it called a *rabbit* joint. Care must be taken to ensure that all cover screws are tight and that no particles of dirt or other foreign matter get in between the cover and the body. Even a small particle could prevent tight closing and might allow the joint to pass flame. Similarly, a careless scratch across the surface, such as a key might make, will destroy the explosionproof suitability of the enclosure.

Fig. 501-3. Ground surfaces of flat or rabbet joint provide release and cooling of internal gases. (Sec. 501.1.)

UL standards on explosionproof enclosures contain rules on “Grease for Joint Surfaces”:

Paint or a sealing material shall not be applied to the contacting surfaces of a joint. A suitable corrosion inhibitor (grease) such as petrolatum, soap-thickened mineral oils, or nondrying slushing compound may be applied to the metal joint surfaces before assembly. The grease shall be of a type that does not harden because of aging, does not contain an evaporating solvent, and does not cause corrosion of the joint surfaces.

501.5. Zone Equipment. Equipment “listed and marked” for installation in “Zone 0, 1, and 2 Locations” may be used, provided it is suitable for the location as determined in accordance with 505.9(C)(2). Specifically, Zone 0 equipment is suitable for Class I Division 1 or 2, and Zone 0, 1, and 2 equipment is suitable for Class I Division 2 locations. The more common Class I locations are those where some process is carried on involving the use of a highly volatile and flammable liquid, such as gasoline, petroleum naphtha, benzene, diethyl ether, or acetone, or flammable gases.

501.10. Wiring Methods. There are only three wiring methods generally permitted in Class I Division 1 locations, two raceways and one cable. The raceways are rigid metal conduit (RMC) and intermediate metal conduit (IMC). Type MI cable is the only cable assembly that is generally permitted in Class I, Division 1 locations ([Fig. 501-4](#)).

Fig. 501-4. Type MI cable is recognized for use in Class I, Division 1 locations, provided that the termination fittings (arrow) are listed as suitable for hazardous location use. (Sec. 501.10.)

There are limited exceptions that broaden the wiring method allowances under certain conditions. Polyvinyl chloride conduit (Type PVC), reinforced thermosetting resin conduit (Type RTRC), and along with high-density polyethylene conduit (Type HDPE) are now permitted to be used (with the customary grounding conductors) in Class I Division 1 locations that exist below grade, provided the conduit is embedded in a concrete pour not less than 50 mm (2 in.) thick around the conduit, and the last 600 mm (2 ft) of the run prior to emergence from grade must be threaded heavy-wall conduit that will accept the required seal fittings and other fittings as required at the point of emergence.

The other exceptions (formatted as positive text, but they still are variances from the normal rule) only apply to “industrial establishments with restricted public access” and with qualified maintenance and supervision in place. Although stated separately, the exceptions cover the same topic, that being special forms of metal-clad cable of particularly robust construction designed for hazardous locations and that feature a gas-tight corrugated armor with an outer nonmetallic jacket. The power version of the cable includes a separate equipment grounding conductor and is designated “Type MC-HL.” The control version of the cable is designated “Type ITC-HL” and is a form of instrumentation tray cable that operates under severe energy limitations, as covered in Art. 727. Termination fittings listed for the application are required in either case.

Optical fiber cable has been recognized in 770.3(A) as acceptable in hazardous locations, and this use is now correlated in 501.10(A)(1)(e). Note that it must be installed within a 501.10(A) raceway,

which circles back to threaded RMC or IMC, and then sealed in accordance with the usual requirements in 501.15. The same correlating provision was added as 501.10(B)(7) for Division 2 locations.

In general, approvals are to be based on the performance of a fitting or piece of equipment when subjected to a specific atmosphere. As applied to rigid metal conduit, to be explosionproof, threaded joints must be used at couplings, and for connection to fittings, the threads must be cleanly cut, five full threads must be engaged, and each joint must be made up tight. Conduit elbows and short-radius capped elbows provide for 90° bends in conduit but only where wires may be guided when being pulled into the conduit, to prevent damaging the conductors by pulling them around the sharp turn in the elbow. [Figure 501-5](#) shows two types of fittings used in hazardous locations to facilitate pull-in of conductors that have stiff or heavy-wall insulation. The capped elbow is especially suited for use in tight quarters.

Fig. 501-5. Conduit elbows and similar fittings may be used where wires may be guided into conduit. (Sec. 501.10.) The conduit elbow at the left must only be used where the conductors may be guided through it during installation, and therefore it cannot be used in the middle of a run.

All fittings, such as outlet, junction, and switch boxes, and all enclosures for apparatus, should have threaded hubs to receive the conduit and must be explosionproof. Explosionproof junction boxes are available in a wide variety of types ([Fig. 501-6](#)). Box covers may have threaded connections with the boxes, or the cover may be attached with machine screws, in which case a carefully ground flanged joint is required.

Fig. 501-6. A wide assortment of boxes, conduit bodies, fittings, and other enclosures are made in explosionproof designs listed for use in Class I locations. (Sec. 501.10.)

A flexible, explosionproof fitting, [as covered in (A)(2)] suitable for use in Class I hazardous locations, is shown in Fig. 501-7. The flexible portion consists of a tube of bronze having deeply corrugated walls and reinforced by a braid of fine bronze wires. A heavy threaded fitting is securely joined to each end of the flexible tube, and a fibrous tubular lining, similar to “circular loom,” is provided in order to prevent abrasion of the enclosed conductors that might result from long-continued vibration. The complete assembly is obtainable in various lengths up to a maximum of 914 mm (3 ft).

Part (A)(2)

to 501.10. Conductivity of flexible fitting is evaluated by voltage-drop test

Voltage drop across fitting must not exceed 150 millivolts, measured between points on conduit $\frac{1}{8}$ in. from each end of the fitting.

Fig. 501-7. A conductivity testing protocol for flexible fittings used in hazardous (classified) locations. (Sec. 501.10.)

Flexible connection fittings that are recognized by **NEC** 501.10(A)(2) for use in Class I, Division 1 locations are intended by UL and the **NEC** to be used where it is necessary to provide flexible connections in threaded rigid conduit systems—as at motor terminals. Use of such flexible fittings must observe the minimum inside radius of bend for which the fitting has been tested. Those data are provided with the fitting.

Note: UL warns that acceptability of the use of flexible connection fittings must be cleared with local inspection authorities. In general, use of such flexible fittings should be avoided wherever possible and should be limited to situations where use of threaded rigid conduit is completely ruled out by the needs or conditions of the application.

Where flexible connection fittings *are* used, the corrugated metal inner wall and the metal braid construction of the fitting provide equipment grounding continuity between the end connectors and the fitting. The UL test for conductivity through a flexible fitting is shown in [Fig. 501-7](#). Although 501.30(B) requires either an internal or an external bonding jumper to be used with standard flexible metal conduit in Class I, Division 2 locations, that rule does not apply to listed flexible fittings.

Part **(A)(2)** indicates that 501.140 permits flexible cord in Class I, Division 1 locations for portable lighting equipment and portable utilization equipment. This rule eliminates any conflict between the clear and direct rules of 501.10(A) on wiring methods and the limited use of portable cord as an alternative to the wiring methods used for fixed wiring. The 2014 **NEC** has added the hazardous locations version of tray cable evaluated for exposed runs (TC-ER-HL) for applications in qualified industrial occupancies with restricted public access and physical protection by location or guarding.

In **Class I, Division 2** locations, explosionproof outlet boxes are not required at lighting outlets or at junction boxes containing no arcing device. However, where conduit is used, it should enter the box through threaded openings, as shown in [Fig. 501-6](#), or if locknut-bushing attachment is used, a bonding jumper and/or fittings (such as bonding locknuts on knockouts without any concentric or eccentric rings left in the wall of the enclosure) must be provided between the box and conduits, as required in 501.30(B).

Part (B) actually leads off with a proforma recognition that wiring methods permitted in Division 1 are also permitted in Division 2. However, the 2017 **NEC** has added heavy walled steel conduits to the list a second time. As Division 1 wiring methods they must be threaded; in their second appearance in Division 2, they can be unthreaded with “listed threadless fittings,” which presumably includes set-screw connectors and couplings. Interestingly, an attempt was made to include EMT at the same time and it failed. The proposed addition of cablebus, however, did succeed. That will be a significant assist for high-capacity feeders because it allows for free-air ampacities.

As noted in part **(B)** of this section, flexible connections permitted in Class I, Division 2 locations may consist of flexible conduit (Greenfield) and also liquidtight flexible metal conduit with approved fittings, and such fittings are not required to be specifically approved for Class I locations. Note that a separate grounding conductor is usually necessary to bond across such flexible connections (there is a control circuit exception for LFMC only), as required in 501.30(B).

501.10(B) also recognizes the use of power-limited tray cable (Type PLTC) on the list of wiring

methods permitted in Class I, Division 2 locations, in accordance with the provisions of Art. 725 covering remote-control, signaling, and low-energy circuits. Similarly, instrumentation tray cable (Type ITC) is also permitted in Class I, Division 2 locations, as covered in Art. 727. And 501.10(B) (5) makes clear that medium-voltage circuits (i.e., circuits over 600 V) may employ the wiring methods covered in the first part of 501.10(B) and, where protected from physical damage, may be made up using medium-voltage cable (shielding governed only by rules in [Chap. 3](#), a 2008 **NEC** change) in cable trays when installed in accordance with Art. 392. And Art. 328 dictates that such cable must be Type MV cable. Metal-clad cable, Type MC and Power and Control Tray Cable, Type TC round out the former list; note that Type AC cable is not on the list. Two new approaches joined the list for the first time in 2008. The heaviest wall versions of Type PVC (i.e., “Schedule 80”) and Type RTRC (i.e., suffix “-XW”) conduits can now be used in Class I Division 2 locations exposed, without concrete encasement. This use is heavily restricted, being limited to industrial occupancies with limited public access and qualified maintenance and supervision, and in addition, these methods are only allowed where “metallic conduit does not provide sufficient corrosion resistance.” In cases where boundary seals are necessary, the seal must be located in the Division 2 area, with the Division 1 wiring method continuing into the Division 2 area until it reaches the seal.

Figure 501-8 shows some applications of wiring methods that are covered by the rules of 501.10. At the top, use of standard flex (Greenfield) in a Division 1 area violates part **(A)** of this section. At the center, use of aluminum-sheathed cable (Type ALS) is okay in a Division 2 area. Even though Type ALS is no longer mentioned in part **(B)**, that type of cable is now covered by Art. 330 and is considered as one form of Type MC cable, which is mentioned in part **(B)** as acceptable in Division 2 areas. At the bottom, use of Type MC is okay in a Division 2 location.

Fig. 501-8. Wiring methods in Class I locations are clearly regulated. (Sec. 501.10.) The bottom drawing applies to Division 2 locations only.

For applications where flexibility is required in Division 2 locations, the acceptable wiring methods are itemized in **(B)(2)**. The 2014 **NEC** has added an interlocking armor Type MC cable to the list, along with certain elevator cables, which have been carried in Table 400.4 as acceptable for this use but never correlated with these rules.

Paragraph **(3)** covers nonincendive field wiring. Review the discussion at 500.7 for a better

understanding of the principles governing this protection technique. To ensure that the nonincendive wiring functions as intended, it must conform to the control drawing and any components must not interconnect this wiring with other circuits. The **NEC** terminology at this point borrows from intrinsically safe provisions in Art. 504, which are discussed at greater length in this book under that article heading. Nonincendive wiring circuits must be run in separate cables unless they are shielded or employ insulation of the specified thickness.

501.15. Sealing and Drainage. The proper sealing of conduits in Class I locations is an important matter. Whether used in an enclosure or in conduit, seals are necessary to prevent gases, vapors, or flames from being propagated into an enclosure or conduit run and to confine an explosion that might occur within an enclosure.

The first note after the first paragraph points out that seal fittings properly installed are not normally capable of preventing the passage of liquids, gases, or vapors if there is a continuous pressure differential across the seal. However, as indicated, seals may be specifically designed and tested for preventing such passage. This explanation, along with the wording in such rules as 501.15(A)(4), makes clear that seals will only “minimize,” not “prevent,” passage of gases or vapors through the seal.

When an explosion takes place within an enclosure because of arc ignition of gas or vapor that has entered the enclosure, flames and hot gases could travel rapidly through unsealed conduits, and the resultant buildup of pressure could exceed the strength of conduit, wireways, or enclosures, causing explosive rupture. *Pressure piling* is the name given to the action that takes place when an explosion occurs inside an enclosure because of flammable gas within the enclosure being ignited by a spark or overheated wiring. When this happens, and there are no seals in the conduits connecting to the enclosure, exploding gas will compress the entire atmosphere within the conduit system and flames or heat will ignite compressed gas complete with the additional fuel that is present along the conduit run, causing another, more powerful explosion or making the initial explosion that much more powerful. Think, for a moment of the vastly improved power provided in a piston of an internal combustion engine when the fuel-air charge is compressed. The pressure builds as the flame front moves through the system of raceways and enclosures, increasing in intensity until a critical element in the system ruptures. To prevent such occurrences, it is mandatory that seal-off fittings be used in certain enclosures or conduit runs to block and confine potentially hazardous vapors.

The necessary sealing may be accomplished by inserting in the conduit runs special sealing fittings, as shown in [Fig. 501-9](#), or provision may be made for sealing in the enclosure for the apparatus. An explosionproof motor is made with the leads sealed where they pass from the terminal housing to the interior of the motor, and no other seal is needed where a conduit terminates at the motor, except that if the conduit is metric designator 53 (trade size 2) or larger, a seal must be provided not more than 18 in. (450 mm) from the motor terminal housing.

Fig. 501-9. Seal fitting is filled with compound to prevent passage of flame or vapor through the conduit. (Sec. 501.15.)

Class I, Division 1

Part (A) of this section covers mandatory use of seals in Class I, Division 1 locations:

1. A seal is required in each and every conduit (regardless of the size of the conduit) entering (or leaving) an enclosure that contains one or more switches, CBs, fuses, relays, resistors, or any other device that is capable of producing an arc or spark that could cause ignition of gas or vapor within the enclosure or any device that might operate hot enough to cause ignition. The 2014 **NEC** quantifies this concept as exceeding 80 percent of the autoignition temperature of the specified gas or vapor. In each such conduit, a seal fitting must be placed never more than 18 in. (450 mm) from such enclosure. The Code rule has eliminated the phrase that said seals had to be installed “as close as practicable” to the enclosure—leaving the remainder of the requirement, that the seal must not be more than 18 in. (450 mm) from the enclosure, intact. As shown in [Fig. 501-10](#), a conduit seal fitting is installed in the top conduit and one of the bottom conduits—close to the enclosure of the arcing device. But a seal is not used in the conduit to the pushbutton because that is a factory-sealed device and that seal is not over 18 in. (450 mm) from the starter. This complies with the intent of the Code rule, as well as the rule of 501.15(C), which recognizes “approved integral means for sealing,” as in the pushbutton. [Figure 501-11](#) shows a seal fitting as close as possible to a box housing a receptacle.

EXCEPTION

Sealing fitting *NOT* NEEDED

Explosionproof enclosure for tumbler switch with mercury-tube contacts.

Fig. 501-10. Seal should be in each conduit within 18 in. (450 mm) of the sealed enclosure, center, but may not be needed at all, bottom. (Sec. 501.15.)

Fig. 501-11. Seal fitting is as close as possible to enclosure, providing maximum effectiveness. (Sec. 501.15.)

The exception to part **(A)(1)** notes that a seal is not required in a conduit entering an enclosure for a switching device in which the arcing or sparking contacts are internally sealed against the entrance of ignitable gases or vapors. Such conduit is applied to a condition similar to a conduit connection to an explosionproof junction box—that is, any gas that enters the enclosure will contact only wiring terminals and is not exposed to arcs. But because a conduit seal is always required for any conduit of metric designator 53 (trade size 2) size or larger that enters a junction box or terminal housing, this exception permits elimination of the conduit seal *only* for conduits of metric designator 41 (trade size 1½) size or smaller that enter an enclosure for switching devices with sealed or inaccessible contacts—such as mercury-tube switches, as shown at the bottom of [Fig. 501-10](#). Any switch, CB, or contactor with its contacts in a hermetically sealed chamber or immersed in oil might be applied under this exception. The stand-alone paragraph following (2) on large entries applies generally and makes an important point in this regard. A factory-sealed enclosure is only recognized as sealing itself. However close it may be to another enclosure requiring a seal, it does not qualify as providing that seal for the adjacent enclosure.

Recognition of sealed-contact devices without a separate conduit seal is similar to recognition of “an integral means for sealing” [501.15(C)(1)], which is a seal provision that is manufactured directly into some enclosures for Class I equipment.

But questions have always risen about the acceptability of boxes or fittings between the sealing fittings and the enclosure being sealed. This section identifies the devices that may be used between the seal and the enclosure. Explosionproof unions, couplings, reducers, elbows, and capped elbows are the only enclosures or fittings permitted between the sealing fittings and the enclosure. A reducing bushing (a *reducer*) may be connected at a conduit entry to an explosionproof enclosure so that the bushing is connected between the seal and the enclosure. Because a reducer is commonly used to provide a conduit bushing in the wall of an enclosure and does not pose a threat to the integrity of the seal function, reducers have been added to the list of devices permitted to be used between a seal and the enclosure it supplies. The rule clearly rules out the use of a box or any similar large-volume enclosure between the seal fitting and the enclosure being sealed, as shown in Fig. 501-12. Undoing accepted practice since the 1978 **NEC**, the placement of a conduit body not larger than the raceway trade size between the seal and the enclosure is, as of the 2017 **NEC**, prohibited “due to the increased volume in the raceway system.” No further substantiation was offered for this dramatic change.

Fig. 501-12. Any type of junction *box* may not be used between seal and enclosure. (Sec. 501.15.)

The fittings listed as acceptable for use between the seal and the enclosure were selected on the basis that their internal volume was sufficiently small as to prevent the accumulation of any dangerous volume of gas or vapor. Acceptability was based on limiting the volume of gas or vapor that may accumulate between the seal and the enclosure being sealed. It was on this basis also that conduit bodies are prohibited from being of a larger size than the conduit with which they are used. If they were permitted, they would present the opportunity for accumulation of a larger volume of gas or vapor, which is considered objectionable.

Figure 501-13 shows an interesting variation on this concern for use of a box between a seal and an enclosure. *No splices are permitted within seal-off fittings*, according to the *UL Hazardous Location Equipment Directory*. The illustration shows a round-box type of seal fitting that is used for pulling power and control wires. Such a fitting takes a large, round,

threaded cover equipped with a pouring spout. The cover, shown removed, is readily unscrewed to provide maximum unobstructed access to the fitting interior, which facilitates damming either one or both conduit hubs. When the cover is replaced, it can be rotated so the spout points up to permit compound fill. This fitting can be used to seal conduit regardless of its direction or run.

Fig. 501-13. Seal fitting of the round box type is used to seal the conduit run into the bottom of an explosionproof starter enclosure, with flexible fitting connection to the Class I, Division 1, Group D motor below and a watertight Class I cord connector control cable. (Sec. 501.15.)

2. A seal is required in any conduit run of metric designator 53 (trade size 2) size or larger, where such a conduit enters an “enclosure or fitting” that is required to be explosionproof and houses terminals, splices, or taps, as shown in [Fig. 501-14](#). Note in such cases, however, that the rule does not call for the seal to be “as close as practicable” to the enclosure or fitting, as required for a housing of an arcing or sparking device. Here, it simply requires that the seal be not over 18 in. (450 mm) away from the enclosure.

Fig. 501-14. Seals for conduits to junction boxes or fittings are required only for conduits of 2-in. (53-mm) size and larger. (Sec. 501.15.)

Another example of seal application in accordance with parts (1) and (2) of 501.15(A) is shown in [Fig. 501-15](#).

Fig. 501-15. Seal fittings are very close to points where conduits enter the motor starter enclosures. Seals are not required for the conduits entering the junction box (arrow) because they are not metric designator 53 (trade size 2) or larger size—although seals may be used there. (Sec. 501.15.)

Part (3) of 501.15(A) covers use of a single seal to provide the required seal for a conduit connecting two enclosures. Where two such pieces of apparatus are connected by a run of conduit not over 3 ft (900 mm) long, a single seal in this run is considered satisfactory if located at the center of the run. [Figure 501-16](#) shows this rule. Although the wording is not detailed, the reference to “within

18 in. (450 mm) of such enclosure” must be understood to be 18 in. (457 mm) measured along the conduit, to avoid the misapplication of the rule shown in Fig. 501-17. The single seal at A is not over 18 in. (450 mm) from the CB enclosure and is literally not over 18 in. (450 mm) from the starter (it is 10 in. from the starter). But that use of a single seal for the two enclosures violates the Code intent that the 18 in. (450 mm) in each case *must* be measured along the conduit.

Fig. 501-16. A single seal serves two conduit entries into separate enclosures. (Sec. 501.15.)

Fig. 501-17. Although this complies with the rule literally, it is a violation of the intent. (Sec. 501.15.)

Part (4) requires a seal in each and every conduit that leaves the Class I, Division 1 location—whether it passes into a Division 2 location or into a nonhazardous location. This required seal may be installed on either side of the boundary *and* within 10 ft (3.0 m) of the boundary (Fig. 501-18). There must be no union, coupling, box, or fitting between the sealing fitting and the point where the conduit leaves the hazardous location. The rule does specify a maximum distance that must be observed between the sealing fitting and the boundary, and that distance is 10 ft (3.0 m). The purpose of this sealing is twofold: (1) The conduit usually terminates in some enclosure in the Division 2 or nonhazardous area containing an arc-producing device, such as a switch or fuse. If not sealed, the

conduit and apparatus enclosure are likely to become filled with an explosive mixture and the ignition of this mixture may cause local damage in the Division 2 or nonhazardous location. (2) An explosion or ignition of the mixture in the conduit in the nonhazardous area would probably travel back through the conduit to the hazardous area and might cause an explosion there if, because of some defective fitting or poor workmanship, the installation is not completely explosionproof. If the conduit is unbroken (no union, coupling, etc.) between an enclosure seal and the point where the conduit leaves the hazardous area, an additional seal is not required at the boundary. [Figure 501-19](#) shows two violations where conduit leaves the hazardous area.

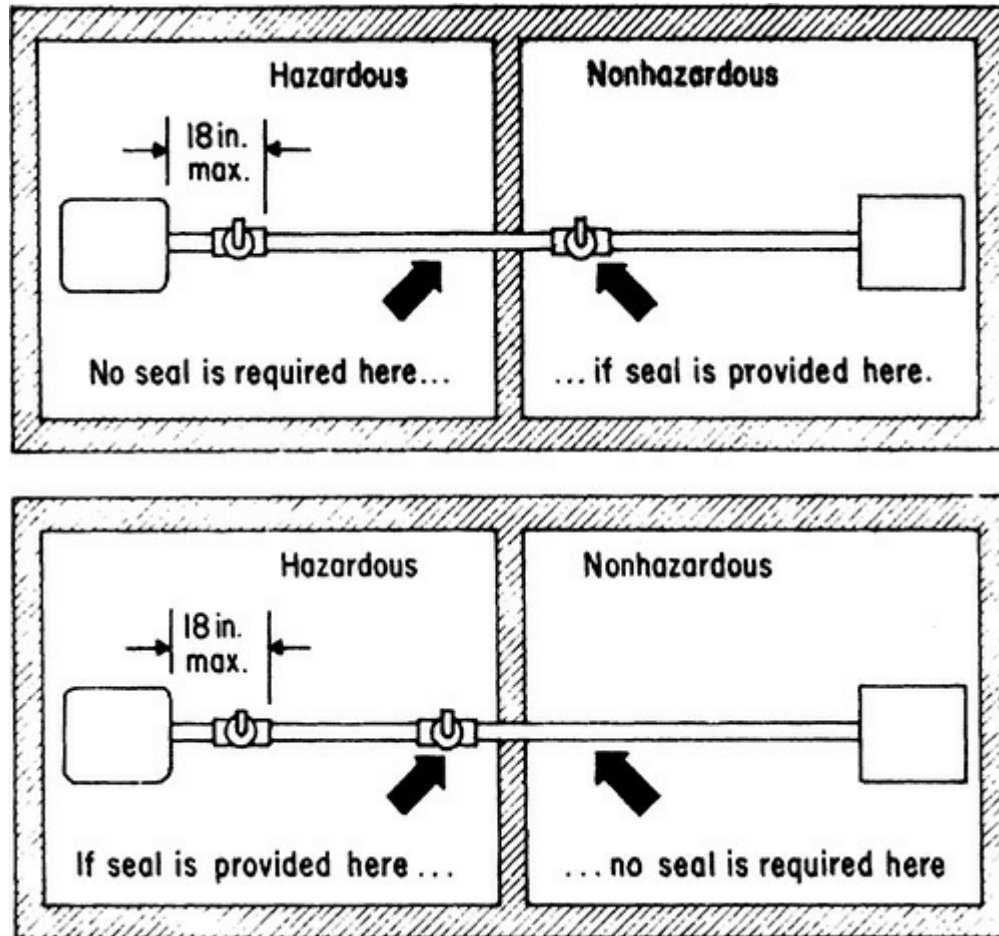

Fig. 501-18. Conduit must be provided with seal fitting where it crosses boundary. (Sec. 501.15.)

VIOLATION! — Coupling not permitted between seal and the boundary

VIOLATION! — EMT not permitted in Class I location

Fig. 501-19. These violate rules on seal fittings where conduit crosses boundary. (Sec. 501.15.)

Exception No. 1 to 501.15(A)(4) covers the case where a metal conduit system passes from a nonhazardous area, runs through a Class I, Division 1 hazardous area, and then returns to a nonhazardous area. Such a run is permitted to pass through the hazardous area without the need for a seal fitting at either of the boundaries where it enters and leaves the hazardous area. But the wording of this exception requires that such conduits, in order to be acceptable, must contain no union, coupling, box, or fitting in any part of the conduit run extending 300 mm (12 in.) into each of the

nonhazardous areas involved (Fig. 501-20).

Conduit length in hazardous area must not contain any union, coupling, box, or other fitting within the hazardous area and for 12 in. beyond each boundary.

Fig. 501-20. Seals may be eliminated for conduit passing “completely through” hazardous area. (Sec. 501.15.)

For some installations of conduits crossing boundaries, straightforward application of **NEC** rules on conduit sealing is difficult. Most of these cases involve determination as to what constitutes the boundaries of a hazardous area; the Code provides no definition. The inspection authority should be consulted in cases not specifically covered by the Code. Because there are no provisions in the Code that *prohibit* the use of seals, “if in doubt, seal” would be a safe practice to follow.

At the top of Fig. 501-21, the conduit run is sealed within 18 in. (450 mm) of an explosionproof enclosure, as shown, and extends into a concrete floor slab, emerging in a nonhazardous area. It is not clear what constitutes the boundary of the Class I, Division 1 area. Must a seal be placed at A or might it instead be placed at B in the nonhazardous area? An **NEC** Official (now “Formal”) Interpretation, pertaining to a hospital operating room, ruled that the entire concrete slab through which the conduit traveled constituted the boundary of the hazardous area, and that the seal could be placed either at A, where the conduit leaves the hazardous area, or at B, where it enters the nonhazardous area. But some authorities may require seals at A and B. With a seal at A and not at B, a heavier-than-air gas or liquid (such as gasoline) might penetrate a crack in the floor, enter the conduit through a coupling, and pass into the enclosure in the nonhazardous area. Or a seal at B but not at A might not prevent vapor in the conduit from entering the nonhazardous area through a coupling in the concrete and then through a crack in that floor. That kind of gas passage has occurred.

Fig. 501-21. Conduit in floor-slab boundary may require seals at both A and B. (Sec. 501.15.)

In some instances, area classifications are already spelled out in the **NEC**, and it is interesting to see how this problem is addressed, because the panel has been inconsistent. For example, at an aircraft hangar (Art. 513) the hazardous location specifically extends below the hangar floor, as required in 513.8(B). On the other hand, in a comparable location at a vehicle service station, the area below the floor is unclassified as covered in 511.3. Over the last few Code cycles the Code-making panel has been moving away from classifying the below-grade and the below-floor areas unless there is an actual opening such as a pit. The belief has been that the availability of oxygen in such areas is too low (fuel-air mixture too rich) to support combustion. Although that is certainly true in the earth or concrete itself, it may very well not be true if a conduit, with its included air and couplings, traverses such a location. In areas where a classification is made in the **NEC**, it must be respected, but in general it raises concerns for other comparable areas where area classifications are done by engineers as refereed by local inspection authorities.

At the bottom of [Fig. 501-21](#), the conduit run is not in the floor slab, but in the ground below the slab. Now what constitutes the boundary? Can the seal still be placed either at point A or at point B? Code rules applying to gasoline stations and aircraft hangars may be used as a guide. The real question is whether the ground beneath the slab is a hazardous or nonhazardous location. Section

514.8 used to define dispensing and service-station wiring and equipment, any portion of which is below the surface of a hazardous area, as a Class I, Division 1 location. Effective with the 2005 **NEC**, however, the classification stops at the grade boundary, as just noted. A similar change occurred at the same time in Art. 511, when the rule of 511.4(A)(1) in the 2002 **NEC** was deleted. However, as just noted, the below-grade classification continues for aircraft hangars.

Figure 501-22 is a wiring layout for a Class I, Division 1 location. The wiring is all rigid metal conduit with threaded joints. All fittings and equipment are explosionproof; this includes the motors, the motor controller for motor no. 1 (lower part of Fig. 501-22), the pushbutton control station for motor no. 2 (upper part of Fig. 501-22), and all outlet and junction boxes. The panelboard and controller for motor no. 2 are placed outside the hazardous area and hence need not be explosionproof.

Fig. 501-22. Required seals are shown in points marked S. (Sec. 501.15.)

Each of the three runs of conduit from the panelboard is sealed just outside the hazardous area. A sealing fitting is provided in the conduit on each side of the controller for motor no. 1 (lower part of Fig. 501-22). The leads are sealed where they pass through the frame of the motor into the terminal housing, and no other seal is needed at this point, provided that the conduit and flexible fitting enclosing the leads to the motor are smaller than 2 in. (50.8 mm). The pushbutton control station for motor no. 2 (upper part of Fig. 501-22) is considered an arc-producing device assuming it is part of a conventional Class 1 control circuit (referring now to the energy level and not the area classification, that is with an Arabic and not a Roman numeral) and must comply with 501.115(A). Therefore, the conduit is sealed where it terminates at this device.

A seal is provided on each side of the switch controlling the lighting fixture. One of these seals is in the nonhazardous room and that single seal serves as both the seal for the arcing device and the seal for conduit crossing the boundary. The lighting fixtures are hung on rigid conduit stems threaded to the covers of explosionproof boxes on the ceiling.

About seal fittings In using seal fittings in conduits in hazardous locations, application data of UL must be observed, as follows:

- Conduit seal-off fittings to comply with **NEC 501.15** must be used *only* with the sealing compound that is supplied with the fitting and specified by the fitting manufacturer in the instructions furnished with the fitting.
- Seal-off fittings are listed for sealing listed conductors in conduit, where the conductors are thermoplastic insulated, rubber covered, or lead covered.
- Any instructions supplied with a seal-off fitting must be carefully observed with respect to limitation on the mounting position (e.g., vertical only) or location (e.g., elbow seal). [Figure 501-23](#) shows a variety of available seal fittings. Sealing fittings are designed for vertical orientation only, for optional vertical or horizontal positioning, or as combination elbow seals. Others are compatible with conduits installed at any angle, because covers can be rotated until sealing spouts point upward.

Fig. 501-23. A variety of seal fittings are suited to different applications. (Sec. 501.15.)

Because conduits are installed vertically, horizontally, and at angles and require ells, tees, and offsets, the fittings used for sealing differ in construction features, orientation, and method of sealing.

Sealing fittings intended solely for vertical orientation have threaded, upward-slanting ports slightly larger than conduit hub openings to permit asbestos-fiber dams to be tamped into fitting bases. The dam prevents the fluid-sealing compound from running down into the conduit before the seal has solidified.

A second type of fitting is designed for either vertical or horizontal positioning. These units are identified by two seal-chamber plugs that can be removed to facilitate tamping dam fibers into both conduit hubs when the device is aligned horizontally. The compound is poured into the chamber through the larger of the two ports. The ports are then replugged, and the plugs tightened flush with

their collars. When these fittings are oriented vertically, however, only lower conduit hubs need be dammed.

A third type of seal, which can be oriented in any position, is shown in the center of [Fig. 501-23](#) and is described in [Fig. 501-13](#). This same fitting may be used as a drain-type seal when its spout is turned down.

Elbow seals (as at upper right of [Fig. 501-23](#)) are double-duty devices that are practical either when horizontal conduits must elbow down to connect with an enclosure's top (as indicated) or when vertical conduits must turn to enter explosionproof enclosures horizontally. In either case, sealant application openings must slant upward.

Another fitting, designed for drainage purposes, is installed only in vertical runs of conduits. Where conduit is run overhead and is brought down vertically to an enclosure for apparatus, any condensation of moisture in the vertical run would be trapped by the seal above the apparatus enclosure. The lower part of [Fig. 501-23](#) shows a sealing fitting designed to provide drainage for a vertical conduit run. Any water coming down from above runs over the surface of the sealing compound and down to an explosionproof drain, through which the water is automatically drained off. These fittings permit passage of condensation while also blocking the passage of explosive pressures or flames. They are equipped with plugs containing minute weep holes that can either be opened and closed periodically as need develops or allow continuous drainage.

Drain-type seal fittings must be oriented so that compound-application ports remain above the lower downward-slanting drainage plugs. To install the seal and drain, both ports are unplugged and the lower conduit hub is dammed. The drainage plug hole is then closed temporarily by a washer through which a rubber core is inserted. This core protrudes into the upper part of the sealing chamber, although it must be guided so as not to remain in contact with any of the conductors. Sealing compound is then poured into the chamber through the upper access port, which is replugged and screwed tight.

After the compound has initially set (but has not yet had time to permanently harden), the washer is removed and the rubber core is pulled down and out. This creates a clear drainage canal, which extends from above the seal down into the drainage weep hole. A drainage plug is then screwed into the threaded hole, with not less than five full threads engaged to fulfill the requirement for an explosionproof joint.

Class I, Division 2

Because Division 2 locations are of a lower degree of hazard than those in Division 1, the requirements for sealing as given in 501.5(B) are somewhat less demanding, as follows:

1. Where the rules of other sections in Art. 501 require an explosionproof enclosure for equipment in a Division 2 location, all conduits connecting to any such enclosure must be sealed exactly the same as if it were in a Division 1 enclosure. And the conduit, the nipple, or any fitting between the seal and the enclosure being sealed must be approved for use in Class I, Division 1 locations—as specified in 501.15(A).

In Class I, Division 2 locations, each piece of apparatus that produces arcs or sparks, such as a motor controller, switch, or receptacle, must be in an explosionproof enclosure, and the seals required here serve to complete that explosionproof enclosure. Although the frequency of hazardous gas or vapor releases in Division 2 locations is severely curtailed by definition, the

occurrence of arcs in equipment in switches, etc., is routine, and may be expected to occur in the presence of any gas or vapor release, however infrequent. The only way to respond to this set of conditions is to make certain that the arcing equipment is contained, and the **NEC** does exactly that.

As shown in [Fig. 501-24](#), where a nonexplosionproof enclosure is permitted by other sections to be used in a Division 2 location a seal is *not* required in any size of conduit. Note that in Division 2 locations there is *not* always the need to seal conduits metric designator 53 (trade size 2) and larger, as required in Division 1 locations, by 501.15(A)(2). The reason for the permission to use conventional boxes and to avoid seals around them in Division 2 locations requires a review of the reason for such seals in Division 1 locations. The issue in Division 1 was the need to segment the conduit system so it would not fail due to pressure piling from an internal explosion. The only way to have such an explosion is to have large amounts of fuel-air mixtures migrating into the conduit system over time. That is possible in a Division 1 location where the hazardous chemicals are expected to be routine, and it is impossible in a Division 2 location where any vapor or gas release will be very infrequent.

Fig. 501-24. Seals are not required for conduits connected to nonexplosionproof enclosures that are permitted in Division 2 locations. (Sec. 501.15.)

2. Any and every conduit passing from a Class I, Division 2 area into a nonhazardous area must be sealed in the same manner as previously described for conduit passing from a Division 1 area into a Division 2 or nonhazardous area ([Fig. 501-25](#)). Rigid metal conduit or IMC must be used between the seal and the point where the conduit passes through the boundary. There is language to the effect that these boundary seals need not be explosionproof, provided they are “identified for the purpose of minimizing passage of gases under normal operating conditions.” However, as of this writing no such seal has been developed and marketed, so the only practical option is the explosionproof variety.

Fig. 501-25. This is a violation; a seal *is* required. (Sec. 501.15.)

Exception No. 1 to part **(B)(2)** is worded the same as Exception No. 1 in part **(A)(4)** for Class I, Division 1 locations. Exception No. 1 to 501.15(B)(2) covers the case where a metal conduit system passes from a nonhazardous area, runs through a Class I, Division 2 hazardous area, and then returns to a nonhazardous area. Such a run is permitted to pass through the hazardous area without the need for a seal fitting at either of the boundaries where it enters and leaves the hazardous area, provided that the conduit in the hazardous area does not contain unions, couplings, boxes, or fittings. In a Class I, Division 2 location, the same prohibition against unions, couplings, and so on, is applicable, and the method in [Fig. 501-26](#) is not acceptable if seals are omitted at the boundary crossings. A seal would not be needed at A, B, C, or D, if the conduit passed through the Class I, Division 2 location without any coupling or other fittings in the conduit.

Fig. 501-26. Couplings in conduit through Division 2 location would require seals at the boundaries. (Sec. 501.15.)

Exception No. 2 to part **(B)(2)** addresses installations where the conduit passing from the Class I, Division 2 location into an unclassified location does not enter any enclosures that produce an arc or spark. Such an installation does *not* require a conduit seal, provided it is also installed outdoors, or if

the conduit system is installed in a single room, it may be installed indoors. But in no case should the unsealed conduit be connected to any enclosure that contains a source of ignition. The outdoor locations work by abundant ventilation and the indoor locations because if all the wiring is in the same room, it is all at the same atmospheric pressure and will not transmit fumes.

Exception No. 3 recognizes that where an enclosure or room is unclassified because it is pressurized to prevent accumulation of an explosive concentration, there is no need to seal the raceway where it leaves the Division 2 location and enters the pressurized spaces because the press will prevent gas from entering that unclassified area.

Exception No. 4 eliminates sealing for those portions of the conduit system that satisfy *all* the conditions given in parts (1) to (5). The conditions, taken together, describe a conduit layout for which it would be impossible for fumes to enter the raceway to begin with.

Part (C) of 501.15 sets regulations about the kind of seals that must be used where seals are required by foregoing rules. Part (1) calls for an integral seal within the enclosure itself or use of a separate seal fitting in each conduit connecting to the enclosure, as previously described. The use of factory-sealed devices eliminates the need for field sealing and generally is less expensive to install. In fittings of this type, the arcing device is enclosed in a chamber, with the leads or connections brought out to a splicing chamber. No external sealing fitting is required (Fig. 501-27). If separate seals are used, they must be accessible. Do not bury a seal fitting, or place it behind or within fixed partitions, unless an access door is provided.

Fig. 501-27. Seal in conduit is not needed where enclosure has built-in seal. (Sec. 501.15.)

Where a seal fitting is used in the conduit, it must be *explosionproof*. The sealing compound must develop enough mechanical strength as it hardens to withstand the forces of explosions. Seals used only to prevent condensation accumulation do not have to be explosionproof; a vaportight seal is sufficient for that purpose.

A seal must be *vaportight* to minimize the passage of gases and vapors. To do that, the sealing compound must adhere to the fitting and to the conductors. It must expand as it hardens to close all voids without producing objectionable mechanical stresses in the fitting.

Liquid or condensed vapor may present a problem in Class I locations. Where such is the case, joints and conduit systems must be arranged to minimize entrance of liquid. Periodic draining may be necessary, which necessitates the inclusion of a means for draining in the original design of the motor or of the conduit system generally; explosionproof drain fittings are available for this purpose.

Installation instructions furnished by the manufacturer must be carefully followed. The seal fitting must be carefully packed with fibrous damming material, which packs more tightly and effectively around conductors when it is dampened, and then filled with the compound supplied with the fitting to

a depth at least equal to the inside diameter of the conduit and never less than 5/8 in. deep, as required in part (3) and in the UL standard on seal fittings. New designs are now on the market that use self-expanding epoxy compounds that are explosionproof without the need of fiber damming to separate the conductors and keep the compound in place, and significantly reducing the labor time in the process.

Part (2) of 501.15(C) covers the compound used in seals (Fig. 501-28). The sealing compound used must be one that has a melting point of not less than 200°F (93°C) and is not affected by the liquid or gas that causes the location to be hazardous. Most of the insulating compounds commonly used in cable splices and potheads are soluble in gasoline and lacquer solvents and hence are unsuitable for sealing conduits in locations where these liquids are used. A mixture of litharge and glycerin is insoluble in nearly all liquids and gases found in Class I locations and meets all other requirements, though this mixture is open to the objection that it becomes very hard and is difficult to remove if the wires must be pulled out. No sealing compounds are listed by UL as suitable for this use except in connection with the explosionproof fittings of specific manufacturers.

Fig. 501-28. Conduit seal fitting must be carefully packed with fibrous damming material, which packs more tightly and effectively around conductors when it is dampened and then filled with the compound supplied with the fitting to a depth at least equal to the inside diameter of the conduit and never less than 5/8-in. deep (UL standard). This type of seal is for vertical mounting only. (Sec. 501.15.)

Part (4) prohibits splices or taps in seal fittings.

Part (5) recognizes use of listed Class I assemblies that have a built-in seal between a compartment housing devices that may cause arcs or sparks and a separate compartment for splicing or taps. Conduit connection to the splice or tap compartment requires a seal fitting only in conduit of metric designator 53 (trade size 2) or larger, as specified for junction boxes in 501.15(A)(1)(2).

Part (6) directs conduit fill to be not more than 25 percent of the raceway's cross-sectional area.

This will require the use of Tables 4 and 5 in [Chap. 9](#), simply because the conductor fill values in the tables of App. C are based on 40 percent fill. Ensure that the total conductor cross-sectional area—determined by adding together all the conductor cross-sectional area dimension(s) given in Table 5—is not more than 25 percent of the “Total Area” column for the particular raceway and size shown in Table 4.

A fitting is to be evaluated on the basis of a conduit with the same trade size, and conductor fill in that fitting must be no greater than 25 percent of the cross section, unless the fitting is specifically marked for greater fill. This is because the original work on current seal designs and test work was done to the 1968 **NEC**, which set a maximum conduit fill of 25 percent on new work and 40 percent on rework. Since a seal cannot be opened and repoured after it has been sealed, it cannot be reworked and it made sense to do the tests based on a 25 percent fill. Of course the **NEC** now allows a 40 percent fill by right even on initial installations. The industry response was to write the 25 percent limit into the **NEC**, along with an option for a higher fill if the manufacturer was willing to submit to the required testing.

Some manufacturers are meeting the higher fill by taking a seal fitting already designed and tested (at 25 percent) for a certain size of conduit and then drilling and tapping the female conduit entries one standard size smaller, and adjusting the installation directions accordingly. A similar approach can be done in the field using threaded reducers and then comparing the 40 percent fill on the smaller raceway with the permitted 25 percent fill on the larger seal fitting. One of the reasons for inserting the various mentions of “reducers” as being permitted on both sides of seal fittings was to accommodate this procedure.

The way the **NEC** rule is written makes it imperative to track the installation instructions, because the instructions will always trump the percentage called out in the rule. If the instructions allow a greater fill than 25 percent, then whatever the instructions allow is permitted by 501.15(C) (6), and if the instructions insist on a smaller fill, then that becomes the limit by 110.3(B).

Part **(D)** covers seals for cables in Class I Division 1 locations, whether run in conduit or as open cables as now permitted for Types MI and MC-HL cables—the only power cables permitted by 501.10(A)(1)(b) and 501.10(A)(1)(c) to be used in Class I, Division 1 locations. Type MI cable is inherently sealed with respect to its interior, and the listed fitting described in 501.10(A)(1)(b) is all that is needed. Type MC-HL cable is covered in (1) of this rule. The cable must be sealed at any terminations in the hazardous area with listed fittings that include provisions for removing the nonmetallic jacket, the cable armor, and incorporating sealant that envelops each conductor individually and makes up to the components of the armor such that the entry of gases and vapors into the cable assembly is minimized. Type MC-HL cable, like all metal-clad cable, is eligible to be produced by 330.104 in control sizes as small as 18 AWG.

If produced as a shielded twisted pair, it could be covered by the exception following, which allows such cable to be treated as a single wire at the cable connector/seal-off, provided there is an approved means in place at the actual termination area to prevent the propagation of flame into the cable core and to minimize the entry of gas and vapors. There are epoxy mastics that have been evaluated for this purpose and so this is a practical alternative; however, careful attention to installation instructions is crucial. With respect to data applications using twisted-pair cabling, each pair can be split out and sealed without untwisting the pair.

However, if the cable is shielded the proper procedure is more complicated because the shielding may be applied to each pair individually, or to the entire group of twisted pairs (usually four pairs)

taken collectively. The product listing for this mastic and the installation instructions that come with it only cover shielding on the individual pairs. Sources within the Code panel indicate that this was the only form the panel considered in writing this part of the exception. If the shielding is applied just under the cable jacket and over the entire group, then as of this writing the product cannot be used based on the literal text of the product directions. Since the product acceptance criterion in the **NEC** is “approved” the decision comes down to the inspector. It would certainly not be unreasonable to approve the product conditioned on the shielding being formed into a wire at the point where the cable jacket ends, and then the mastic being applied to the conductor pairs, the shield made into a wire, and the cable jacket end all as a whole.

The 2017 **NEC** added a degree of flexibility regarding seal placement for cables that directly correlates with the rules for raceways in 501.15(A)(1). The seal for the cable assembly can be up to 18 in. from the enclosure, with the same general constraints regarding allowable fittings not larger than the entry trade size permitted between the seal and the enclosure.

The other two options for cables in Division 1 both involve cable run inside of conduit. Taken in reverse order, (3) covers cable that cannot transmit gases or vapors through its core. One example of this cable is the old “flooded” telephone cables that have been used for generations for below-grade voice telephone circuits. Such cables are available for Ethernet applications, although the content of the gel filling needs to be monitored because it varies and may not be chemically compatible with one or more chemicals on-site. The sealing process in this case works by sealing to the outside of an intact cable assembly.

The other possibility, in (2), involves a cable in conduit where the cable assembly can transmit gases and vapors. The default approach is to open up the cable assembly and seal to each of the enclosed conductors. And here again the cable can be treated as a single conductor run through a normal conduit seal, provided the same sort of approved means as in (D)(1) Exception is employed at the jacket termination within the enclosure to prevent substantial gas or vapor migration through the cable core.

Part (E) covers sealing of any of the cables permitted by 501.10(B) in Division 2 locations. The first topic concerns where such cables enter a box that encloses arcing or sparking equipment that must be explosionproof. In such cases the same rules and the same exception (No. 2 in this case) apply as for Division 1 terminations in the same locations, together with the same lack of clarity around shielding applied to multipair cables. In addition, an enclosure that is pressurized (Type Z in this case, Division 2 to nonhazardous) does not require a boundary seal. This directly correlates with 501.15(B)(2) Exception No. 3 for the equivalent situation involving conduit.

The second topic covers cable constructions that don’t pass vapors or gases through their cores, in this case with a defined upper limit on the rate of passage being, logically, that allowed for seal fittings generally in the product standard. Cables that are not gas-blocked must have their terminations sealed to make them so, as described above. Cables that do not have an impervious sheath, such as conventional interlocking armor metal-clad cable, must simply have a boundary seal such that the act of leaving the classified area does not spread the classification to a previously unclassified location.

Part (F) covers drainage. Paragraphs (1) and (2) cover drainage provisions for control equipment; means must be provided for its periodic removal. The simplest way to accomplish this is to use a seal with a drain fitting in a conduit entry below the control enclosure. For motors, since they are factory sealed, the drainage provisions must be made at the factory.

501.17. Process Sealing. This section, new as of the 2011 **NEC**, is a comprehensive rewrite

and expansion of what used to be a third numbered paragraph under the “Drainage” subsection in prior editions. The subject is electrical equipment that is directly connected to a process containment vessel or piping system involving chemicals that are or could become fuel for fire or explosions. Examples cited in the text include canned pumps, submersible pumps, and instrumentation that measure temperature, flow, chemical composition, or pressure of such process fluids. Liquefied natural gas systems are but one of many examples of these applications. If the process/electrical system interface relies on a single-sealing element to separate the process fluid from the electrical system, such as a diaphragm, compression seal, or tube or other mechanism, there must be an additional step taken to guard against the consequences of the single-element failure. Process-connected electrical equipment that does not rely on a single seal, or that is listed and marked “single seal” or “dual seal” can be used without additional steps. The **NEC** provides four options if additional steps need to be applied, but the list is not limiting and others can be submitted for approval. The four options available are:

- A barrier suitable for the temperature and pressures involved with the process, and arranged so the failure of the initial process seal will become obvious through visible leakage, an audible whistle, or other monitoring methods.
- Electrical connections through a listed Type MI cable assembly, rated to withstand not less than 125 percent of both the process pressure and maximum process temperature (in degrees Celsius).
- A drain or vent between the single-process seal and the conduit or cable seal such that the electrical seal is not pressurized above a 6-in. water column (1493 Pa) and arranged so the initial sealing failure is obvious using the same options as for the barrier method.
- An add-on secondary seal, which must be rated for the conditions in the event of a failure in the process seal. This reflects current technological developments in this area.

501.20. Conductor Insulation, Class I, Divisions 1 and 2. For economic reasons and greater ease in handling, nylon-jacketed Type THHN-THWN wire, suitable for use where exposed to gasoline, has in most cases replaced lead-covered conductors.

An excerpt from the UL Guide Card information that applies to this subject states as follows:

Wires, Thermoplastic.

Gasoline Resistant TW—Indicates a TW conductor with a jacket of extruded nylon suitable for use in wet locations, and for exposure to mineral oil, and to liquid gasoline and gasoline vapors at ordinary ambient temperature. It is identified by tag marking and by printing on the insulation or nylon jacket with the designation “Type TW Gasoline and Oil Resistant I.”

Also listed for such use is “Gasoline Resistant THWN” with the designation “Type THWN Gasoline and Oil Resistant II.”

Note that other thermoplastic wires may be suitable for exposure to mineral oil, but, with the exception of those marked “Gasoline and Oil Resistant,” reference to mineral oil does not include gasoline or similar light-petroleum solvents.

The conductor itself must bear the marking legend designating its use as suitable for gasoline exposure; such designation on the tag alone is not sufficient.

501.25. Uninsulated Exposed Parts, Class I, Divisions 1 and 2. Uninsulated exposed

parts operating not over 30 V (15 V in wet locations) can be used, but only where intrinsically safe (Div. 1 or 2) or nonincendive (Div. 2) protection applies.

501.30. Grounding and Bonding, Class I, Divisions 1 and 2. The parent text of this section now (2014 NEC) includes express language that these provisions apply regardless of voltage. This requirement is also in 250.100, and as a result the entire technical content of this rule resides here in [Chap. 5](#), and the former informational note pointing to 250.100 for additional requirements has been deleted. Special care in the grounding of all equipment is necessary in order to prevent the possibility of arcs or sparks when any grounded metal comes in contact with the frame or case of the equipment. All connections of a conduit to boxes, cabinets, enclosures for apparatus, and motor frames must be so made as to secure permanent and effective electrical connections. To be effective, this form of construction is not only necessary in the spaces that are classed as hazardous, but should also be carried out back to the point where the connection for grounding the conduit is made to the grounding electrode system serving the premises. Outside the space where the hazardous conditions exist, threaded connections should be used for the conduit, unless bonding techniques are used for connections to knockouts in sheet metal enclosures. Any conduit emerging from a Division 1 or Division 2 location must have a bonded path of equipment grounding from the hazardous location back to the bonded service equipment, to the bonded secondary of a transformer that supplies the circuit into the hazardous location, or, as covered in the exception, under certain conditions, to the bonded main building disconnect.

The last sentence in part (A) states that the service-type bonding required to the “point of grounding” means the special bonding requirements must be brought back to the point in the system where the grounded circuit conductor is connected to the grounding electrode. For disconnects grounded per 250.32(B)(1) Exception No. 1, that is the main building disconnect. But for hazardous locations in outbuildings where the outbuilding disconnect is within the main building, the service-type bonding must be carried back to the main building. That is, because the outbuilding disconnect is grounded as required by 250.32(D)—which prohibits connecting the neutral to the grounding electrode—the connection between the neutral and the grounding electrode conductor will be in the main building.

If the circuits to a hazardous location are supplied from a separately derived system (as from a transformer or from a generator on the load side of the service), bonded conduit connections are required only back to the transformer or generator and not back to the service ground. It is only necessary to bond back to the point where the neutral and equipment grounding conductor of the supply system are bonded together. In that case, the low-impedance ground-fault current return path to the transformer or generator neutral will ensure quick fault-clearing action of the circuit protective devices.

The net effect of the wording in part (A) of this section is to require the use of “service bonding” techniques [250.92(B)] throughout the length of a continuous path from the raceway and equipment in a hazardous location all the way back to the first point at which the system neutral is bonded to the system equipment grounding terminal or bus and both are connected to a grounding electrode—either at the transformer in the system or at a generator or at the service equipment if there is no voltage change in the system ([Fig. 501-29](#)). This means that every raceway termination in the ground return path to the service or transformer secondary must be a threaded metal conduit connection to a threaded hub or boss on a fitting or enclosure or any connection to a sheet metal KO must use one of the following methods:

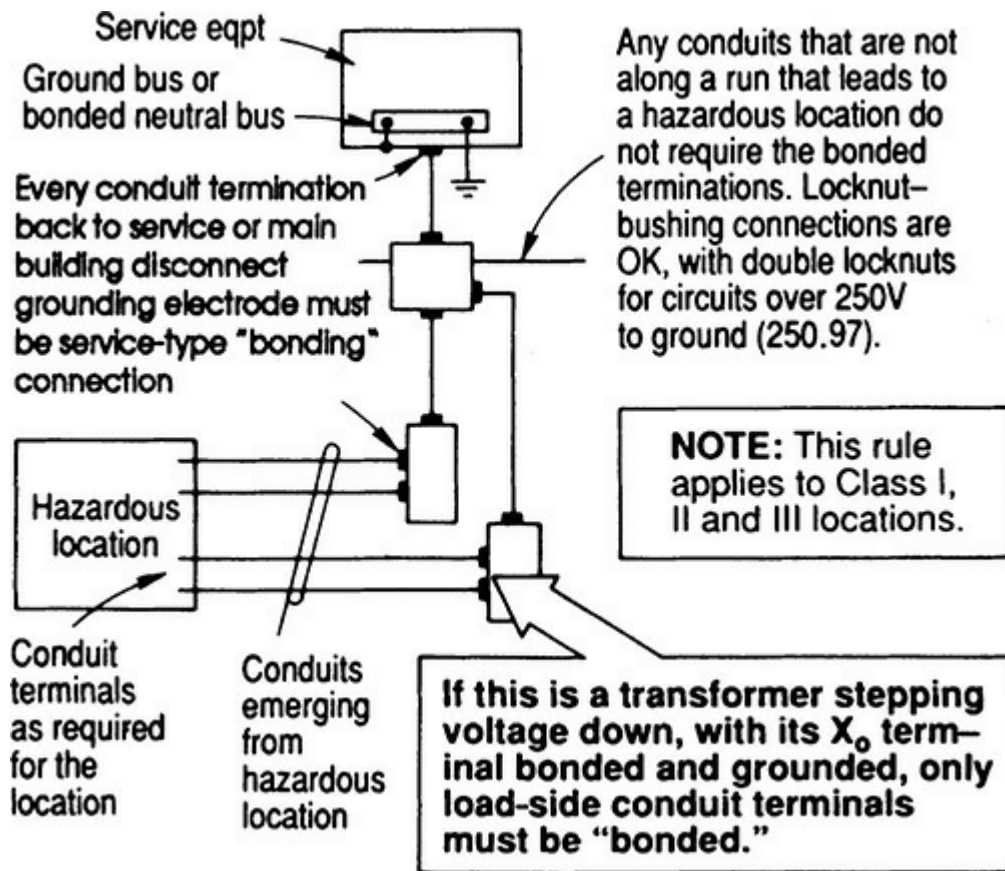

Fig. 501-29. Bonding of raceways and equipment must be made back to service ground. (Sec. 501.30.)

1. A bonding bushing with a bonding jumper to a grounding terminal within the enclosure, on a KO that is clean or has rings left in the enclosure wall.
2. A bonding bushing that does not require a jumper when used on a clean KO. The various techniques that must be used instead of locknut and bushing or double-locknut-and-bushing are described in the figures accompanying Sec. 250.92.

In addition, although 250.118 allows flexible wiring methods in certain sizes and with certain overcurrent protection ahead of them to function as equipment grounding paths, these wiring methods are disallowed from using those provisions in hazardous locations. The wiring methods can be used, but only with a properly sized bonding conductor installed, regardless of the raceway size or the overcurrent protective ratings.

At the top, [Fig. 501-30](#) shows a violation of part (A). Although 501.10(B) permits a sheet metal junction box (nonexplosionproof) in a Division 2 location, bonding through that enclosure (and all the way back to the service) may not be done simply by locknuts and bushings—not even the double-locknut type. At the bottom, the bonding jumpers satisfy the rule here. From Table 250.122, a No. 8 copper bonding jumper is the minimum acceptable size to be used with a 100-A-rated protective device, for connecting each bushing to the box.

Fig. 501-30. Bonding bushings with jumpers comply with grounding rule. (Sec. 501.30.)

According to the exception for part **(B)** for Class I, Division 2 areas, liquidtight flexible metal conduit, in lengths not over 6 ft, may be used without a bonding jumper (an internal or external equipment grounding conductor) to enclose conductors protected at not more than 10 A. This permission is given only for circuits to a load that is “not a power utilization load.” The same use of liquidtight flex is permitted for Class II and Class III locations, in 502.30(B) and 503.30(B).

501.115. Switches, Circuit Breakers, Motor Controllers, and Fuses. Part **(A)** effectively requires explosionproof enclosures (listed for Class I locations, which means suitable for use in Division 1 areas), although purged enclosures are not ruled out. Explosionproof equipment is required in Class I areas only. And any of the equipment covered by 501.115(A), including its enclosure, must be listed as an assembly. In addition, the equipment must operate at a temperature low enough that it will not ignite the atmosphere around it.

Division 1 Electrical equipment described must be explosionproof and specifically designed for the respective class and group.

Division 2 Equipment selected must be explosionproof only in certain cases. Purged and

pressurized enclosures are recognized as an alternative to explosionproof types, as noted in 500.7(D). General-purpose enclosures may be used only if all arcing parts are immersed under oil or enclosed within a chamber that is hermetically sealed against the entrance of gases or vapors. Oil-immersed contacts are permitted in general-purpose enclosures where the power circuit interruption takes place under at least 50 mm (2 in.) of oil and under at least 25 mm (1 in.) for control contacts. Another alternative, very popular today, is to leave the seal to the factory and mount a device with a factory-sealed explosionproof housing in a general-purpose enclosure. Solid-state switching, with no actual contacts involved, is permitted provided the surface temperature of the apparatus in the general-purpose enclosure does not exceed 80 percent of the autoignition temperature of the hazardous substances involved. If one of these conditions is not satisfied, the enclosure must be explosionproof.

Figure 501-31 shows two explosionproof panelboards. Each panelboard consists of an assembly of branch-circuit CBs, each pair of CBs being enclosed in a cast-metal explosionproof housing. Access to the CBs and to the wiring compartment is through handholes with threaded covers, and threaded hubs are provided for the conduits. Individual CBs and motor starters are also shown. Panelboards for light and power are limited in the UL Guide Card information [see discussion at 110.3(B) for details]. Listed panelboards for Class I and Class II hazardous locations are for “lighting and *low-capacity* power distribution.” *High-capacity* panelboards (such as 1200-A floor-standing panels) and switchboards must be kept out of hazardous locations wherever possible. Enclosure requirements and details are generally the same as those described under “General Rules” and for CBs and boxes. Typical hazardous-location panelboards are shown at the right in [Fig. 501-32](#).

Fig. 501-31. Explosionproof panelboards (arrows) are assemblies made up of circuit-breaker housings coupled to wiring enclosures. Large explosionproof CB enclosure at center feeds the panelboards. Explosionproof motor controllers are at lower left. (Sec. 501.115.)

Fig. 501-32. Explosionproof panelboards (at right) are combined with separate enclosures for motor starters on a rack, to make up a “modular assembly,” which is listed by UL under “Industrial control equipment”—which may be assembled either at the factory or in the field. (Sec. 501.115.)

“Industrial control equipment” is a broad category in the UL Guide Card information [see discussion at 110.3(B) for details], covering “control panels and assemblies” and “motor controllers.” Control panels and assemblies include both enclosures and the components within them, such as motor controllers, pushbuttons, pilot lights, and receptacles (Fig. 501-33). Either a single enclosure or a group of interconnected enclosures may be used for mounting the components. Where a number of interconnected enclosures are included in an assembly, it is called a *modular assembly* and may be assembled either at the factory or in the field. An example of that is shown in Fig. 501-32.

Fig. 501-33. Combination motor starter is typical explosionproof control unit for Class I locations. Note the drain-type seal fittings that provide for draining the conduits of any accumulated condensation or other water. (Sec. 501.115.)

Components are provided with the enclosures, to be installed either at the factory or in the plant. Wiring between components of modular assemblies is to be field-installed. Conduit seal-off fittings must be used in accordance with 501.15.

As noted in part **(1)** of part **(B)(1)**, in a Class I, Division 2 location, a general-purpose enclosure may be used for a circuit breaker, a motor controller, or switch *if* “interruption of current occurs within a factory sealed explosionproof chamber.” This is a condition under which a general-purpose enclosure may be used for a current-interrupting device—instead of requiring a Class I, Division 1 enclosure.

A snap switch in an explosionproof enclosure is shown in [Fig. 501-34](#). If a snap switch has an internal factory seal between the switch contacts and its supply wiring connection in its enclosure, it will be so identified by a marking on it. Such switches (not the one in the illustration) do not require a seal fitting in a conduit entering the enclosure. The integral seal satisfies 501.15(A)(1) Exception item 3 and 501.15(C)(5).

Fig. 501-34. Explosionproof enclosure suits snap switch to use in hazardous location. (Sec. 501.115.)

As noted in part **(B)(2)**, isolating switches in Class I, Division 2 locations may be used in general-purpose enclosures either with or without fuses in the enclosure. In previous Code editions, this rule recognized a general-purpose enclosure only for an isolating switch that did *not* contain fuses. But because the fuse in such a switch is for short-circuit protection and neither the switch nor the fuse operates as a “normal” interrupting device, fuses are permitted in isolating switches in general-purpose enclosures.

With reference to subparagraph **(B)(3)**, it is assumed that fuses will very seldom blow, or CBs will very seldom open, when used to protect feeders or branch circuits that supply only lamps in fixed positions. In Division 2 locations the conditions are not normally hazardous but may sometimes become so. Fuses are permitted in general-purpose enclosures if their operating element is oil-immersed, or hermetically sealed, or of a nonindicating and filled current-limiting type. This would exclude plug fuses, renewable cartridge fuses, or other common fuses, which would need to be in an enclosure suited for the location.

Part **(B)(4)** provides that listed fuses in luminaires used for supplementary overcurrent protection are permitted in Class I, Division 2 locations.

501.120. Control Transformers and Resistors. The term *control transformer* is commonly applied to a small dry-type transformer used to supply the control circuits of one or more motors, stepping down the voltage of a 480-V power circuit to 120 V.

Part **(A)** requires either explosionproof or purged and pressurized enclosures for Division 1 locations—the same as required for meters and instruments in 501.105(A).

501.125. Motors and Generators. Four different types of motor applications are recognized for use in a Class I, Division 1 location. The first is a motor approved for Class I, Division 1 locations, such as an explosionproof motor. The totally enclosed, fan-cooled motor (referred to as a TEFC motor) is available in a form listed by UL for use in explosive atmospheres. A motor of a type approved for use in explosive atmospheres of the TEFC type is shown in Fig. 501-35. The main frame and end housings are made with sufficient strength to withstand internal pressures due to

ignition of a combustible mixture inside the motor. Wide metal-to-metal joints are provided between the frame and housings. Circulation of the air is maintained inside the inner enclosure by fan blades on each end of the rotor. At the left side of the sectional view, a fan is shown in the space between the inner and outer housings. This fan draws in air through a screen and drives it across the surface of the stator punchings and out through openings at the drive end of the motor. The motors described in (2) and (3) of part (A) of this section are the only ones available for Class I, Group A and B locations and for medium-voltage, high-horsepower applications. The cost of ducts and ventilating systems limits their application in other areas.

Fig. 501-35. A motor approved for use in the explosive atmosphere of a Class I, Division 1 location

is the basic one of the four types recognized for such locations. (Sec. 501.125.)

A fourth option, available since the 1975 **NEC**, originated with the petroleum industry and consists of a motor operating in liquid and with controls that assure that it cannot actually start until entirely purged and comes off line in the event that its medium of submergence fails. The 2017 **NEC** modified this rule by conditioning it on use by industrial establishments with restricted public access and qualified maintenance and supervision.

The UL Guide Card information [see discussion at 110.3(B) for details] lists motors for Class I, Group C and D locations. To date, UL lists no motors for Groups A and B; therefore, where such conditions are encountered, motors must be located outside the hazardous area or must conform to the alternate arrangements and conditions of 501.125(A). Air or inert-gas purging are recognized as alternate methods. Motors suitable for Group C and D, Class I locations are designated as explosionproof.

In part **(B)**, the rule relaxes the requirements for Division 2 areas somewhat. In Class I, Division 2 locations, open or nonexplosionproof enclosed motors may be used if they have no brushes, switching mechanisms, or integral resistance devices. This includes conventional squirrel-cage three-phase motors. However, motors with any sparking or high-temperature devices must be approved for Class I, Division 1 areas, as previously described. A note (No. 4) addresses the potential issues arising in these environments from piston engines, such as typical power generators. The note references an ISA standard covering the applicable safety requirements in such cases.

As of the 2017 **NEC**, the issue of shaft bonding devices is addressed. These devices, installed either inside or outside the motor housing, have sliding contacts running on the shaft and keep the shaft at ground potential in order to reduce bearing failures from arcing that have been reported on motors fed from inverter based variable speed drives. The contact devices are permitted provided it can be determined that any energy discharged during operation is insufficient to be an ignition threat in the specific hazardous environment. A new informational note (No. 5) points to the applicable provisions of the UL standard that cover the process to determine incendivity.

“Motors and Generators, Rebuilt” May Be Listed

A number of years ago, a procedure was established to provide third-party certification of rewind or rebuilt motors in hazardous locations. Refer to the UL Guide Card information [see discussion at 110.3(B) for details] on hazardous-location equipment for motor-repair centers authorized to provide certified repairs.

501.130. Luminaires. In these locations, part **(A)** requires that each luminaire be *identified as a complete assembly* for the Class I, Division 1 location and marked to show the maximum wattage permitted for the lamps in the luminaire (**Fig. 501-36**). Reference to the listings in the UL Guide Card information shows many manufacturers listed for Class I luminaires for use in various groups of atmospheres. Listings range from “Class I, Group C” to “Class I, Groups A, B, C, and D.” For application of a luminaire in a particular group, it is simply a matter of ensuring that a manufacturer’s luminaire is listed for Class I and the group. The designation “Class I” indicates that the luminaire is suitable for Division 1, except where the listing contains the phrase “Division 2 only” following the “Class I” reference or following the “Class I” plus group references.

Fig. 501-36. Fluorescent luminaire, fed by Type MI cable, is listed and marked as an explosionproof unit for use in a Class I, Division 1 location. (Sec. 501.130.)

Part (A)(3) permits support of a suspended luminaire on rigid metal conduit, IMC, or an explosionproof flexible connection fitting. Such application is acceptable provided the luminaire stem is no longer than 12 in. (300 mm), unless lateral bracing is provided. Where bracing *is* needed, it must be provided not more than 12 in. (300 mm) from the luminaire end of the stem. As indicated, where flexibility is needed, a flexible fitting, no longer than 12 in. (300 mm) is permitted.

Class I, Division 2 locations In these locations, the selection of a suitable luminaire becomes a little more involved and has caused problems in the field. Correlation between the requirements of 501.130 and the application data and listings of UL must be carefully established.

Watch Out! Controversy! 501.130(B)(1) does *not* say that a luminaire in a Division 2 location must “be listed for the Class I, Division 2 location.” Instead, 501.130(B)(1) gives a description of the type of luminaire that would be acceptable, citing a number of requirements:

1. If the lamps under normal conditions reach a surface temperature exceeding 80 percent of the autoignition temperature (in degrees Celsius) of the surrounding gas or vapor, the luminaire must have been tested in order to determine the operating temperature, or “T code” [see **NEC** Table 500.8(C)]. The other possibility is to use a Division 1 luminaire rated for the location.
2. The luminaire must be protected from physical damage by suitable guards or “by location”—which can be taken to mean that mounting it high or otherwise out of the way of any object that might strike or hit it eliminates the need for a guard. If falling sparks or hot metal from the luminaire could possibly ignite local accumulation of the hazardous atmosphere, then an enclosure or other protective means must be used to eliminate that hazard.

3. If the luminaire is pendant mounted, it must meet a slightly relaxed version of 501.130(A)(3) for Division 1 equivalents. The only difference is that the set-screws to prevent the threaded joints from loosening in Division 1 are not required here.
4. Luminaires for portable lighting must generally meet Division 1 requirements; however, if they are mounted on movable stands such that they are protected from physical damage in any position, and connected by flexible cord in accordance with 501.140, they need only comply with (B)(1). The rule recognizes the common need for temporary lighting for maintenance work in Class I, Division 2 locations, where handlamps would not be adequate.
5. Any switches on the luminaire must have their contacts hermetically sealed.
6. Any ballasts or other control equipment must meet 501.120(B). Since ballasts would come under (B)(1) (“coils and windings”) they would qualify for ordinary location enclosures.

Figure 501-37 shows a Class I, Division 1 luminaire that could be used in a Division 2 location. But it is not necessary to use a Division 1 luminaire and have questions develop.

Fig. 501-37. In a Class I, Division 2 location, a lighting fixture listed for Class I, Division 1 would satisfy—such as this factory-sealed mercury-vapor luminaire in a Class I, Group D location. Otherwise, a fixture listed for Class I, Division 2 must be used. (Sec. 501.130.)

For many years in Class I, Division 2 locations, simply an enclosed- and gasketed-type luminaire was the usual choice. The luminaire does not need to be explosionproof but must have a gasketed globe. The primary requirement is that any surface, including the lamp, must operate at not over 80 percent of the autoignition temperature of the gas or vapor that may be present. The effect of 501.130(B)(1) is to recognize the use of general-purpose luminaires if the conditions of luminaire-

operating temperature and atmosphere-autoignition temperature are correlated as required or if the luminaire has been tested to verify its safety. At best, the described task of determining the suitability of a general-purpose luminaire for use in the hazardous location by relating its lamp-operating temperature to 80 percent of the atmosphere-ignition temperature could be difficult for any electrical designer and/or installer. It also seems highly unlikely that any of them would have the facilities or the experience to perform the testing described in the last part of the Code rule and make a sound judgment on the suitability, even though the manufacturer provides the necessary temperature data on the luminaire. It was the intention of the authors of that last part of the Code rule that the testing mentioned be done by a “qualified testing agency” (such as UL, Factory Mutual, ETL). As a result of such testing, luminaires for Class I, Division 2 locations would be approved and listed on the same basis that luminaires are certified for Class I, Division 1 locations.

Class I, Division 2 luminaires are listed in two ways in the Guide Card information [see discussion at 110.3(B) for details]. Some are listed as “Class I, Division 2 only,” without reference to group or groups. Others are listed with an indication of the groups for which they are listed—for instance, “Class I, Groups A, B, C, and D, Division 2 only.” Great care must be used in evaluating the detail of these listing designations. If such a luminaire is not marked otherwise, the temperature of the luminaire is lower than the autoignition temperature of any of the atmospheres for which it is listed. Where a Class I group designation is not mentioned, the luminaire must not be used where its marked operating temperature is greater than the autoignition temperature of the hazardous atmosphere. Class I, Division 2 luminaires with *internal* parts operating over 212°F (100°C) will be marked to show the actual operating temperature of internal parts.

Based on the foregoing, precise enforcement of the **NEC** and OSHA insistence on the maximum use of third-party-certified products would seem to suggest the following approach:

1. In Class I, Division 1 locations, only luminaires listed by a nationally recognized test lab may be used.
2. Because luminaires are listed for Class I, Division 2 locations (in the UL Guide Card information), any luminaire in a Class I, Division 2 location *must be listed* for that application (or, of course, a Class I, Division 1 luminaire could be used). Consistent with OSHA’s rationale on the matter of listing, if a third-party-certified product is available (that is, Class I, Division 2 luminaires), then use of a nonlisted luminaire in a Class I, Division 2 location could draw an objection, but only from OSHA and not from someone enforcing the **NEC**.

Recessed Luminaires

Recessed luminaires of both incandescent and electric-discharge lamp types are listed in the UL Guide Card information and are suitable only for dry locations, unless marked “Suitable for Damp Locations” or “Suitable for Wet Locations.” Other rules are as follows:

- Each luminaire is marked to show the minimum temperature rating of conductors used to supply the luminaire. Care must be taken to observe all such markings on these luminaires with respect to the number, size, and temperature rating of wires permitted in junction boxes or splice compartments that are part of such luminaires. Generally, no allowance is made in such boxes or compartments for heat produced by current to other loads that may be fed by taps or splices in the luminaire supply wires within the JB or splice compartment. Allowance is made only for the I^2R heat input of the current to the luminaire itself. If the luminaire is recognized for carrying

through other conductors to other loads, the luminaire will be marked to cover the permitted conditions of wiring. This is consistent with the principle covered in **NEC 410.21** (second paragraph).

- Luminaires are listed to ensure safe application in both Class I, Division 1 and Class I, Division 2 locations.
- In every Class I, Division 1 luminaire, the wiring compartment for supply circuit connections is internally sealed from the lamp chambers.
- Luminaires that may be used as raceways for carrying through circuit conductors other than those supplying the luminaires are marked “Suitable for Use as Raceway” and show the number, size, and type of wires permitted.
- Luminaires are marked to show suitability for installation in concrete and some may be used *only* in concrete.
- Luminaires are marked when they may be used *only* with fire-resistive building construction.
- Some luminaires are marked to show acceptable use *only* in Class I, Division 2 locations.

501.135. Utilization Equipment. This section covers devices that utilize electrical energy—other than luminaires and motors or motor-operated equipment. Electric heaters in Class I, Division 1 locations must be listed for such application. The UL Guide Card information [see discussion at 110.3(B) for details] lists convection-type heaters under “Heaters,” for Groups C and D. Industrial and laboratory heaters—heat tracing systems, hot plates, paint heaters, and steam-heated ovens—are also listed.

According to 501.135(B)(1)(1), Exception No. 2, in a Class I, Division 2 location, electrically heated utilization equipment may be used *if* some current-limiting means is provided to prevent heater temperature from exceeding 80 percent of the autoignition temperature of the gas or vapor. Such current limitation may be part of the control equipment for the heater to ensure safe operation by preventing dangerously high temperatures.

501.140. Flexible Cords, Class I, Divisions 1 and 2. Although 501.10(A) does not mention flexible cord as an approved method of general wiring in Division 1 locations, it is mentioned for flexible connections in 501.10(A)(2). The allowances in Part (A) are not inconsistent and do permit such cord for connection of portable equipment. The concept is also applied in 501.105(B)(6), which permits cord-and-plug connection of process control instruments in Division 2 locations, to facilitate replacement of such units, which are not portable equipment but are subject to interchange. 501.10(B)(2)(5) also covers use of cord in Division 2 locations.

An explosionproof handlamp, listed for use in Class I locations, is an example of portable equipment covered by this rule, which requires that a three-conductor cord be used and that the device be provided with a terminal for the third, or grounding, conductor, which serves to ground the exposed metal parts. Such handlamps are listed under “Portable Luminaires for Use in Hazardous Locations” in the UL Guide Card information [see discussion at 110.3(B) for details], which notes that flexible cords should be used only where absolutely necessary as an alternative to threaded rigid conduit hookups. Cords, plugs, and receptacles must be protected from moisture, dirt, and foreign materials. Frequent inspection and maintenance are critically important. Consultation with inspection authorities is always recommended where plug and receptacle applications are considered.

Flexible cord is recognized in industrial occupancies with qualified maintenance and supervision to supply equipment that requires a range or speed of motion that necessitates the use of flexible cord

with its inherently flexible, very finely stranded conductors. The use of cord in these applications requires protection for the cord, either by location or through the use of guards. Flexible cord is also recognized with submersible pumps in wet-pits. For these applications the cord is permitted to pass through a conduit run unspliced back the industrial control panel or other power source supplying it. This is a rare example of a specific allowance for cord in conduit as covered in 400.12(6). Cord is also permitted for mixers that must travel in and out of open tanks. The 2011 **NEC** added another application, that of supplying power to maintenance carts for refineries and other industrial plants that contain equipment including receptacles to supply portable utilization equipment. In the event the cord enters or is supplied from an enclosure or fitting required to be explosionproof, the cord must terminate with a connector or attachment plug listed for the applicable protection scheme used to maintain the suitability of the enclosure for the surrounding environment. In a Division 2 location that does not require explosionproof equipment, the termination can be through a conventional listed plug, or a listed cord connector. The cord must be “of continuous length,” but if the application is in conjunction with a maintenance cart as just described, one cord can feed the cart and another can feed the portable equipment fed from the cart.

When flexible cord is permitted in accordance with (A), Part **(B)** covers how to install it. It must be extra-hard-usage cord, such as Type SO, STO, or SOOW, containing an equipment ground, and arranged so there will not be any tension transmitted to the conductor connections at either end. Wherever connected to an enclosure or fitting required to be explosionproof, the connection must be through a cord connector (or attachment plug) that has been listed for that application and location. The cord may also be connected through a listed cord connector used in conjunction with a seal listed for the hazardous location. In Division 2 locations for applications where the terminating equipment is not required to be explosionproof, it is sufficient to apply a listed attachment plug or cord connector. The cord must be of continuous length. To connect the maintenance cart applications allowed in (A)(5), the continuous cord rule is applied twice, once from the main power supply to the temporary portable assembly, and once again for each connection from the assembly to each portable utilization equipment.

501.145. Receptacles and Attachment Plugs, Class I, Divisions 1 and 2. The basic rule calls for receptacles and plug caps to be approved for Class I locations, which suits them for use in either Division 1 or Division 2 locations. They must be part of the premises wiring system unless provided in accordance with 501.140(A). One of the motivations for this clarification was to disqualify receptacles becoming energized through energized cords, in violation of 406.7(B). The exception notes that cord connection of process control instruments in Class I, Division 2 locations does not require devices approved for Class I locations. General-purpose receptacles may be used as outlined in 501.105(B)(6).

Figure 501-38 shows a 3-pole 30-A receptacle and the attachment plug, which is so designed as to seal the arc when the circuit is broken, and therefore is suitable for use without a switch. The circuit conductors are brought into the base or body through rigid conduit screwed into a tapped opening and are spliced to pigtail leads from the receptacle. The receptacle housing is then attached to the base, the joint being made at wide flanges ground to a suitable fit. All necessary sealing is provided in the device itself, and no additional sealing is required when it is installed. The plug is designed to receive a three-conductor cord for a 2-wire circuit or a four-conductor cord for a 3-wire, 3-phase circuit, and is provided with a clamping device to relieve the terminals of any strain. The extra conductor is used to ground the equipment supplied.

Fig. 501-38. Receptacle and plug must generally be explosionproof type for Divisions 1 and 2. (Sec. 501.145.)

UL data are as follows:

- Class I receptacles for Division 1 or Division 2 locations are equipped with boxes for threaded metal conduit connection, and a factory seal is provided between the receptacle and its box.
- Receptacles for Class I, Division 2 only may be used with general-purpose enclosures for supply connections, with factory sealing of conductors in the receptacle. The plugs for such receptacles are suitable for Class I, Division 1 locations.
- Frequent inspection is recommended for flexible cords, receptacles, and plugs, with replacement whenever necessary.
- For Class I, interlocked CBs and plugs are made for receptacles so that the plug cannot be removed from the receptacle when the CB is closed and the CB cannot be closed when the plug is not in the receptacle ([Fig. 501-39](#)).

Fig. 501-39. A receptacle with a plug interlocked with a circuit breaker is an explosionproof assembly with operating safety features. (Sec. 501.145.)

Mechanical-interlock construction requires that the plug be fully inserted into the receptacle and rotated to operate an enclosed switch or CB that energizes the receptacle. The plug cannot be withdrawn until the switch or breaker has first deenergized the circuit.

The delayed-action type of plug and receptacle has a mechanism within the receptacle that prevents complete withdrawal of the plug until after electrical connection has been broken, permitting

any arcs or sparks to be quenched inside the arcing chamber. Insertion of the plug seals the arcing chamber before electrical connection is made. Threaded conduit connection to the CB compartment is provided. The plug is for Type S flexible cord with an equipment grounding conductor.

501.150. Signaling, Alarm, Remote-Control, and Communication Systems. Nearly all signaling, remote-control, and communication equipment involves make- or-break contacts; hence, in Division 1 locations all devices must be explosionproof, and the wiring must comply with the requirements for light and power wiring in such locations, including seals.

Figure 501-40 shows a telephone having the operating mechanism mounted in an explosionproof housing. Similar equipment may be obtained for operating horns or sirens. Figure 501-41 shows fire-alarm hookups at a distillery.

Fig. 501-40. Explosionproof telephones are made and listed for Class I, Groups B, C, and D, and must be connected with the necessary seal fittings required in conduits to enclosures housing arcing or sparking devices. [Sec. 501.150(4).]

Fig. 501-41. Fire-alarm and control equipment at outdoor tank car delivery and pumping station of a distillery is housed and connected to comply with conduit and seal rules for a Class I, Division 1, Group D location. (Sec. 501.150.)

Referring to subparagraph **(B)**, covering Division 2 locations, it would usually be the more simple method to use explosionproof devices, rather than devices having contacts immersed in oil or devices in hermetically sealed enclosures, though mercury switches, which are hermetically sealed, may be used for some purposes. Of course, reference to 501.15(A) recognizes the use of purged enclosures as an alternative method.

The UL Guide Card information [see discussion at 110.3(B) for details] lists “Telephones” as follows:

- Telephones, sound-powered telephones, and communications equipment and systems are listed for Class I and Class II use in Division 1 locations and are explosionproof equipment. Such equipment complies with 501.14(A) and (B).
- Intrinsically safe sound-powered telephones are also listed for Class I, Division 1, Group D and may be used in both Division 1 and Division 2 locations in accordance with 501.14(A) and (B).

The Guide Card information also lists “Thermostats,” “Signal Appliances” (which include fire alarms and fire detectors), “Solenoids,” and “Sound Recording and Reproducing Equipment.”

ARTICLE 502. CLASS II LOCATIONS

502.1. Scope. Referring to 500.5(C), the hazards in Class II locations are due to the presence of combustible dust. These locations are subdivided into three groups, as follows, and not all equipment is suitable for all groups:

- Group E, atmospheres containing metal dust
- Group F, atmospheres containing carbon black, coal dust, or coke dust
- Group G, atmospheres containing grain dust, such as in grain elevators

Any one of four hazards, or a combination of two or more, may exist in a Class II location: (1) an explosive mixture of air and dust, (2) the collection of conductive dust on and around live parts, (3) overheating of equipment because deposits of dust interfere with the normal radiation of heat, and (4) the possible ignition of deposits of dust by arcs or sparks. Combustible dust is now formally and objectively defined in Art. 500; refer to the discussion at 500.5 for more information. The 2014 NEC has revised upward the maximum size threshold for combustible dusts from passing a US #40 standard sieve or smaller (420 microns or 0.017 in.) to passing a US #35 standard sieve or smaller (500 microns or 0.020 in.).

A number of processes that may produce combustible dusts are listed in 500.6. Most of the equipment listed as suitable for Class I locations is also dusttight, but in accordance with 502.5 it should not be taken for granted that all explosionproof equipment is suitable for use in Class II locations. Some explosionproof equipment may reach too high a temperature if blanketed by a heavy deposit of dust. Grain dust will ignite at a temperature below that of many of the flammable vapors.

Location of service equipment, switchboards, and panelboards in a separate room away from the dusty atmosphere is always preferable.

In Class II locations, with the presence of combustible dust, UL standards call for a type of construction designed to preclude dust and to operate at specified limited temperatures. Dust-ignitionproof equipment is generally more economical to use in Class II areas; however, explosionproof devices are often used if such devices are approved for Class II areas and for the particular group involved.

Dust-ignitionproof equipment is enclosed in a manner that excludes dusts and does not permit arcs, sparks, or heat generated or liberated inside the enclosure to cause ignition of exterior accumulations or atmospheric suspensions of a specified dust on or in the vicinity of the enclosure. Any assemblies that generate heat, such as luminaires and motors, are tested with a dust blanket arranged to equal in thickness “the maximum amount of dust that can accumulate” to simulate the operation of the device in a Class II location.

502.6. Zone Equipment. Equipment “listed and marked” per 506.9(C)(2) for installation in Zone 20 locations may be used in Class II, Division 1, provided it is suitable for the same dust environment and a compatible temperature classification. Also, Zone 20, 21, and 22 location equipment is suitable for comparable dust exposures in Class II Division 2 locations.

502.10. Wiring Methods. Part (A) covers Division 1 locations. The wiring methods are essentially the same for Class II, Division 1 as they are for Class I, Division 1. Conduit connections to fittings and boxes must be made to threaded bosses, as covered in (A)(3). For fittings and boxes, only those used for taps, splices, or terminals in locations of electrically conductive dusts (metal, carbon, etc.) must be identified for Class II locations.

Optical fiber cable has been recognized in 770.3(A) as acceptable in hazardous locations, and this use is now correlated in 502.10(A)(1)(4). Note that it must be installed within a 502.10(A) raceway, which circles back to threaded RMC or IMC, and then sealed in accordance with the usual requirements in 502.15. The same correlating provision was added as 502.10(B)(8) for Division 2 locations. The 2017 **NEC** added recognition here [in (5)] of Type ITC-HL cable. This is an exact import from 501.10(A)(1)(d), and this book covers it in that location.

As covered in part (A)(2), where a flexible connection is necessary, it would usually be preferable to use a dusttight flexible fitting. Standard flexible conduit may not be used, but liquidtight flexible metal conduit or liquidtight flexible nonmetallic conduit may be used, with a bonding jumper as required by 502.30(B). The use of an extra-hard-service cord that has one conductor serving as a grounding conductor with listed dusttight fittings is permitted. In addition, the use of interlocking-armor Type MC cable with a nonmetallic jacket over the armor is permitted for flexible connections provided the termination fittings are listed for Class II Division 1 exposures.

In Division 2 locations, in order to provide adequate bonding, threaded fittings should be used with IMC or rigid metal conduit, but EMT may also be used (Fig. 502-1). The requirement for close-fitting covers could best be taken care of by using dusttight equipment. The standard type of pressed steel box cannot be used in any case where the box contains taps or splices. Where no taps, splices, or terminals are used in a box, a sheet metal box may be used, but all conduit connections to boxes that do not have threaded hubs or bosses must be of the bonded type, as required by 502.30(B) and described with illustrations under 501.30(B).

Fig. 502-1. EMT is okay, but the wireway *must* be dusttight. (Sec. 502.10.)

The list of permitted cables is also greatly increased. Type MC cable in any form is allowed, with listed termination fittings. It is also allowed in cable tray (see below). Type PLTC and Type ITC cables are allowed in tray as well for control work. Type MC cable (and also Type MI and TC) is acceptable cable for use in ladder, ventilated channel-type, and ventilated trough cable tray; however, there must be a cable diameter of open space separating each run of cable, or, only in cases where the Type MC is listed for use in Class II, Division 1 locations, it can be run without the spacings.

Two new approaches joined the list for the first time in 2011. The heaviest wall versions of Type PVC (i.e., "Schedule 80") and Type RTRC (i.e., suffix "-XW") conduits can now be used in Class II Division 2 locations exposed, without concrete encasement. This use is heavily restricted, being limited to industrial occupancies with limited public access and qualified maintenance and supervision, and in addition, these methods are only allowed where "metallic conduit does not

provide sufficient corrosion resistance.” Optical fiber cable joined the list in the 2014 **NEC** on the same basis as it arrived in Art. 501 and is now located at 501.10(B)(1)(8). The 2017 **NEC** added cablebus as an additional option.

Nonincendive field wiring is also permitted for these locations, under the same provisions as apply to Class I Division 2. Refer to the discussion at 501.10(B)(3) for more information on this topic.

All boxes and fittings must be dusttight, defined in Art. 100 as “constructed so that dust will not enter under specified test conditions.” Flexible connections in Division 2 locations must observe the rules given in part **(A)(2)**.

502.15. Sealing, Class II, Divisions 1 and 2. Note that sealing or other isolation is required only for conduits entering a dust-ignitionproof enclosure that connects to an enclosure that is not dust-ignitionproof. Seals are not generally required in Class II areas; however, where a raceway connects an enclosure *required to be* dust-ignitionproof and one that is not, means must be provided to prevent dust from entering the dust-ignitionproof enclosure through the raceway. A seal in the conduit is one acceptable way of doing this, with the seal any distance from the enclosure ([Fig. 502-2](#)). Where used, a seal must be accessible. This seal does not have to be explosionproof, and electrical sealing putty is sufficient. However, if the connecting raceway is horizontal and at least 10 ft (3.0 m) long, or if it is vertical, extending down from the dust-ignitionproof enclosure and at least 5 ft (1.5 m) long, or any combination of horizontal and downward length that provides an equivalent resistance to dust transmission, no sealing is necessary anywhere in the conduit. For example, a conduit that went 8 ft (2.5 m) horizontally and turned 2 ft (600 mm) down would certainly be an equivalent distance. The distance between and orientation of the enclosures are considered adequate protection against dust passage. And that applies in Division 1 and Division 2 locations wherever the “dust-ignitionproof” requirement is specified by one of the sections of this article.

Fig. 502-2. A seal fitting must be used in short [less than 10-ft (3.0 m)] connections, as shown at top, but is not required, as shown at bottom.

The next-to-last sentence of this section permits use of conduit *without* a seal between a dust-ignitionproof enclosure that is required in a Class II location and an enclosure in an unclassified location (Fig. 502-2, bottom). This added permission is made because, unlike gases or vapors, dust does not travel very far within conduit.

502.30. Grounding, Class II, Divisions 1 and 2. The requirements of this section are the same as those of 501.30. Refer to the discussion and illustrations in that section.

502.35. Surge Protection, Class II, Divisions 1 and 2. A common application of this surge protection is found in grain-handling facilities (grain elevators) in localities where severe lightning storms are prevalent. Assuming a building supplied through a bank of transformers located a short distance from the building, the recommendations are, in general, as shown in the single-line diagram in Fig. 502-3. The surge-protective equipment consists of primary lightning arresters at the transformers and surge-protective capacitors connected to the supply side of the service equipment.

The lightning arrester ground and the secondary system ground should be solidly connected together. All grounds should be bonded together and to the service conduit and to all boxes enclosing the service equipment, metering equipment, and capacitors.

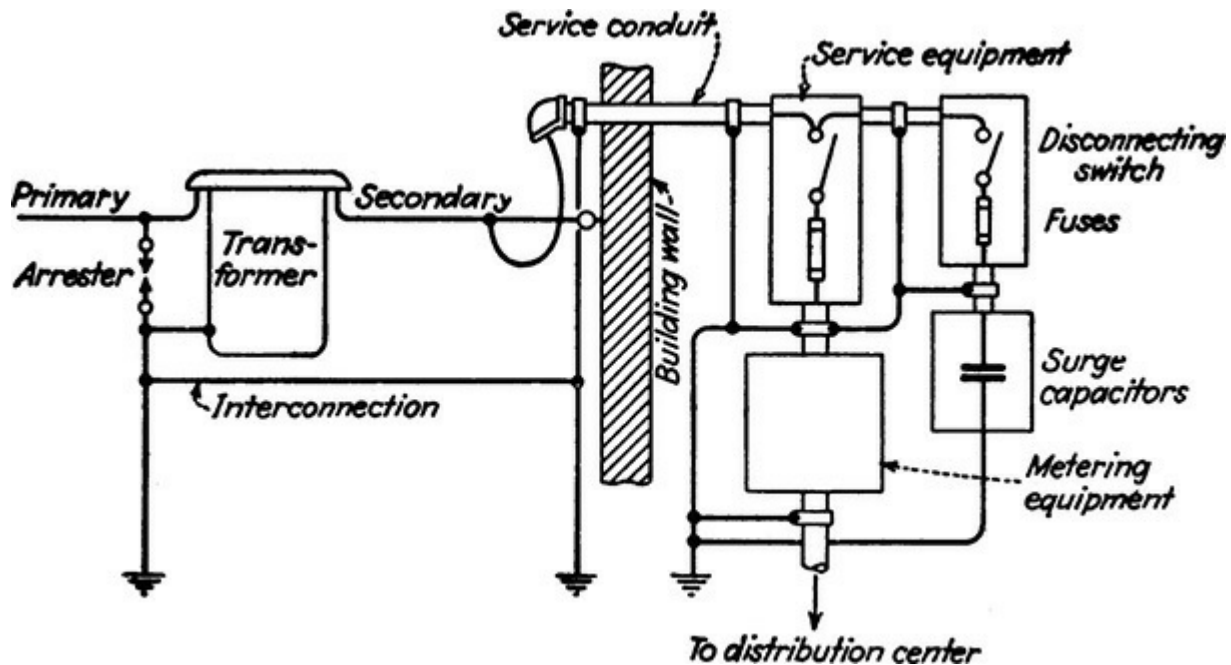

Fig. 502-3. Surge protection is often used to protect Class II systems against lightning. (Sec. 502.35.)

502.100. Transformers and Capacitors. Part (A) requires the use of a Code-constructed transformer vault for a transformer or capacitor that contains oil or other liquid dielectric that will burn, when used in a Class II, Division 1 location.

Dry-type transformers must either be approved as a complete assembly for Class II, Division 1 use, and UL now has product categories open in this area, both for medium-voltage transformers and for units 600 V and below, or a conventional transformer can be placed in a vault. A vault used for these purposes must be as covered in Art. 450 but with self-closing fire doors on both sides of the wall as well as weather-stripping or equal on those doors if they communicate with a Division 1 location. But transformers can be kept out of the hazardous areas, and part (A)(3) prohibits any use of a transformer or capacitor in a Class II, Division 1, Group E (metal dust) location. UL's category for capacitors does not appear to include hazardous locations, so they would have to be thoroughly separated from the Class II area, either by using a vault or some other method.

Part (B) requires a vault for any oil-filled or high-fire-point liquid-insulated transformer or capacitor in a Division 2 area. A dry-type unit in a Division 2 area may be used either in a vault or without a vault if the unit is enclosed within a tight metal housing without any openings and only if it operates at 600 V or less. There are no special requirements for capacitors in Division 2 locations, except that they must not contain oil or any other "liquid that will burn" if they are not within a vault.

502.115. Switches, Circuit Breakers, Motor Controllers, and Fuses. Note that part (A)(1) calls for "dust-ignitionproof" enclosures, which might involve the sealing called for in 502.15.

Most of the enclosed switches and circuit breakers approved for Class I, Division 1 locations are also approved for use in Class II locations.

Switches conforming to the definition of the term *isolating switch* would seldom be used in any

hazardous location. Such switches are permitted for use as the disconnecting means for motors larger than 100 hp.

Enclosures for this equipment in a Division 2 application must be dusttight.

502.120. Control Transformers and Resistors. This part of Art. 502, like many others, used to use the expression “tight metal housings without ventilating openings” for Division 2 applications. That terminology was changed to “dusttight,” which involves an actual testing protocol. The same change occurred in 502.150(B)(1).

502.125. Motors and Generators. In Class II, Division 1 locations, motors must be dust-ignitionproof (approved for Class II, Division 1) or totally enclosed with positive-pressure ventilation, and operating under the temperature limitations for Class II equipment that are set forth in 500.8(D)(2).

Part **(A)(2)** refers to a totally enclosed pipe-ventilated motor. A motor of this type is cooled by clean air forced through a pipe by a fan or blower. Such a motor has an intake opening, where air is delivered to the motor through the pipe from the blower. The exhaust opening is on the opposite side, and this should be connected to a pipe terminating outside the building, so that dust will not collect inside the motor while it is not running.

For Class II, Division 2 locations, part **(B)** permits use of totally enclosed, nonventilated motors and totally enclosed, fan-cooled (TEFC) motors in addition to totally enclosed, pipe-ventilated and dust-ignitionproof motors. In addition, a totally enclosed water-air-cooled motor would be permitted. This rule eliminates any interpretation that only a labeled motor (dust-ignitionproof) is acceptable for Class II, Division 2 locations. Experience has shown the other motors as covered in the exception to be entirely safe and effective for use in such locations. There are other limitations on the exception, however. The motor must be easily reached for routine maintenance, and the dust must be nonabrasive and nonconductive in character, and the expected accumulations of dust must be “moderate.” Since these are Division 2 locations, that is not an unreasonable hurdle. The 2017 **NEC** added recognition within the exception to “sealed bearings, bearing isolators, and seals.” This responds to current developments in motor designs for these environments.

Motors of the common totally enclosed type without special provision for cooling may be used in Division 2 locations, but to deliver the same horsepower, a plain totally enclosed motor must be considerably larger and heavier than a motor of the open type or an enclosed fan-cooled or pipe-ventilated motor.

The UL Guide Card information [see discussion at 110.3(B) for details] lists motors for Class II, Division 1 and 2, Group E, F, and G locations.

502.128. Ventilating Piping. In locations where dust or flying material will collect on or in motors to such an extent as to interfere with their ventilation or cooling, enclosed motors that will not overheat under the prevailing conditions must be used. It may be necessary to require the use of an enclosed pipe-ventilated motor or to locate the motor in a separate dusttight room, properly ventilated with clean air (430.16).

The reference to ventilation is clarified in this section. Vent pipes for rotating electrical machinery must be of metal not lighter than No. 24 MSG gauge, or equally substantial. They must lead to a source of clean air outside of buildings, be screened to prevent entry of small animals or birds, and be protected against damage and corrosion.

In Class II, Division 1 locations, vent pipes must be dusttight. In Division 2 locations, they must be

tight to prevent entrance of appreciable quantities of dust and to prevent escape of sparks, flame, or burning material.

Typical conditions to which these requirements may apply include processing machinery or enclosed conveyors where dust may escape only under abnormal conditions, or storage areas where handling of bags or sacks may result in small quantities of dust in the air.

502.130. Luminaires. Luminaires used in Class II, Division 1 areas must prevent the entry of the hazardous dust and should prevent the accumulation of dust on the luminaire body. In Division 1 locations, all luminaires must be approved for that location, and display the lamp type and power. Where metal dusts are present, luminaires must be specifically identified for use in Group E atmospheres. Luminaires are listed by UL as suitable for use in all three of the locations classed as Groups E, F, and G, for Divisions 1 and 2.

The purpose of the latter part of subparagraph **(A)(3)** is to specify the type of cord to be used for wiring a chain-suspended luminaire. It is not the intention to permit a luminaire to be suspended by means of a cord pendant or drop cord. Except for the allowance for the use of cord to a chain-hung luminaire, the requirements are essentially the same for pendants here and in Art. 501. The cord termination at the luminaire must employ a listed dusttight fitting, in accordance with 502.10(A)(2)(5).

The Division 2 requirements for fixed lighting have been tightened, and now require dusttight enclosures together with a specified lamp type and maximum lamp wattage such that the worst-case exposed surface temperature will not exceed the limits in 500.8(D)(2). These requirements will be difficult to verify compliance to without the services of a testing laboratory. For Class II, Group G, Division 2 areas, luminaires normally are the enclosed and gasketed type. However, in addition, such luminaires must not have an exposed surface temperature exceeding 329°F (165°C).

There are portable handlamps approved for use in any Class II, Group G location—that is, where the hazards are due to grain dust.

The UL Guide Card information [see discussion at 110.3(B) for details] notes that a Class II luminaire for Divisions 1 and 2 is tested for dusttightness and safe operation in the dust atmosphere for which it is listed. A note points out the importance of effective maintenance—regular cleaning—to prevent buildup of combustible dust on such equipment.

502.135. Utilization Equipment. As noted in part **(B)(1)**, Exception, dusttight metal-enclosed radiant heating panels may be used in Class II, Division 2 locations even though they are not approved for Class II locations. The exception to this section will permit such electric-heat panels provided that the surface temperature limitations from 500.8(D)(2) are satisfied. Heaters of this type are available with low surface temperature.

502.140. Flexible Cords—Class II, Divisions 1 and 2. [Figure 502-4](#) shows flexible cord used in a Division 2 area of a grain elevator (Class II, Group G). As of the 2014 **NEC**, the provisions for the use of flexible cord in Class II locations almost exactly mirror those for Class I locations, with the continuous length rule of 501.140(B)(5) now repeated in this location. In this way the new provisions in 502.140(A)(5) for temporary portable assemblies such as maintenance carts line up with the requirement for continuous cords.

Fig. 502-4. Flexible cords and listed connectors are used in a grain elevator that handles combustible grain dust. (Sec. 502.140.)

502.10 permits its use in Division 1 and Division 2 areas of Class II locations. Listed cord connectors are recognized for use in Class II, Group G locations, using Types S, SO, ST, or STO multiconductor, extra-hard-usage cord *with* a grounding conductor. Cord connectors for connecting extra-hard-service type of flexible cord to devices in hazardous locations must be carefully applied, with cord connectors listed for the dust location or a listed cord connector entering a listed seal for the location; either option being permitted for Division 1. However, a Division 2 exposure simply requires a listed dusttight cord connector.

The UL Guide Card information [see discussion at 110.3(B) for details] notes, under “Receptacles with Plugs,” that Type S flexible cord should be frequently inspected and replaced when necessary.

502.145. Receptacles and Attachment Plugs. Class II receptacles listed as approved for Division 1 locations are equipped with boxes for threaded metal conduit connection, and a factory seal is provided between the receptacle and its box. Only receptacles and plugs listed for Class II locations are permitted in Division 1 areas. The section has been restructured in the 2014 **NEC**, with the Class II suitability requirement moved to the parent text where the same requirement applies equally for both Division 1 and Division 2 exposures. The requirement for receptacles being part of the premises wiring reflects the same concerns about enforcement of 406.7(B) as motivated the same requirement in 501.145.

Frequent inspection is recommended for flexible cords, receptacles, and plugs, with replacement whenever necessary.

As shown in [Fig. 501-39](#) for Class I locations, for Class II locations interlocked CBs and plugs are also made for receptacles so that the plug cannot be removed from the receptacle when the CB is closed and the CB cannot be closed when the plug is not in the receptacle.

ARTICLE 503. CLASS III LOCATIONS

503.5. General. The small fibers of cotton that are carried everywhere by air currents in some parts of cotton mills and the wood shavings and sawdust that collect around planers in woodworking plants are common examples of the combustible flyings or fibers that cause the hazards in Class III, Division 1 locations. Wood flour, as produced in some finishing operations, is classified as combustible dust if it meets the 500- μ m particulate size limit of the definition (see 500.2 and the commentary in this book at 502.1). A cotton warehouse is a common example of a Class III, Division 2 location.

503.6. Zone Equipment. Equipment “listed and marked” for installation in combustible dust environments under the zone classifications system per 506.9(C)(2) as suitable for Zone 20 can be used in Class III Division 1 locations provided it does not operate at high temperature. Specifically it must not have a temperature classification over T120°C for equipment that is subject to overload and T165°C for other equipment. Similar to the case of combustible dust, the test protocol requires an accumulation of the subject fibers/flyings to be arranged so that they equal in thickness the maximum amount that can accumulate. Comparable equipment rated for Zone 20, 21, or 22 can be used for Class III Division 2 locations.

503.10. Wiring Methods. Type PVC and RTRC conduit, EMT, and Type MC (metal-clad cable) are permitted for Class III, Division 1 locations, in addition to rigid metal conduit, IMC, Type MI cable, and dusttight wireways. Type MC (Art. 330) includes interlocked armor cable, corrugated metal armor, smooth aluminum-sheathed cable (known until the 1978 **NEC** as Type ALS), and smooth copper-sheathed cable (also known until the 1978 **NEC** as Type CS).

Cable trays with ladder, ventilated trough, or ventilated channel construction are permitted in these locations, provided the allowable wiring methods are in a single layer with a maintained spacing not less than the diameter of the larger adjacent cable. The permitted cables are Type TC, MI, or MC; MC cable is also available in a form listed for use in comparable Class II locations, and these cables do not require spacing between adjacent cables. The 2017 **NEC** added cablebus to the list as well, without limitation.

Nonincendive field wiring is also permitted for these Division 1 locations, under the same provisions as apply to Class I and Class II Division 2. Refer to the discussion at 501.10(B)(3) for more information on this topic.

Fittings and boxes must be dusttight, whether or not they contain taps, joints, or terminal connections. As part (A)(2) notes about flexible connections, it is necessary to use dusttight flexible connectors, liquidtight flexible metal or nonmetallic conduit, or extra-hard-usage flexible cord that complies with 503.140. Interlocking-armor Type MC cable with an outer plastic jacket is also recognized for this purpose, provided the terminating fittings are dusttight.

Part (B) requires the same wiring methods for Division 2 as for Division 1. As indicated in [Fig. 503-1](#), there are no seal requirements in Class III locations. By exception only in areas used only for storage and without machinery, open wiring on insulators is still permitted.

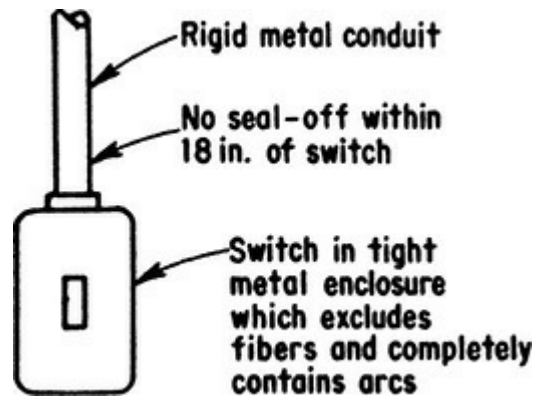

Fig. 503-1. Seals are not required in Class III enclosures or conduit, but all boxes and fittings must be dusttight. (Sec. 503.10.)

503.30. Grounding and Bonding. These requirements are identical to Class I and II.

503.115. Switches, Circuit Breakers, Motor Controllers, and Fuses, Class III, Divisions 1 and 2. Enclosures for this equipment in a Class III location must be dusttight—as determined under defined test conditions.

503.120. Control Transformers and Resistors. These enclosures must be dusttight. In addition, equipment suitable for Class III locations must function at full rating without developing surface temperatures high enough to cause excessive dehydration or gradual carbonization of accumulated fibers or flyings. These devices have the same surface temperature limitations as Class II equipment, and the construction is similar.

503.125. Motors and Generators, Class III, Divisions 1 and 2. UL lists no Class III motors as such; however, totally enclosed pipe-ventilated motors or totally enclosed nonventilated motors, depending on the needs of the application, and the so-called lint-free or self-cleaning textile squirrel-cage motors are commonly used. The latter may be acceptable to the local inspection authority if only moderate amounts of flyings are likely to accumulate on or near the motor, which must be readily accessible for routine cleaning and maintenance. Or the motor may be a squirrel-cage motor, or a standard open-type machine having any arcing or heating devices enclosed within a tight metal housing without ventilating or other openings.

503.130. Luminaires—Class III, Divisions 1 and 2. In Class III, Division 1 and 2 areas, luminaires must minimize the entrance of fibers and flyings and prevent the escape of sparks or hot metal. And again, the surface temperature of the unit must be limited to 329°F (165°C). Available luminaires are third-party-certified (by a national test lab) for Class III locations, Divisions 1 and 2. In the past, enclosed and gasketed types of luminaires, of the type that was used in Class I, Division 2 areas, have been acceptable as suitable for use in this application. But because there are listed Class III luminaires available, inspection agencies and OSHA might insist on use of *only* listed luminaires in such applications, to be consistent with the trend to third-party certification. Pendants follow similar rules as in Class II, including the allowance for cord where it does not actually support the luminaire, and the requirements to avoid breakage of conduit stems at their threads.

503.155. Electric Cranes, Hoists, and Similar Equipment, Class III, Divisions 1 and 2. A crane operating in a Class III location and having rolling or sliding collectors making contact with bare conductors introduces two hazards:

1. Any arcing between a collector and a conductor rail or wire may ignite flyings of combustible

fibers that have collected on or near the bare conductor. This danger may be guarded against by proper alignment of the bare conductor and by using a collector of such form that contact is always maintained, and by the use of guards or barriers that will confine the hot particles of metal that may be thrown off when an arc is formed.

2. Dust and flyings collecting on the insulating supports of the bare conductors may form a conducting path between the conductors or from one conductor to ground and permit enough current to flow to ignite the fibers. This condition is much more likely to exist if moisture is present. Operation on a system having no grounded conductor makes it somewhat less likely that a fire will be started by a current flowing to ground. A recording ground detector will show when the insulation resistance is being lowered by an accumulation of dust and flyings on the insulators, and a relay actuated by excessively low insulation resistance and arranged to trip a CB provides automatic disconnection of the bare conductors when the conditions become dangerous.

ARTICLE 504. INTRINSICALLY SAFE SYSTEMS

504.1. Scope. This NEC article covers design, layout, and installation of electrical equipment and systems that are not capable of releasing sufficient electrical or thermal energy to ignite flammable or combustible atmospheres.

504.2. Definitions. *Associated apparatus* is equipment that is not necessarily intrinsically safe, but that affects the energy levels in intrinsically safe circuits and that are therefore relied upon to maintain the intrinsic safety of those circuits. An example is an intrinsic safety barrier, such as the one shown schematically in Fig. 504-1, which limits the current and voltage in the protected circuit. This type of equipment must be listed (see 504.4). Note that the two diodes in this barrier both must fail in order for the system to lose its intrinsic safety. This is an example of a cardinal principle of these systems, that no single component failure regardless of the source of fault can introduce ignition-capable energy into an intrinsically safe circuit.

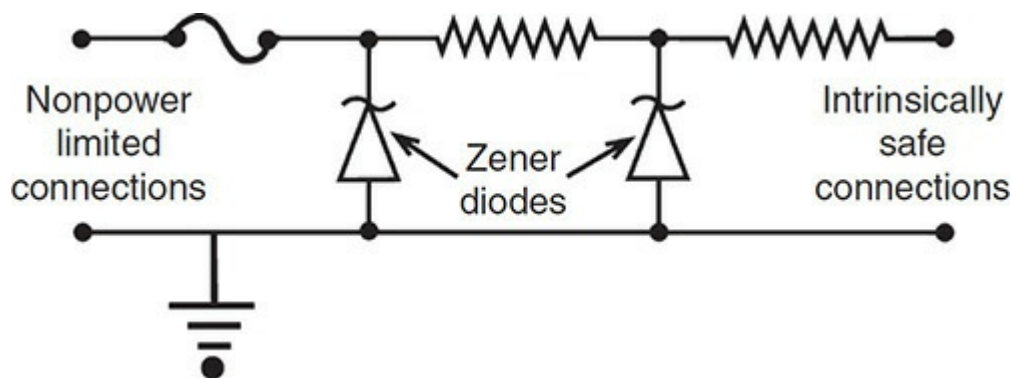

Fig. 504-1. Zener diodes have a very high resistance until their breakdown voltage is reached, at which point they begin to conduct with very little resistance. They are set a few volts higher than the circuit design voltage. When they conduct, the circuit voltage cannot go higher than that for which the manufacturer selected the diodes, and the resistor (sized by Ohm's law to pass only the designed magnitude of current at that breakdown voltage) keeps the current within limits as well. This will be true even on a large overvoltage condition, which is usually defined for test purposes as 250 V [designated "U" in 504.10(A) informational note No. 2, an international symbol for potential

difference]. There are two Zener diodes in these units so if one fails the protection is still available. This is only one of several approaches, but it is widely employed. If necessary to achieve an even higher level of redundancy, a third diode could be supplied so the unit will work as intended even after two internal faults.

A *control drawing* is defined in 500.2. It is produced by the manufacturer of the system or apparatus and it details the allowable interconnections between the intrinsically safe circuit components and any associated apparatus or other such components.

Simple apparatus is a component with well-defined electrical characteristics that has minimal impact on the energy levels of the system. The definition includes useful parameters that describe the scope of simple apparatus, and the informational note that follows it provides clear examples and guidance. This terminology creates a class of components that do not require listing if they are on the control drawing (see 504.4 Exception) and that can be used to customize an intrinsically safe installation properly and without the necessity of approaching the manufacturer for a revised control drawing.

504.10. Equipment Installation. The basic rule requires adherence to the terms of the control drawing, as identified on the apparatus. General-purpose enclosures are permitted unless otherwise specified in the documentation provided by the manufacturer of apparatus considered for installation within them, as covered in (C). Simple apparatus does not need to appear on the control drawing provided it is not used to interconnect two different intrinsically safe circuits. The energy level resulting from two such circuits in combination would require careful review.

Some associated apparatus is designed to work in the hazardous environment as part of the intrinsically safe circuit, in which case it can be in the classified environment in ordinary location enclosures. Other such apparatus must be in nonhazardous areas or otherwise protected by enclosures suitable for nonpower-limited exposures. The Zener barrier in Fig. 504-1 is a good example, because on its input side it will be connected to nonpower-limited circuits by definition. Simple apparatus as covered in (B), is permitted in the hazardous environment without restrictions provided, based on the power levels available to it, that it cannot overheat to the point of creating an ignition hazard.

This section concludes in part (D) with a formula and a table to assist making the assessment as to whether apparatus qualifies for connection to a given intrinsically safe system without a reevaluation of the system and the control drawing. The table is based on a T4 (135°C) classification because that is below the autoignition temperatures of almost all likely agents. One notable exception is carbon disulfide (CS₂) with an autoignition temperature of 90°C needing a T6 (85°C) classification; however, that is a very unusual chemical and the T4 threshold is a reasonable one. The process also addresses energy generating devices, particularly thermocouples. Care must be taken when adding multiple such items to a circuit, because there may quickly be sufficient cumulative effects to make the system no longer intrinsically safe. The bottom line, as reflected in the parent language of the subsection, is that the surface temperature of the simple apparatus must not exceed the ignition temperature of the hazardous agent(s).

504.30. Separation of Intrinsically Safe Conductors. This section is perhaps the most important for electricians because IS systems can use conventional wiring methods including Class 2 cabling per Art. 725 (see 504.20), but the separation rules are absolutely critical in maintaining the safety of these systems. Routing these circuits near power circuits can induce ignition capable energy into wiring that is entirely unprotected. Even running these circuits next to each other can have

unpredictable effects for the same reason. This section splits the separation rules accordingly.

Part (A) covers separation from nonintrinsically safe wiring, for which there are three possibilities which this analysis covers in the following order: separation between wiring methods (3), separation within wiring methods (1), and separation within enclosures (2). Note that these separation requirements are significantly more severe than even the requirements for Class 2 control circuits in 725.136.

Intrinsically safe wiring in the form of stand-alone wiring methods, including cables or raceways clipped to a building surface, has its own separation requirements. As covered in (A)(3), this wiring must run at least 50 mm (2 in.) from all other wiring that is not intrinsically safe, even limited-energy control circuits. This rule does not apply, however, if the intrinsically safe wiring is in Type MC or Type MI cable, and it does not apply if the nonintrinsically safe wiring is in a raceway, or in copper (not stainless steel) Type MI cable, or in one of the types of MC cable where the metal armor is a qualified equipment grounding conductor as provided in 250.118. This includes most instances of smooth or corrugated Type MC cable, and it also would include the new type of interlocking-armor Type MC cable with the full-sized aluminum bonding conductor run in direct contact with the cable armor.

Intrinsically safe wiring must also, in accordance with (A)(1), be excluded from any raceway, cable tray, or cable assembly containing nonintrinsically safe wiring. There are four exceptions to this general rule, two of which involve nonincendive wiring. This wiring operates under comparable power constraints as intrinsically safe wiring, but it lacks some of the safeguards with respect to maintaining its protective qualities under some fault conditions. Review the discussion at the end of 500.7 for more information. Because the power levels are comparable, the two types of systems are allowed to run together provided they meet the separation rules in part (B).

The other two exceptions address intrinsically safe wiring routed with nonintrinsically safe wiring of any description, including Class 2 control circuits that are not qualified as intrinsically safe. Exception No. 2 allows these systems to run together provided all of the conductors in at least one of the systems is in a metal-armored cable assembly that meets the equipment grounding qualifications in 250.118 as described above for systems run together in the open. Exception No. 1 covers primarily cable tray and some surface raceways and allows a common location if the intrinsically safe wiring is at least 50 mm (2 in.) away from other systems and secured in that location, such as by cable ties to the rungs of a ladder-type cable tray. The other option requires a physical barrier that compartmentalizes the cable tray or surface raceway; said barrier to be grounded, or approved if nonmetallic.

Part (A)(2) takes on the most challenging task, as in the case of Class 2 control work, of landing on common equipment or otherwise running in the same enclosure along with nonintrinsically safe wiring without compromising safety. The conductors must be tied down so that if one comes loose from a terminal it will be unlikely to come in contact with any other terminal. There is a list of four items at this point. Item (1) calls for the customary 50 mm (2 in.) spacing and items (2) and (3) call for barriers, either 20-gauge sheet metal or an approved insulating partition, which as of the 2014 NEC must extend to within 1/16 in. of the enclosure walls. In this context the third note at the end of the section suggests that the usual control panel wiring ducts are acceptable provided there is at least a 19 mm (3/4 in.) separation maintained between systems. Item (4) recognizes the same metal-armored cable assemblies recognized in (A)(3) and previously discussed.

Part (B) covers separation between different intrinsically safe circuits. These circuits must be

segregated through the use of a grounded metal shield, or through the use of 10 mil insulation unless another size is identified for this purpose. An additional basic requirement that applies to these connections generally states that clearances between terminations must not be less than 6 mm (¼ in.) unless the clearance is modified in the control drawing.

The 2014 **NEC** has added part (C), which sets a minimum spacing between the uninsulated portions of field wiring where it has been stripped and connected to a terminal, and “grounded metal or other conducting parts.” That distance must not be less than 1/8 in.

504.50. Grounding. The basic rule requires connection to the supply system equipment grounding conductor, but the note following reminds users that some control drawings specify an earth connection in addition to the equipment grounding conductor connection. This is particularly true with Zener diode barriers as shown in [Fig. 504-1](#), which often want their ground plane to have a local earth reference. Associated apparatus and cable shielding must be grounded as required in the control drawing. If an earth connection is specified, it must be made as close as possible to the system, and to the nearest building steel or water pipe as set forth in 250.30(A)(4). The next choice of electrode would be a concrete-encased electrode or ground ring, and only if none of those were available could another one on the 250.52 list, such as rod, pipe, or plate electrodes, or other underground metal structures be used.

504.60. Bonding. Intrinsically safe apparatus must be bonded within the hazardous location in accordance with the relevant section of the applicable hazardous location article. If the circuits are wired using metal raceways, then the metal raceways must be bonded in accordance with the same rules. Somehow, this latter requirement applies even in nonhazardous locations, which begs the question of what exactly would be the “applicable” hazardous location article in such cases. However, Sec. 30 of the usual articles and Sec. 25 of the zone articles read pretty much the same, disallowing locknut bonding and asking for bonding jumpers back to the applicable main or system bonding jumper.

504.70. Sealing. This is a major change effective with the 2008 **NEC**. This section has always said that where seals were otherwise required for conventional wiring, they would be required for intrinsically safe circuit wiring to minimize the passage of gas or vapor or dust. The next sentence went on to say that the seal did not need to be explosionproof, and ended at that. This was usually taken to mean sealing putty. Now, using the identical wording as in 501.15(B)(2) for Class I Division 2 boundary seals, the seal must be “identified for the purpose of minimizing the passage of gases permitted under normal operating conditions and shall be accessible.” As previously discussed in 501.15(B), there are no such seals on the market as of this writing, other than the usual explosionproof seal. If enforced as written, this means explosionproof seals.

This will have a major impact on wiring practice in many facilities, because it is customary to rewire these control circuits from time to time. Sealing putty stays flexible and can be removed easily. Explosionproof sealing compound cannot be removed; the entire fitting must be cut out of the pipe run. Then the conduits need to be rethreaded, which is at best inconvenient and time consuming, and at worst borders on the impossible and requires significant repiping. Take care to anticipate future needs as much as possible when wiring these systems the first time.

504.80. Identification. Intrinsically safe wiring must be prominently and permanently identified as such throughout the premises wiring systems wherever it is run. All terminals and junction points must be so identified. All wiring methods used, whether cable or raceway, for intrinsically safe wiring must be labeled as such in the field, at intervals not exceeding 7.5 m (25 ft) and at least once

between all partitions, and so arranged that the IS circuits can be easily traced throughout the facility. Underground circuits get identified where they come out of the ground and are accessible. If the color light blue is not in use for other purposes, it is allowed to be an intrinsic safety color code, valid for raceways and cable trays and boxes, in addition to individual conductors.

ARTICLE 505. ZONE 0, 1, AND 2 LOCATIONS

This Code article is intended as an alternate method for classifying Class I hazardous locations. Under the traditional **NEC** rules, hazardous (classified) locations are divided into divisions depending on how frequent the hazardous atmosphere or dusts are expected to be present. If the hazardous material is merely in secure storage, that storage area gets a less severe classification than an area where people routinely work with it. Under the traditional rules the former location is Division 2 and the latter is Division 1. This article is now designed as a stand-alone article. All requirements regarding seals and other provisions that at one time were incorporated by reference from Art. 501 have been duplicated here, so the article stands on its own with regard to technical requirements for the hazardous environment. Of course the [Chap. 3](#) rules on conduit support, etc., continue to apply.

The zone concept goes one step further and divides the traditional Division 1 locations into Zone 1 and Zone 0, the latter classification reserved for areas such as inside a vented tank where the hazardous agent exists on a routine basis. They then assign more stringent requirements to the Zone 0 locations. Areas like Division 2 in the traditional approach have a Zone 2 classification. Places throughout the world that use this approach consistently also tend to have a work environment that is much more intensively engineered and supervised than areas using the Class and Division system. Having made these distinctions, and thereby having excluded the worst case (Zone 0) from Zone 1, and generally operating in a context of more comprehensive engineering support, the **NEC** allows products into Zone 1 locations that traditional Code practices would exclude from Division 1, including nonexplosionproof lighting.

At the time this came into the **NEC** (1996) it was bitterly contested. Many thought it would rapidly supersede the Class and Division approach. This has not happened, in part because the economic benefits of this system chiefly involve a cost comparison between Division 1 and Zone 1, with the Zone system the clear winner. However, Division 1 applications have steadily declined in extent, in comparison with Division 2 that has expanded to the same degree. The reason, in large part, is environmental regulation. Where large facilities would once classify (justifiably so based on the chemical releases) huge spaces as Division 1, they now have redesigned the equipment so all those flammable organic compounds are tightly contained, and the Division 1 area now is an infinitesimal proportion of what was there before. They are doing this to save on the costs of chemicals (much of which are derived from oil), and because if they ever continued to release the enormous quantities of chemicals of yesteryear, the government would fine them out of business. Since there is really no difference between Division 2 and Zone 2, the economic reason to abandon the traditional system largely disappeared. There are some major industrial players using the zone system, but the traditional system continues to do well. Another factor is that Zone 0 does not permit power connections, only control wiring of extremely limited energy, but the Division system does permit power connections in those areas.

505.2. Definitions. As in the case of 500.2, most of the defined terms here are the protection techniques that can be applied, as covered elsewhere, to address the hazardous environment. A good example is “Increased Safety ‘e’” This is the technique frequently employed with luminaires in which they meet a standard of performance appropriate to Zone 1, and quite inappropriate to Division 1, which includes environments where the flammable agents are present on a routine basis.

505.5. Classification of Locations. This is where the differences between Zone 0, 1, and 2 are formally sorted out. Because the amount of time that a flammable agent is present has a major bearing on whether a location is Zone 0 or 1, there has been extensive discussion on this point in other publications. The current informal consensus on a rule of thumb is that if the hazardous gas or vapor is present for more than 1000 h per year (just over 10 percent of the time), it is Zone 0; and Zone 1 applies from there down to 10 h per year, with Zone 2 any time less than 10 h per year.

505.6. Material Groups. Article 505 uses different designations and groupings for the various hazardous gases than does Art. 500. 505.6 gives the group designation and spells out which gases are included in that group.

The familiar method given in Art. 500 has four gas groups, A, B, C, and D. But there are only three designations for gas groups in Art. 505: IIC, IIB, and IIA. Basically stated, Art. 500 groups can be equated to Art. 505 groups as follows:

Art. 500	Art. 505
Groups A and B	IIC
Group C	IIB
Group D	IIA

505.7. Special Precaution. This section covers three very different topics. Part (A) covers the implementation of the Zone system, and requires qualified persons to do the work, including the installation and field inspections involved. The former requirement for a licensed professional engineer was not continued in the 2008 **NEC**.

Part (B) covers dual classifications. In general the Zone system cannot be used on an opportunistic basis, with the zone concept applied to one machine as convenient, and the class and division method to an adjacent wet-well. [Fig. 505-1](#) shows the principles at work. The two systems cannot ever overlap, and only Zone 2 may abut, but only Division 2 and never Division 1. As shown in [Fig. 505-2](#), part (C) covers reclassifications, which are permitted, provided all of any given space classified because of a given gas or vapor becomes reclassified as part of this process.

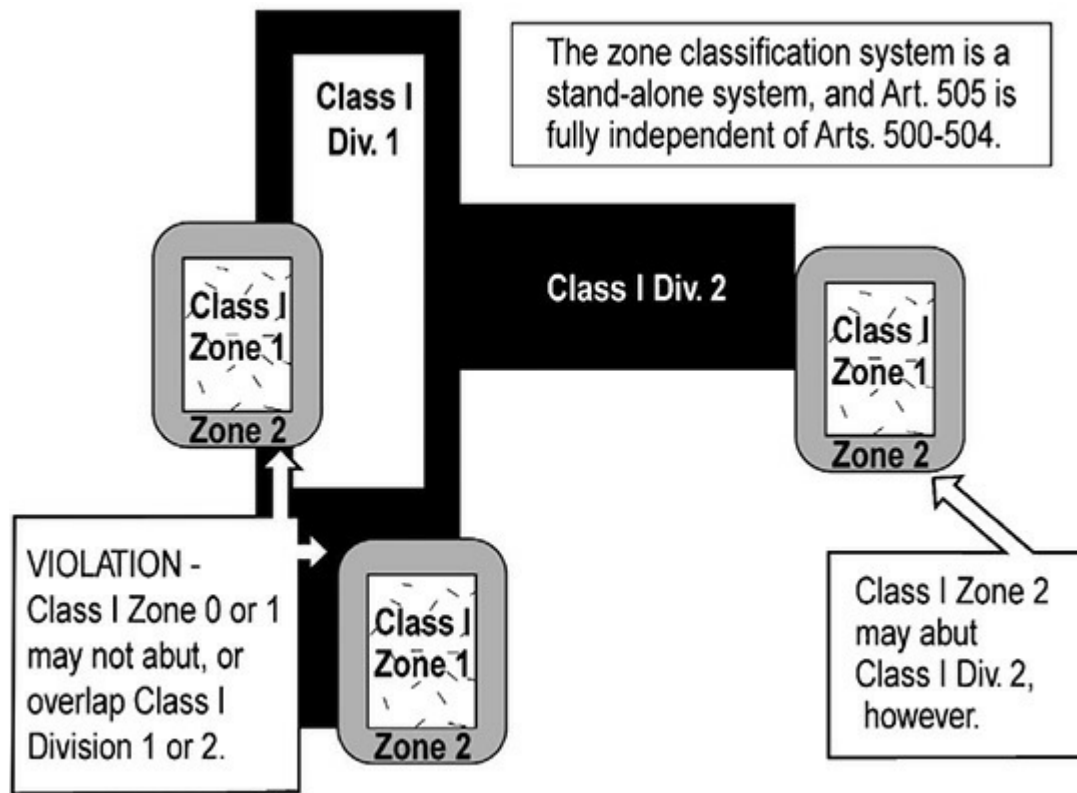

Fig. 505-1. The Zone classification system is not a mix and match option with an existing class and division system. [Sec. 505.7(B).]

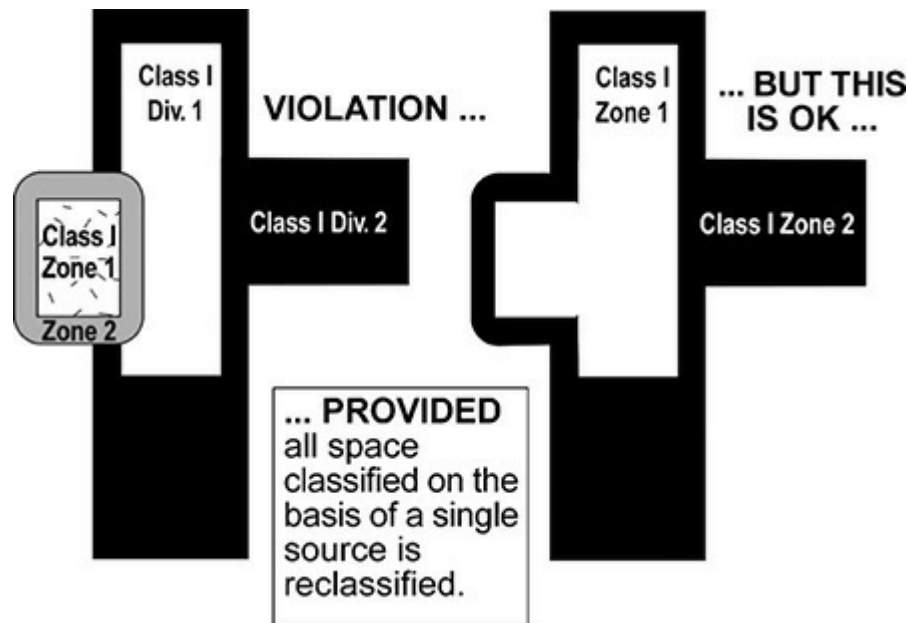

Fig. 505-2. An existing facility can be reclassified under the Zone system. [Sec. 505.7(C).]

Part (D) covers a rule that has no counterpart in the class and division coverage in the **NEC**. As shown in [Fig. 505-3](#), flameproof equipment (the zone counterpart to explosionproof) has a minimum spacing between the flange openings and adjacent solid obstacles not a part of the wire equipment, including steel columns and strut, adjacent walls, etc. The **NEC** spacing applies unless the equipment is listed for a different interval.

Fig. 505-3. Flameproof enclosures must observe clearance limits between the flanged joints and adjacent obstructions. [Sec. 505.7(D).]

Part (E) covers the simultaneous presence of both dust and gas or vapor. Both factors must enter the selection process for equipment and choice of wiring method. The operating temperature is very important because it is often lower for dusts (or fibers) than it is for gases and vapors.

Part (F), new in the 2014 NEC, requires that where the commonly employed “increased safety” (“e”) is being used as the protection technique, the short-circuit current available for field-wiring connections in Zone 1 locations must not exceed 10,000 A (RMS symmetrical). This limit correlates with the default limit given in UL 508A that would come into play when constructing an industrial control panel. Current limiting fuses and circuit breakers are available that are capable of significantly reducing the let-through currents to downstream connection points. The 2017 NEC adds recognition of equipment listed and marked for higher available fault current.

505.9. Equipment. As is the case with the division classification system given in Art. 500, the zone classification system permits the use of equipment suited for a more hazardous location within a lesser hazardous location. Any equipment listed for Zone 0 may be used in Zone 1 or 2 locations provided the equipment is listed for the same gas group. And any equipment listed for Zone 1 may be used in Zone 2 locations of the same gas group.

Part (C)(2) covers the extensive marking designations for zone-classified equipment in a series of five informational notes and a protection designation table. This material includes the area classification, the American standard designation (AEx), the protection technique, the gas or vapor classification involved from 505.6, and the temperature classification from (D) below. Since some associated apparatus to intrinsically safe systems is only appropriate where applied outside the hazardous area, but still requires a rating, it is shown in brackets, with an example that coordinates with the table. Some equipment includes a barrier that allows it to connect to Zone 0 located

equipment but be installed in a lower-hazard Zone 1 environment; the marking in this case would be 0/1 with the slash mark indicating the barrier. Note 4 explains “equipment protection level” (or “EPL”) markings. These are somewhat confusing, since no **NEC** rule takes note of them. However, the note does allow users to sort out the required **NEC** markings from these performance notations.

Table 505.9(D)(1) in the Code gives the temperatures that correspond to the “T” designation assigned to a piece of equipment. Note that because of a new 505.9(C)(2) Exception No. 3, as of the 2014 **NEC**, cable termination fittings do not require a marked operating temperature or temperature class. The major difference between this table and Table 500.8(C), which applies to the division system of classification, is the number of designations. The table for the zone system has only six different temperature ratings: T1 through T6, which range from 85°C (185°F) to 450°C (778°F). The division system temperature table has 14, which also range from 85°C (185°F) to 450°C (778°F), but with eight other intermediate values between T1 and T6.

505.15. Wiring Methods. This section identifies those wiring methods that may be used in the different zones. As covered in part (A), for Zone 0, only intrinsically safe circuits may be installed in Zone 0 locations. The intrinsically safe circuits are as covered in Art. 504, and since the wiring is intrinsically safe, no specification as to wiring method need be made here.

Additionally, fiber-optic cable of the nonconductive type, which, as defined in 770.2, contains no metallic components, may be installed in Zone 0 locations. This system excludes any other equipment or wiring from being installed within the Zone 0 classified area, including power circuits of any type. Only the Class and Division system accommodates power wiring in these environments, as part of Division 1.

The rule of part (B) indicates the acceptable wiring methods for Zone 1 locations. Intrinsically safe wiring would be permitted for obvious reasons. Also, any of those wiring methods permitted in Class I, Division 1 locations—501.10(A)—would also be suitable for use within a Zone 1 location.

The 2014 **NEC** has added Type TC-ER-HL cable to the list, but with a physical size restriction to cable diameters of 1 in. or less, and including the limitations of 336.10(7) which presumably focus on the mechanical protections envisioned in that article. This wiring method is permitted in 501.10(A), but with interesting modifications. Under the class and division system it appears without a physical size restriction and without the express reference to 336.10(7). However, it is not included for general wiring; it is only included in 501.10(A)(2) as a permitted wiring method for use at flexible connections. The zone system, having included this as general wiring, only mentions flexible cord and the usual flexible fittings for both Division 1 and Zone 1 in its version of these requirements, at 505.15(B)(2).

Part (C) covers Zone 2 wiring. In this case the rules correlate with 501.10(B) for Division 2 almost exactly. The zone rule for MV cable includes an additional requirement for shielding or armor.

It should be noted that all sealing requirements spelled out in **505.16** must be satisfied where the zone system of classification is applied. Those requirements line up almost exactly with the rules in Art. 501 but not in all cases. [Figure 505-4](#) shows one interesting difference where an increased safety enclosure in a Zone 1 application gets a seal not because it is an ignition source, but because an ignition elsewhere must be arrested before it reaches that enclosure. Part of that consideration is what type of threads is used between the seal and the enclosure. The waiver from the 50 mm (2 in.) spacing limit is conditioned on only NPT male to NPT female, fully tapered joints on both sides. A typical conduit connection of NPT threads on the pipe to the typical straight threads in a coupling does not

comply with the exception and reverts to the 50 mm (2 in.) limit. The reason for this limitation is that some increased safety equipment is very fussy about environmental contaminants getting into it, and it is believed a plumbing style limit on threaded joints is preferable.

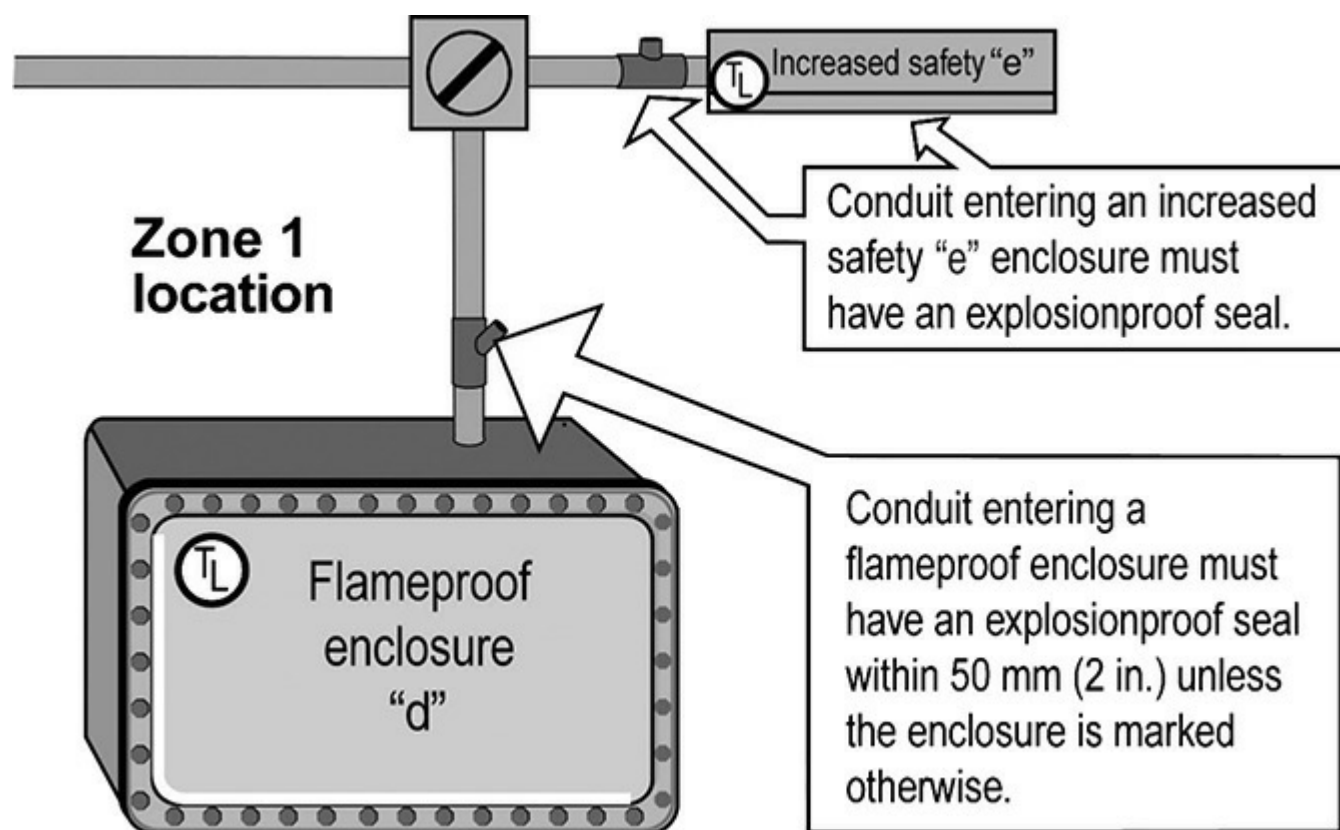

Fig. 505-4. The seal at the flameproof enclosure completes the enclosure and must be within 50 mm (2 in.). The seal at the increased safety enclosure is only to protect that enclosure from the conduit system, and if only conventional, tapered-thread, heavy-wall conduit joints intervene, with both male and female threads tapered, need not be within 50 mm (2 in.). [505.16(B)(1).]

505.17. Flexible Cables, Cords and Connections. This section lines up well with 501.140, combining both parts (A) and (B) in one grouping. As of the 2014 **NEC** it now contains a second part (B) that imports the content of 501.105(B)(6) for process instrumentation connections and makes it applicable to Zone 2 locations.

505.20. Equipment Requirements. The equipment permitted within any of the hazardous locations classified according to the zone system described in Art. 505 must comply with 505.20.

As required by 505.20(A), in Zone 0 locations, equipment specifically *listed* for use in Zone 0 locations, may be used. Equipment listed as intrinsically safe in accordance with Art. 504 with the evaluation having been done with respect to the same gas and suitable temperature class is permitted.

According to the basic rule in 505.20(B), any equipment that is listed for use in Zone 1 locations, or, as covered in the exception, any equipment approved for use in Division 1 or Zone 0 locations within the same gas group and with "suitable temperature class" may be used. Notice that the temperature marking does not have to correspond directly to the maximum permitted. It simply must be "suitable." This wording recognizes that the temperature designations in 500.8(C) are more finely graduated than those in 505.9(D)(1) and therefore there will not be 1:1 correspondence between markings.

Part (D) is new in the 2014 NEC although the concept is not. In addition to the normal hierarchy of groups, with IIC being more severe than IIB, which is in turn more severe than IIA, the rule allows for a specific mention of an outlying gas. The classic example, used in the informational note following, is hydrogen, which is a IIC gas. This is a IIC environment, and the IIC category includes extremely hazardous gases including acetylene for which there is very little to choose from in terms of equipment. On the other hand, due to the increased prevalence of hydrogen in connection with fuel cells, batteries, and other applications, there is a definite market for IIB equipment that although part of the next level down, it has been additionally adapted and tested to the specific demands of a hydrogen environment. This evaluation process allows for this, and thus, "IIB +H₂." Be careful: the underlying hierarchy does not necessarily correspond to the traditional system; there are many examples of Class I equipment that will not comply with Class II requirements, for example.

505.22. Increased Safety "e" Motors and Generators. This section covers the connections to motors in Zone 1 locations. The provisions here make a number of modifications of allowances permitted in Art. 430 (Fig. 505-5).

Fig. 505-5. Increased safety motors require disallowance of some permissions normally granted in motor circuits. (Sec. 505.22.)

505.26. Process Sealing. This repeats the new comprehensive treatment of this subject in 501.17. It must be repeated here because Art. 505 is a stand-alone article. Refer to the discussion at 501.17 for complete information on this topic.

ARTICLE 506. ZONE 20, 21, 22 LOCATIONS FOR COMBUSTIBLE DUSTS

OR IGNITIBLE FIBERS/FLYINGS

506.1. Scope. This article extends the zone classification system to traditional Art. 502 coverage locations, with Art. 503 locations tagged on. The requirements line up with Art. 502 in a logical way, except that here again the Division 1 areas are divided into a zone (Zone 20) where the combustible agent is continuous for long periods, and a zone where the threat is routine (Zone 21) but not continuous. And as in Zone 0, the only wiring permitted in Zone 20 is intrinsically safe wiring, essentially for instrumentation. Zone 22 rounds out the area classifications, and lines up with Division 2. This article is in very limited usage in areas subject to **NEC** jurisdiction, if at all, and is at present primarily an academic exercise.

The 2014 **NEC** has added crucial information to round out the coverage of this article in a new Sec. 506.6. This presents the major material groupings for dusts, which agree with those in Arts. 502 and 503, but in a different order. Combustible metal dusts come first, in 506.6(A) as Group IIIC, and correspond to Group E in the traditional system. The next grouping includes both Group G dusts, such as flour, and Group F dusts (carbonaceous dusts that present an explosion hazard) in 506.6(B) as Group IIIB. The last is 506.6(C), which covers solid particles larger than the new cut point of 500 μm for dust. This category, Group IIIA, corresponds to Class III in the traditional system. Note that 506.20(D) is comparable to 505.20(D) and creates a hierarchy not replicated in the traditional system. In this article, IIIC equipment can be used for IIIB or IIIA exposures, and IIIB equipment can be used for IIIA exposures. Be careful not to generalize this to Class II applications under Art. 502.

ARTICLE 510. HAZARDOUS (CLASSIFIED) LOCATIONS—SPECIFIC

This unusual two-section article sets the organizational context for the six articles that follow, which all cover areas and occupancies that may contain hazardous atmospheric quantities of flammable gases or vapors. These articles provide prescriptive area classification requirements and related provisions in the specified occupancies; the procedures for actually wiring those occupancies to address the hazardous (classified) areas as described are included in Arts. 500 through 504, with [Chaps. 1 through 4](#) as the default requirements as always. Note that Arts. 513, 515, and 516 have been harmonized with the zone system, and the reference to the earlier articles may need to be updated to include Arts. 505 and 506. The article concludes with the recognition that the AHJ may need to referee the application of some rules under unusual conditions in the specified occupancies.

ARTICLE 511. COMMERCIAL GARAGES, REPAIR AND STORAGE

511.1. Scope. This article covers occupancies engaged in service and repair operations for self-propelled vehicles fueled by flammable liquids or gases. Note that motorboats are self-propelled vehicles meeting this description, and 555.22 requires the service and repair facilities for such motor craft comply with this article.

511.2 Definitions. This article relies on extracted material from **NFPA 30A** for many of its requirements. Because that other standard organizes its requirements in this area around the distinction between a major and a minor repair garage, it made sense to extract those definitions and then organize the area classifications in the same way. One of the key distinctions between the two

definitions is whether or not vehicle fuel tanks would be removed as part of anticipated repair operations, and that provides a useful and quick point of reference to decide which is which. The minor repair operations, typified by the quick-lube facilities, will not be doing that kind of work.

NFPA 30A includes a variety of important rules that are not within the scope of the **NEC**. For example, operations involving open flame or electric arcs, including fusion, gas, and electric welding, should be restricted to areas specifically provided for such purposes. Approved suspended unit heaters may be used, provided they are located not less than 8 ft (2.5 m) above the floor and are installed in accordance with the conditions of their approval.

The question often arises, “Does diesel fuel come within the classification of volatile flammable liquids, thereby requiring application of Art. 511 to places used exclusively for repair of diesel-powered vehicles?” 514.3(A) reads: “Where the authority having jurisdiction can satisfactorily determine that flammable liquids having a flash point below 38°C (100°F), such as gasoline, will not be handled, such location shall not be required to be classified.”

The **NFPA** Inspection Manual, under identification of flammable liquids, says, “Minimum flash points for fuel oils of various grades are: No. 1 and No. 2, 100°F; No. 4, 110; No. 5, over 130; No. 6, 150 or higher. Actual flash points are commonly higher and are required to be higher by some state laws. No. 1 fuel is often sold as kerosene, range oil or coal oil.”

Diesel fuel is a Class III flammable liquid, having flash points above 70°F (21°C). One listing of flash points of flammable liquids showed no diesel fuel below 120°F (49°C). Therefore, a diesel fuel installation may be classified as a nonhazardous area and wired as such, unless it can be firmly established that the particular fuel has a flash point under 100°F (38°C). But, of course, the authority enforcing the Code is the one responsible for classifying such areas as nonhazardous.

511.3. Classification of Locations. In part (A) the **NEC** clearly establishes that parking garages used for parking or storage need not be classified. And in part (B) the **NEC** brings Art. 514 into the picture in addition to Art. 511 when fuel dispensing takes place in a service bay. The remainder of the section is a very easily applied set of two tables that implement a three-part decision tree that, as text prior to the 2017 **NEC**, specifies the applicable area classifications. There are three questions to consider about any Art. 511 location: (1) Is it a major or minor repair garage; (2) Is it part of the floor, or the ceiling, or a pit in the floor; and (3) is it ventilated or not in terms of minimum **NEC** requirements. [Figure 511-1](#) has the entire section diagrammed in an easy-to-apply chart.

511.3 Classification of Locations.

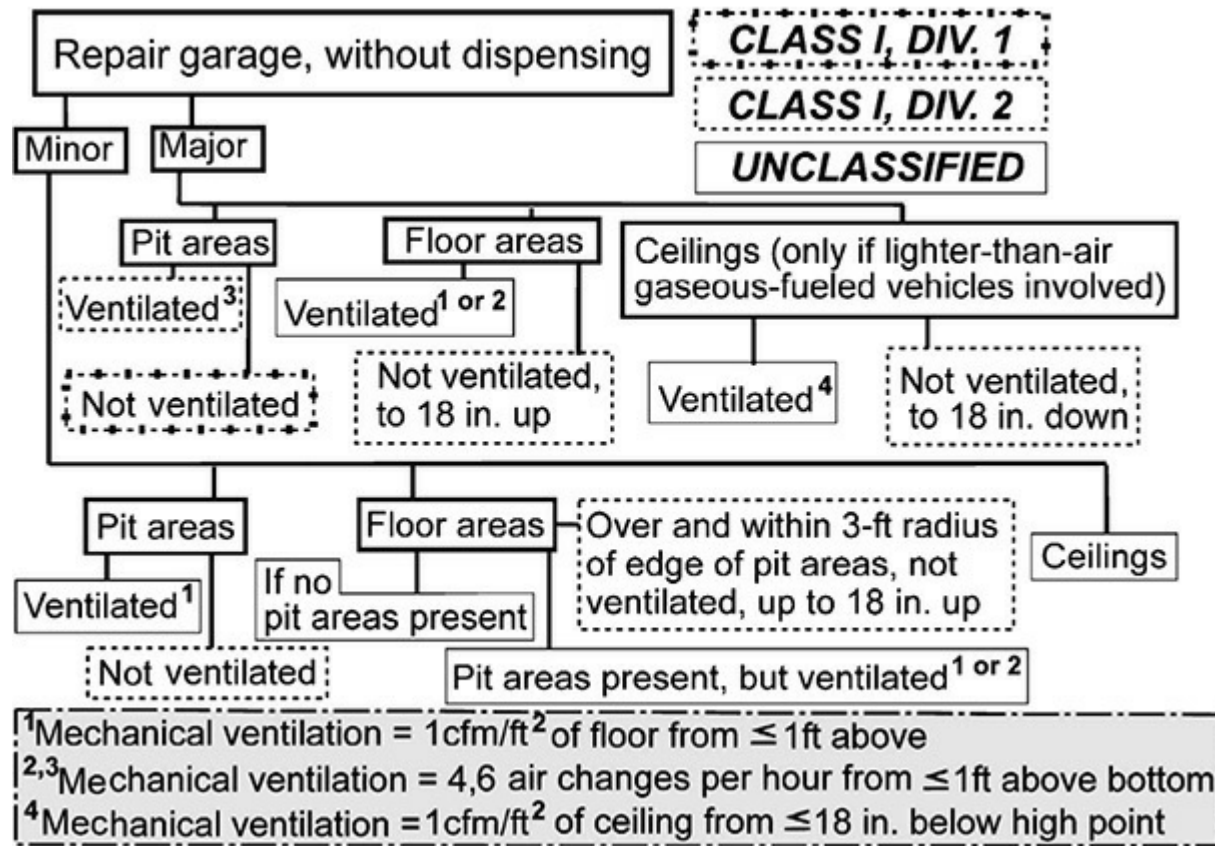

Fig. 511-1. Area classifications now follow a table, which implements the three-fork decision tree previously used here. Fig. 511-1 is a graphic representation of the same requirements. (Sec. 511.3.)

Note that the areas below grade or in the floor slab that are below classified areas are not classified, and therefore an unbroken conduit running straight through the 450 mm (18-in.) zone and into the slab need not be sealed, either at its entry point or at its point of emergence if the conduit there is also unbroken. At the end of the section there are answers to two potential modifications to the area classifications. The first is that alcohol-based windshield washer fluid does not by itself generate an area classification. The second is that adjacent areas that are positively pressurized or independently ventilated or cut off by building construction do not need to be classified. This is covered in Fig. 511-2.

Fig. 511-2. Hazardous areas must be carefully established. (Sec. 511.3.)

511.4 Wiring and Equipment in Class I Locations. Note (B)(2) of this section, which requires that if a luminaire on a cord reel can reach into Class I locations (usually 450 mm (18 in.) above the floor), the luminaire must be identified as suitable for Class I Division 1 exposures.

511.7. Wiring and Equipment Installed Above Class I Locations. The rules here apply to the lubritorium areas in service stations and *any* other space above the defined hazardous locations. Part (A) is the list of acceptable wiring methods.

Part (B) notes that equipment that may produce arcs or sparks and is within 12 ft (3.7 m) of the floor above hazardous areas must be enclosed or provided with guards to prevent hot particles from falling into the hazardous area, but lamps, lampholders, and receptacles are excluded. Standard receptacles are okay. Luminaires that are within 12 ft (3.7 m) of the floor over hazardous areas, over traffic lanes, or otherwise exposed to physical damage, must be totally enclosed, as required in part (B).

511.8 Underground Wiring. This section brings over from Art. 514 the wiring method rules for underground wiring, including the allowance for nonmetallic raceways except over the last 2 feet that has to be steel, arranged with equipment grounding return continuity. It does not bring over the area classification rules. It does not, therefore, classify the underground area and require seals at a point of emergence, unless of course, it runs from a classified area within the service area and therefore would require a boundary seal.

511.10. Special Equipment. In part (B), the requirements for battery-charging cables and connectors are similar to the requirements for outlets for the connection of portable appliances, except that when hanging free the battery-charging cables and connectors may hang within 6 in. (150 mm) from the floor. The common form is a plug that is inserted into a receptacle on the vehicle, and,

because the prongs are “alive,” they must be covered by a protecting hood.

511.12. Ground-Fault Circuit-Interrupter Protection for Personnel. This rule is shown in Fig. 511-3.

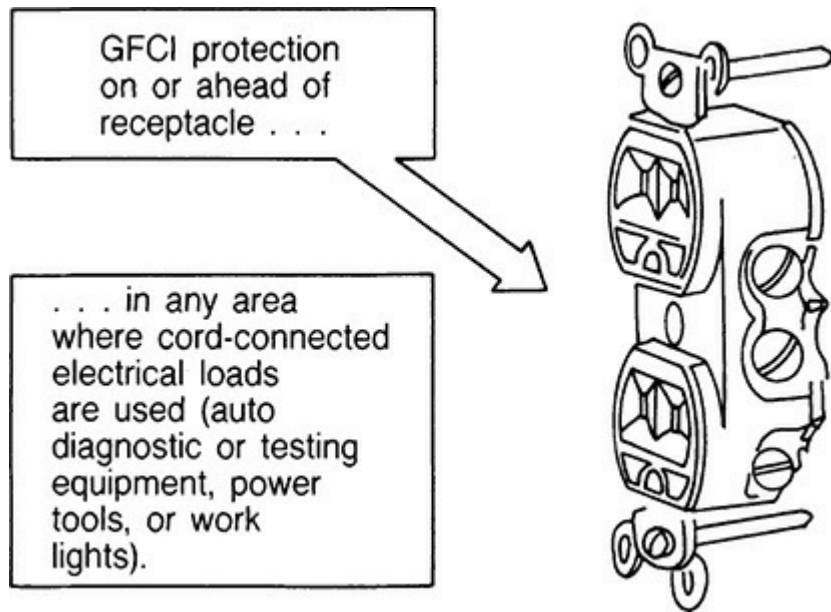

Fig. 511-3. GFCI protection is required for all 125-V, single-phase, 15- and 20-A receptacles where electrical auto-testing equipment, electrical hand tools, and portable lighting are used. (Sec. 511.10.)

ARTICLE 513. AIRCRAFT HANGARS

513.3. Classification of Locations. Figure 513-1 shows the details of hangar classifications. The entire floor area up to 18 in. (450 mm) above the floor, and adjacent areas not suitably cut off from the hazardous area or not elevated at least 18 in. (450 mm) above it, are classified as Class I, Division 2 locations. Pits below the hangar floor are classified as Class I, Division 1. Within 5 ft (1.5 m) horizontally from aircraft power plants, fuel tanks, or structures containing fuel, the Class I, Division 2 location extends to a level that is 5 ft (1.5 m) above the upper surface of wings and engine enclosures.

Fig. 513-1. Boundaries of hazardous areas are clearly defined. (Sec. 513.3.)

There is a new part of this section as of the 2008 **NEC** to address the needs of hangars where aircraft will be painted. Note that the classified envelope in for these hangars is much larger than the conventional hangar, because the dimensions are both larger and they apply to the entire plane and not just the outer margin of the engines, and in addition there is a very large part of the overall envelope that is Class I Division 1. In effect, this area classification melds the traditional aircraft rule with the open paint spray area rules in Art. 516, and this makes sense because that is exactly what these hangars are.

513.7. Wiring and Equipment Not Installed in Class I Locations. Luminaires and other equipment that produce arcs or sparks may not be general-use types but are required to be totally enclosed or constructed to prevent escape of sparks or hot metal particles if less than 10 ft (3.0 m) above aircraft wings and engine enclosures, as indicated in [Fig. 513-1](#).

513.8 Underground Wiring. This section is different for the comparable ones in these articles in that a raceway running below a classified location is considered to be in that location, and therefore seals would be required upon emergence in an unclassified area.

ARTICLE 514. MOTOR FUEL DISPENSING FACILITIES

514.2. Definition. As noted under 511.2, there is a question about application of the rules of Arts. 511 and 514 to areas used for service of vehicles using diesel fuel and to dispensing pumps and areas for diesel fuel. Fuel with a flash point above 100°F (38°C) may be ruled to be *not* “a volatile flammable liquid,” to which the regulations of Arts. 511 and 514 are addressed.

Note that vehicle repair rooms or areas and lubritoriums at gas stations must comply with Art. 511.

514.3. Classification of Locations. As noted, Table 514.3(B)(1) delineates and classifies the various areas at dispensing pumps and service stations. This table, which now includes zone classifications, brings the Code rules into agreement with data given in **NFPA 30A**, *Code for Motor Fuel Dispensing Facilities and Repair Garages*.

Figure 514-3 gives a visual representation of the dimensions of Class I locations, both Division 1 and Division 2, as described in the text of Table 514.3. In the wording of Table 514.3, the space within the dispensing-pump enclosure is a Class I, Division 1 location as described in ANSI/UL 87, “Power Operated Dispensing Devices for Petroleum Products.”

Around the outside of a dispenser pump housing, the Division 2 location extends 18 in. (450 mm) horizontally in all directions, from grade up to the height of the pump enclosure or up to the height of “that portion of the dispenser enclosure containing liquid-handling components” ([Fig. 514-1](#)).

Division 1 space is *within* the dispenser, within any pit or box *below* the dispenser, and within the ground below the Class I, Division 2 location.

Fig. 514-1. The shaded space around the outside of the pump enclosures is a Class I, Division 2 hazardous location. (Sec. 514.3.) The island structure and the ground beneath it is no longer classified, but the “entire space within and under dispenser pit or containment” is Class I Division 1 [Table 514.3(B)(1)].

In the table, there is no direct statement that the ground under the Division 1 and Division 2 locations at a dispenser island is a Division 1 location. In fact, these areas are no longer classified because there isn't enough air to support combustion. The pits under the dispensers etc., are

classified, however, and the underground raceway still gets sealed at its point of emergence, as covered in 514.8.

Outdoor areas within 20 ft (6.0 m) of a pump are considered a Class I, Division 2 location and must be wired accordingly. Such a hazardous area extends 18 in. (450 mm) above grade. If a building with a below-grade basement is within this hazardous area, gasoline fumes could enter the building if there were any windows within the 18-in. high (450-mm high) classified space, thereby making the basement a Class I, Division 2 area. This condition could be eliminated by “suitably cutting off the building from the hazardous area” by installing an 18-in high (450-mm high) concrete curb between the service station and the residential property or enclosing the window openings up to that height.

Table 514.3(B)(1) sets a 20-ft diameter, 18-in. high (6.0-m diameter, 450-mm high), Division 2 area around each fill-pipe (this is the loose-fill dimension; the equivalent tight-fill connection is half of that) for the underground gasoline tanks at a gas station, as shown in Fig. 514-2.

Note: Below-grade electrical wiring under the hazardous areas shown is not considered to be in a hazardous (classified) area, but sealing rules still apply at emergence from grade.

Fig. 514-2. Class I, Division 2 area extends around pumps and tank fill-pipes. (Sec. 514.3.)

As previously noted, any wiring or equipment that is installed beneath any part of a Class I, Division 1 or Division 2 location is no longer classified as being within a Class I, Division 1 location to the point where the wiring method is brought up out of the ground. However, there is still a sealing requirement that will apply in such cases, including if the conduit emerges under the panelboard, or even runs up to a lighting standard or a sign, as covered in Sec. 514.9.

As covered in Table 514.3(B)(1), under “Dispensing Device, Overhead Type,” where the dispensing unit and/or its hose and nozzle are suspended from overhead, the space within the dispenser enclosure and “all electrical equipment integral with the dispensing hose or nozzle” are classified as Class I, Division 1 areas. The space extending 18 in. (450 mm) horizontally in all directions from the enclosure and extending down to grade level is classified as a Class I, Division 2 area. The horizontal area, for 18 in. (450 mm) above grade and extending 20 ft (6.0 m) measured from those points vertically below the outer edges of an overhead dispenser enclosure, is also classified as a Class I, Division 2 area. All equipment integral with an overhead dispensing hose or nozzle must be suitable for a Class I, Division 1 hazardous area.

Table 514.3(B)(1) notes that the hazardous space around any vent pipe for an underground tank at a gas station is simply a 3-ft radius (900-mm radius) *sphere* (a ball-like volume; Class I, Division 1) and a 5-ft radius (1.5-m radius) *sphere* (Class I, Division 2) around the top opening of a pipe that discharges upward. The space beyond the 5-ft (1.5-m) radius from tank vents that discharge upward and spaces beyond unpierced walls and areas below grade that lie beneath tank vents are not classified as hazardous. Although the area classifications are unchanged, note that the 2014 **NEC** has added a new drawing, [Fig. 514-3\(B\)](#), to illustrate the classification rules regarding aboveground fuel storage tanks and their dispensers.

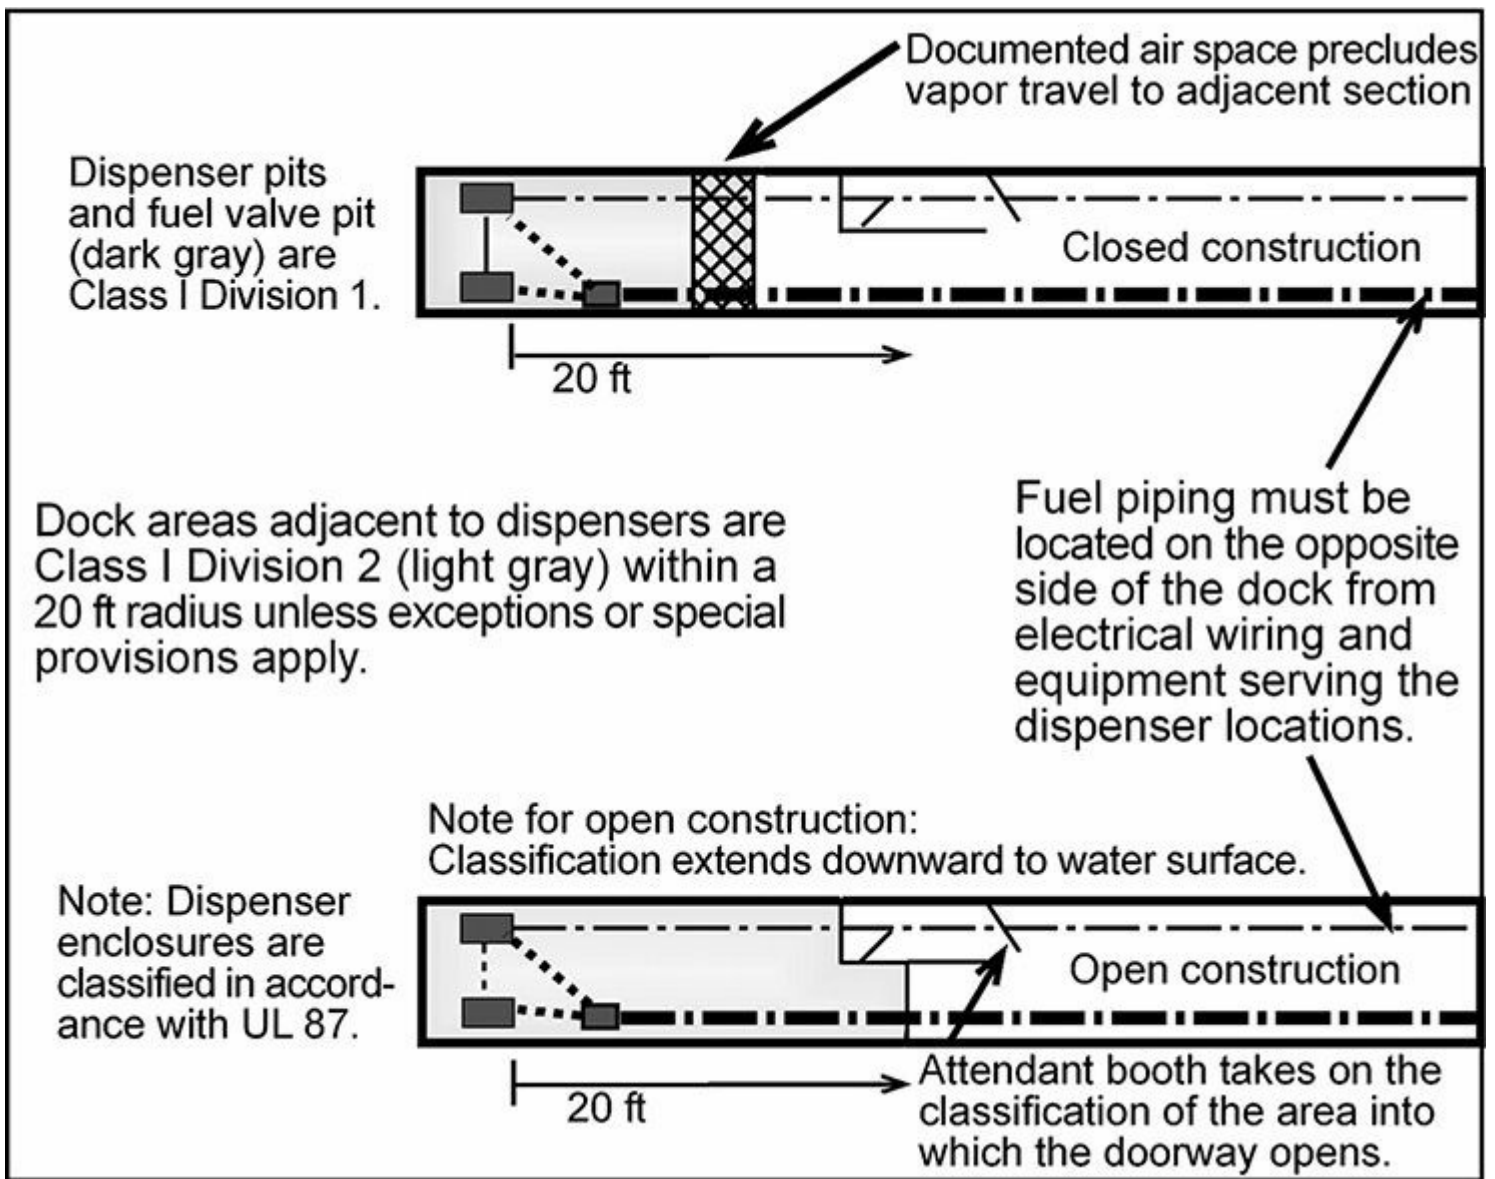

Fig. 514-3. Gasoline pumping areas at a marina must utilize Class I wiring and equipment within the specific classified boundaries. (Sec. 514.3.)

Table 514-3(B)(1) designates a pit or depression below grade in a lubritorium as a Class I, Division 2 location if it is within an unventilated space, but does allow for the possibility of classification as unclassified, for a pit in a repair garage where ventilation exists according to the defined parameters. Refer to Sec. 511.3(C) and (D) on classification of this type of facility.

Sec. 514.3(B)(2) classifies dispensing operations for gaseous fuels. If a dispenser for lighter-than-air fuel is under a canopy, it must be designed to not entrap the gas, or else accept Division 2 classification. LPG operations are similar to gasoline dispensing, but such dispensers must be at least 1.5 m (5 ft) or 3.0 m (10 ft) away, depending on equipment design constraints in 514.3(B)(2). Natural gas classifications only focus on the dispenser.

The 2017 **NEC**, in 514.3(B)(3), added significant new rules for aboveground fuel storage tanks containing gaseous fuels, specifically CNG or LNG, hydrogen, or LP-gas. The first three limit the proximity of those tanks to any property line that “is or can be built upon, any public way, and the nearest important building on the same property.” The specific dimensions are not given, but informational notes cite specific references within the applicable NFPA standards. The fourth rule creates separations (20 ft) between storage tanks containing fuels of different chemical composition,

and also from dispensers using different fuels. An exception waives the separations mandated by the fourth rule if both the gaseous fuel storage and dispensers are at least 50 ft from all aboveground motor fuel storage and dispensing. The fifth and sixth rules needlessly duplicate the rules previously described in 514.3(B)(2) and need no further comment.

Parts (C), (D), and (E) represent the relocation in the 2014 **NEC** of all substantive content formerly within Secs. 555.21(A), (B)(1), and (B)(2) respectively to Art. 514, without substantive changes.

Figure 514-3 shows the rules that define the need for hazardous location wiring at a marina. A fuel-dispensing area at the end of the two piers consists of gasoline dispensers at the pier edge, with a shack for service personnel mid pier. A panel installed in the shack supplies lighting and receptacles in the shack, as well as power for the fuel dispensers. Electrical connections from the dispenser pumps tie into the panel. Each shack takes advantage of provisions that exclude it from classification; the one on top uses an engineered air gap that precludes vapor travel (Sec. 514.3(D) Ex. 2) and the one at the bottom only has openings outside the classified location (Table 514.3(B)(1), "Sales, Storage, Rest Rooms"). Note the differences between open construction and solid construction that extends down to or below the water line.

514.8. Underground Wiring. Note that Exception No. 2 of this rule, which normally requires heavy-wall threaded steel conduits, permits Type PVC and Type RTRC nonmetallic conduit for circuits buried at least 2 ft (600 mm) deep in the earth as shown at the bottom of Fig. 514-4. The 2017 **NEC** added Type HDPE conduit to the list under the same rules as for other nonmetallic conduit materials.

Fig. 514-4. Conduit from pump island must be sealed at panelboard location. (Sec. 514.9.)

Where these nonmetallic conduit types are buried at least 2 ft (600 mm) in the ground, as permitted for underground wiring at a gas station, a length of *threaded* rigid metal conduit or *threaded* IMC, at least 2 ft (600 mm) long, must be used at the end of the PVC or RTRC conduits where they turn up from the 2-ft (600-mm) burial depth. This clarifies that the entire length of these conduits must be down at least 2 ft (600 mm). See [Fig. 514-5](#).

Fig. 514-5. The Type PVC or RTRC conduit permitted in the underground Class I, Division 2 location must never come above the required 2-ft burial depth. (Sec. 514.8.)

The phrase in this rule also requires the 2-ft (600-mm) length of metal conduit to be used on the end of the nonmetallic conduit where the conduit run does *not* turn up, but passes horizontally into the nonhazardous area of a basement. In that case or where the conduit turns up, a length of metal conduit is needed to provide for installation of a seal-off fitting because the conduit is, in effect, emerging from a Class I, Division 1 location below ground, even if we can't describe it that way officially; and a seal is required at the crossing of the boundary between the classified location and the nonhazardous location in, say, the office or other general area of a gas station.

514.9. Sealing. Every conduit connecting to a dispenser pump must have a seal in it, as shown in [Fig. 514-6](#). Conduits connecting to gas pumps are commonly connected through an explosionproof junction box that is set in the pump island, as shown in [Fig. 514-7](#). This box is approved as raintight and provided with integral sealing wells. All the conduits connecting to the box are sealed without need for separate individual sealing fittings. Additional individual seals are required where the conduits enter the pump cavity as shown. And, of course, a seal must be used in each conduit that leaves the hazardous area—such as in the conduit that feeds each lighting standard, with no fitting or coupling between the seal in the base of each standard and the boundary at the 18-in. (450-mm) height where the circuit crosses into nonhazardous areas. And the conduit at bottom right, which extends back to the panelboard, must also be sealed where it comes up out of the earth at the panelboard location.

Fig. 514-6. Seal fitting must be used for every conduit at dispenser. (Sec. 514.9.)

Fig. 514-7. Seals are required in conduits to pumps and to lighting fixtures or signs at points marked S. (Sec. 514.9.)

The luminaires in Fig. 514-7 must satisfy 511.7(B) (by way of 514.7), which refers to “fixed lighting” that may be exposed to physical damage—such as impact by a vehicle. If the luminaires are not at least 12 ft (3.7 m) above the ground, they must be totally enclosed or constructed to prevent escape of sparks or hot metal.

In Fig. 514-4, four seals are shown. Normally, panelboards are located in a nonhazardous location so that a seal is shown where the conduit is emerging from underground, which is where Sec. 514.8

requires it to be.

514.11. Circuit Disconnects. When the electrical equipment of a pump is being serviced or repaired, it is very important that there be no hot wire or wires inside the pump. Because it is always possible that the polarity of the circuit wires may have been accidentally reversed at the panelboard, control switches or CBs must open all conductors, including the neutral.

To satisfy this Code rule, a special panel application is commonly used in gas stations. [Figure 514-8](#) shows how the hookup is accomplished using a gas-station-type panelboard, which has its bussing arranged to permit hookup of standard solid-neutral circuits in addition to the switch-neutral circuits required. Another way of supplying such switched-neutral circuits is with CB-type panelboards for which there are standard accessory breaker units, which have a trip element in the ungrounded conductor and only a switching mechanism in the other pole of the common-trip breaker, as shown. Either 2- or 3-pole units may be used for 2- or 3-wire circuits, rated 15, 20, or 30 A. Use of single-pole circuit breakers with handle ties would be a Code violation. No electrical connection is made to the panel busbar by the plug-in grip on the neutral breaker unit. A wire lead connects line side of neutral breaker to neutral block in panel, or two clamp terminals are used for neutral.

Fig. 514-8. “Gas-station” switches or CBs provide neutral disconnect. (Sec. 514.11.)

In addition, the **NEC** now has special rules to address self-service refueling stations. There must be “emergency shutoff devices or electrical disconnects” located as directed by the AHJ, which

probably in this case would be the fire chief, because the purpose of this rule is to enable a bystander or firefighter to disconnect a pump island in the event of a conflagration. This must be located no less than 6 m (20 ft) or no more than 30 m (100 ft) from the fuel-dispensing equipment they serve. More than one such control is permitted, but they must be interconnected so the effect will be to shut off all power to all dispensers, not just at the island in question. The control must be clearly identified and readily accessible, and for an unattended station, it must be resettable only in a manner approved by the AHJ. As a practical matter, the only way to kill all the power to a given pump island like this is presumably through multiple relays that can, in the control circuit logic, be prevented from resetting the circuit until additional steps are taken as specified by the AHJ, which must include manual intervention. Whatever control method is used, it must open all conductors to the pump island, including any grounded circuit conductors if any, together with all associated power, communications, data, and video circuits. If the facility is attended, then a control point must be readily accessible to the attendant. For unattended facilities, the controls must be readily accessible to patrons, and at least one additional control must be readily accessible to each group of dispensers on an island. Note that the term “attended” requires interpretation, but often means someone responsible is constantly watching, not simply looking up from a cash register now and then. Where so interpreted the term would therefore seem to apply to only a small minority of such stations.

514.13. Provisions for Maintenance and Service of Dispensing Equipment. This rule mandates a lockable disconnecting means for the dispensing unit(s) to allow for safe maintenance or repair of the dispensing equipment. This disconnect must open all sources of supply to the dispensing unit, “including feedback” which would include data and communications sources that are frequently involved with dispenser controls. And the required disconnect may be located remote from, and not within sight of, the dispensing equipment and be lockable in the OPEN or OFF position. Note that in today’s wiring layouts, frequently the motors are underground in enclosures set on or adjacent to the tanks, and the dispensers are for control and measurement only.

514.16. Grounding and Bonding. Because of the danger at gas stations, grounding is very important and the rule here calls for thorough grounding, “regardless of voltage.”

ARTICLE 515. BULK STORAGE PLANTS

515.2. Definition. A flammable liquid is said to become volatile when the ambient temperature is equal to, or greater than, its flash point. Typical flash points are gasoline, -45°F (-43°C); kerosene, 100°F (38°C); diesel oil, 100°F (38°C). Thus, the status of gasoline is definitely established as a volatile flammable liquid regardless of geographical location of the storage facility. Other liquids may change from one state to another depending on the relation of the ambient temperature to their respective flash points. (See Fire Hazard Properties of Flammable Liquids, Gases and Volatile Solids, **NFPA** No. 325M.)

515.3. Class I Locations. This section sets its rules in a table indicating the extent of Division 1 and Division 2 locations at various equipment locations. As with the table in 514.3, this table brings the Code rules into agreement with the relevant **NFPA** standard, in this case, **NFPA 30**, *Flammable and Combustible Liquids Code*. [Figure 515-1](#) shows rules from Table 515.3, covered under “Pumps, Bleeders, Withdrawal Fittings, Meters and Similar Devices, Indoors.”

Fig. 515-1. Space around indoor equipment is a Class I, Division 2 location if adequately ventilated; or a Class I, Division 1 location, if not. (Sec. 515.3.)

For outdoor use of the same kinds of equipment, the 5-ft (1.5-m) radius is reduced to 3 ft (900 mm), the 25-ft (7.5-m) radius is reduced to 10 ft (3.0 m), and the 3-ft high (900-mm high) level is reduced to 18 in. (450 mm). And where *transfer* of gasoline or similar liquid is done outdoors or in a ventilated indoor place, the space around the vent or fill opening becomes a Class I, Division 1 location for 3 ft (900 mm) in all directions from the opening and a Division 2 location out to 15 ft (4.5 m) from the opening.

The hazardous area around a volatile flammable liquid outdoor storage tank (“Tank-Aboveground” in Table 515.3) extends 10 ft (3.0 m) horizontally beyond the periphery of the tank (Fig. 515-2). Code designation is Class I, Division 2, and wiring installations within this range must conform to Code rules for this category. Space around the vent is a Division 1 location.

Fig. 515-2. Sec. 515.3.

515.8. Underground Wiring. This rule is somewhat similar to that of 514.8. However, Sec. 515.9 requires that wiring run below a defined Class I location be considered to be in a Class I Division 1 environment, with seals placed accordingly. Although the semantics are different, the practical result should be the same. Note that 515.8 requires the customary 600-mm (2-ft) heavy wall threaded conduit tail to the point of emergence, and because this will normally be on the other side of a classified location boundary, an accessible seal will also be required at this point.

ARTICLE 516. SPRAY APPLICATION, DIPPING, COATING, AND PRINTING PROCESSES USING FLAMMABLE OR COMBUSTIBLE MATERIALS

516.1. Scope. Note that this article applies to “locations” used for finishing processes—which means open spraying areas as well as enclosed or semienclosed “booths.”

The safety of life and property from fire or explosion in the spray application of flammable paints and finishes and combustible powders depends on the extent, arrangement, maintenance, and operation of the process.

An analysis of actual experience in industry demonstrates that the largest fire losses and greatest fire frequency have occurred where good practice standards were not observed.

This article consists largely of extracted text from two **NFPA** standards (No. 33 and 34). Because of exhaustive modernization within those standards, as of the 2014 **NEC** the front end of this article (Secs. 516.2 through 516.4) cover many different spray configurations and methods, with extensive both new and revised artwork. It is important to recognize that in this article the artwork is not just illustrative; in many cases it carries within it mandatory dimensional provisions. There is complete coverage in a separate subsection of zone classifications. Printing processes have been integrated as appropriate.

516.2. Definitions. The definitions largely carry over from the 2014 complete rewrite, including “Limited Finishing Workstation,” “Unenclosed Spray Area,” “Spray Area,” and “Spray Booth.” The 2017 **NEC** adds “Membrane Enclosure” and “Outdoor Spray Area.” The content of these definitions will be discussed as necessary in the context of the revisions to the actual classification and wiring rules.

516.4. Area Classification. This section, the only one in Part II, covers open containers, spray gun cleaners, solvent recovery units, etc. The **NEC** illustrates these rules in Figure 516-4.

516.5. Area Classifications. This section opens Part III with a discussion focused on melding the two classification systems and the setting the general application considerations for these areas. Two different types of hazardous conditions are present in a paint-spraying operation: the spray and its vapor, which create explosive mixtures in the air, and combustible mists, dusts, or deposits. Each must be treated separately.

In part (C), the interior of every spray booth (1) and some area spraying (3) are Class I or Class II, Division 1 locations depending on whether the atmosphere contains vapors or dusts. When spray operations are not contained within a booth, there is greatly reduced control of flammable atmosphere, and the area of hazard is increased considerably. This is shown in Fig. 516-1, which is a typical specific application of the concept shown in Code Fig. 516-5(D)(1). A Class I or Class II, Division 1 area exists at the actual spraying operation plus a Division 2 area extending 20 ft (6.0 m) horizontally in any direction from the actual spraying area and for 10 ft (3.0 m) up. Although only one corner of the room is used for spraying, the entire room area inside the 20-ft (6.0-m) line around the spraying is classified as Class I or Class II, Division 2 and must be wired accordingly. And the Division 2 area extends 10 ft (3.0 m) above the spray operation.

Fig. 516-1. Open spraying involves Division 1 and Division 2 locations, for Class I or Class II conditions. (Sec. 516.3.)

The **NFPA** “Standard for Spray Application Using Flammable and Combustible Materials” (No. 33) notes that the inspection department having jurisdiction may, for any specific installation, determine the extent of the hazardous “spraying area.”

The interior of any enclosed coating or dipping process must be considered a Class I or Class II, Division 1 location. A Division 2 location exists within 3 ft (900 mm) in all directions from any opening in such an enclosure, as shown in Fig. 516-5(D)(4). Note that today the majority of this type of work is carried out in dedicated spray booths and there are Class I Division 2 boundaries associated with the doorways into such spaces. A similar dimension applies to the openings to open-face and open-front spray rooms, as illustrated in Fig. 516-5(D)(2). Remember that actual spray booths and rooms, in accordance with their revised definitions, are power ventilated. The **NEC** prescribes area classifications for the entry and exit surroundings and the interiors of the associated duct work depending on whether or not the exhaust air is recirculated.

Part (5) provides extensive detail on both the fabrication of and the area classifications that apply to “limited finishing workstations.” This equipment will confine the by-products of a spraying operation but that does not meet the strict requirements for spray booths or rooms; often the sides will consist of curtains, but still with mechanical exhaust and makeup air systems as illustrated in Fig. 516-5(D)(5).

516.6. Wiring and Equipment in Class I Locations. In part (A), spray operations that constitute a hazardous location solely on the basis of the presence of flammable vapors (and no paint or finish residues) contain wiring and equipment for Class I locations, as specified in Art. 501.

Part (B) places tighter restrictions on spray booths or areas where readily ignitable deposits are present in addition to flammable vapors. In general, electrical equipment is not permitted inside any spray booth, in the exhaust duct from a spray booth, in the entrained air of an exhaust system from a spraying operation, or in the direct path of spray, unless such equipment is specifically approved for both readily ignitable deposits and flammable vapor.

However, for that part of the hazardous area where the luminaires or equipment may not be subject

to readily ignitable deposits or residues, luminaires and equipment approved for Class I, Division 1 locations may be installed. The authority having jurisdiction may decide that because of adequate positive-pressure ventilation the possibility of the hazard referred to in paragraph (B) has been eliminated.

Sufficient lighting for operations, booth cleaning, and repair should be provided at the time of equipment installation in order to avoid the unjustified use of “temporary” or “emergency” electric lamps connected to ordinary extension cords. A satisfactory and practical method of lighting is the use of ¼-in thick (6.35-mm thick) wired or tempered glass panel in the top or sides of spray booths with electrical luminaires outside the booth, not in the direct path of the spray, as covered in (C)(4). Parts (C)(1) and (2) cover luminaires that illuminate the spray operation through “windows” in the top or walls of a spray booth, as illustrated in Fig. 516-6(C)(a). Any such luminaire used on the outside of the booth must be approved for a Class I, Division 2 location when used in any part of the top or sides of a booth that is within the Division 2 locations as shown in the various drawings included in 516.5(D) of the Code.

The other alternative is to work with luminaires mounted and serviced from within the spray booth. These are covered in 516.6(C)(3) and the associated artwork. They will be listed for the Division 2 exposure, and more importantly, the listing investigation will review their performance under conditions of paint residue on the glass, resulting in partial entrapment of infrared energy within the luminaire. Overheated paint residues can catch fire at relatively low temperatures, as can be inferred from the field exposure limits given in 516.6(C)(4). For comparable reasons, part (D) places severe limits on the use of portable lighting and other equipment in a spray area during operations.

Part (F) addresses the ignition hazards arising from static discharges associated with spraying and coating operations, and requires that both the operator and all electrically conductive surfaces be grounded. This includes all piping that conveys fluids used for flammable or combustible fluids and all metal parts of the process equipment involved in the coating processes together with all exhaust ductwork and material containers.

Although the 2014 **NEC** was the first time an express reference has been made to the problems of static electricity in Sec. 516.6 covering Class I locations, it has been an ongoing concern in Sec. 516.10 governing electrostatic equipment (both fixed and hand operated) and powder coating for a long time. Informational notes to this effect occur in 516.10(A)(6), in 516.10(B)(4) where in addition to the note the mandatory provisions now include a prescriptive reference to a resistance to ground not to exceed 1 megohm, and in 516.10(C)(4)(b).

516.7. Wiring and Equipment Not Within Classified Locations. This section, very similar (even the same section number) to content in Art. 511, focuses on wiring method and equipment specifications that prevent accidental failures from communicating into the nearby hazardous (classified) location.

Automobile undercoating spray operations in garages, conducted in areas having adequate natural or mechanical ventilation, may be exempt from the requirements pertaining to spray-finishing operations, when using undercoating materials not more hazardous than kerosene (as listed by Underwriters Laboratories in respect to fire hazard rating 30–40) or undercoating materials using only solvents listed as having a flash point in excess of 100°F (38°C). There should be no open flames or other sources of ignition within 20 ft (6.0 m) while such operations are conducted.

516.10. Special Equipment. The requirements in 516.10 cover electrostatic coating operations, often referred to as powder coating. This section is now included with other spray applications in

Part III, and the integration is not yet perfected. For example, 516.10(A) requires automatic systems to comply with 516.6, but 516.6(A) requires adherence to provisions in Art. 501. The powders used in 516.10 fall within the scope of Art. 502, not 501.

516.18. Area Classification for Temporary Membrane Enclosure. This section, one of two in Part IV on this subject, is new as of the 2017 **NEC**. As soon becomes evident in Fig. 516-18 and the informational notes, it covers what can be very large contained areas, such as would be required to cover the large boat in the artwork.

516.29. Classification of Locations. This section, which opens Part V on printing, dipping, and coating processes, covers area classifications. Although comparable chemicals are used, these processes involve different risks than when discharged in the form of a spray and covers adjacent areas to open dipping and coating. They are visually presented in one old drawing showing the worst environmental case of no vapor containment or ventilation [516.29(a)] and three drawings covering operations with varying stages of vapor confinement. The first [516.29(b)] illustrates full peripheral vapor confinement. The second [516.29(c)] has partial vapor containment and ventilation, with the vapors not confined to the process equipment. The fourth drawing [516.29(d)] shows a printing process, a good example of the degree to which the **NEC** has broadened the focus of this article.

The same section includes four generic rules for the accessory areas around one of these operations. The first covers sumps, pits, and trenches; the second covers within 5 ft of a vapor source or the inside of an ink or a dip tank or the like (Division 1 for both). The third covers a 3-ft bubble around Division 1 locations (Division 2); and the fourth the area 3 ft above the floor and extending out 20 ft horizontally from the Division 1 location described in the third rule (also Division 2).

For small operations, 516.29(5) provides some relief on the extent of the Division 2 area. If the entire vapor source area does not exceed 0.5 m² (5 ft²) and the total volume of contents in the dip tank does not exceed 19 L (5 gal), and the vapor concentration does not exceed 25 percent of the lower flammable limit, the area is permitted to be unclassified.

516.35. Areas Adjacent to Enclosed Dipping and Coating Processes. This section, illustrated by Fig. 516-35, provides a three-category area classification for surrounding areas. The interior is Division 1 and the exterior is unclassified, except near openings to the inside, which have the usual 3-ft Division 2 bubble around them.

516.36. Equipment and Containers in Ventilated Areas. This section covers open containers used in conjunction with spraying operations, and points to the comprehensive treatment of the topic in 516.4.

516.37. Luminaires. This section brings in the applicable material from 516.6(C).

516.38. Wiring and Equipment Not Within Classified Locations. This section essentially duplicates 516.7.

516.40. Static Electric Discharges. This section opens by duplicating the requirements in 516.6(F), but also specifically addresses printing operations and requires that provisions be made to remove static charges from nonconductive substrates.

ARTICLE 517. HEALTH CARE FACILITIES

517.1. Scope. Although the **NEC** is *not* intended as a design specification, the requirements for

“electrical construction and installation” given in parts **II** and **III** of Art. 517, essentially present design requirements. For example, the rule in 517.31 mandating segregation of emergency and normal circuits necessitates an additional raceway system with all attendant components. Similarly, the rules for equipment ground-fault protection on the “next level of feeder disconnecting means down stream” as given in 517.17 present a design requirement. Therefore, in reality this article covers the *design and installation* of electric circuits and equipment in hospitals, nursing homes, residential custodial care facilities, mobile health care units, and doctors’ and dentists’ offices. *But* this article does not cover “performance, maintenance, and testing” of electrical equipment in such facilities. Such considerations are covered in other industry standards, such as **NFPA 99**.

Any specific type of health care location—such as a doctor’s office or a dental office—must comply with Code rules whether the location is a sole occupancy itself or is part of a larger facility (such as a hospital containing other types of health care locations) or is within a school, office building, or the like.

To this end, the term “medical office (dental office)” as of the 2017 **NEC** has a formal definition. These offices are not for overnight stays or 24-hour operation. They are for examination, and for minor procedures that may involve local anesthesia or sedation under which the patient does not lose the capacity of self preservation in an emergency. The 2017 **NEC** also expanded the definition of a health care facility to include “mobile enclosures,” reflecting the emergence of relocatable clinic facilities.

Veterinary facilities are not subject to the requirements of Art. 517.

517.2. Definitions.

Patient bed location The location of a sleeping bed in a health care facility. The term also includes the location of procedure tables in critical care areas, which would include an operating table.

Patient care space Any portion of a health care facility where people are examined or treated. An informational note makes it clear the business offices, corridors, lounges, etc. are not patient care areas. The **NEC** divides these areas into five defined classifications; basic (Category 3), general (Category 2), critical (Category 1), support (Category 4), and wet procedure location, which is no longer defined in this category, but given an entirely separate definition because a wet procedure may be carried out in more than one type of location within a patient care space. It is important to remember that electrical officials do not make these classifications. They are the exclusive province of the governing body of the facility based on the types of patient care they anticipate delivering.

Patient care vicinity This term provides a definite value for limiting the area, horizontally and vertically, in which special grounding requirements are to be observed in patient care areas.

Psychiatric hospital This is a facility used around the clock to provide only psychiatric care for not less than four resident patients.

Selected receptacles This phrase designates specific receptacles that will provide power to appliances used for patient care emergencies. A dissenting vote noted that the wording would allow task receptacles of any kind (“ordinarily required for local tasks”) to be supplied by the emergency system, even receptacles as unimportant as those for floor cleaners—which is contrary to the basic concept that the essential system is intended to supply only extremely limited loads.

517.10. Applicability. All the Code rules on “Wiring and Protection” apply to the entire wiring

system in hospitals and to “patient care spaces” of clinics, medical and dental offices, outpatient facilities, and doctor examining rooms or treatment rooms in nursing homes and residential care facilities. The basic rules of Part **II** apply to *all* health care facilities except those areas covered by 517.10(B)(1) and (2).

Part **(B)(1)** exempts those areas of a health care facility that are *not* intended for examining or treating patients. Areas that are dedicated to other purposes—business offices, corridors, waiting rooms, rest rooms, etc.—need not be wired as indicated in Part **II**.

The wording used in part **(B)(2)** is intended to exclude those health care facilities where patient rooms are used “exclusively” as sleeping quarters. The last sentence further reinforces the idea that such rooms are permitted to be exempt only where there is no intention to ever use the rooms as a treatment area.

517.13. Grounding of Receptacles and Fixed Electrical Equipment in Patient Care Spaces. In patient care spaces of *all* health care facilities, nonmetallic wiring methods are excluded, because they do not provide an equipment grounding return path over their outer margin. Refer to the discussion at 517.16 for the reasons behind this requirement. [See also part **(B)** of 517.10.]

Part **(B)** requires the use of a separate, green (no stripes of any color permitted) insulated equipment grounding conductor run with the branch-circuit conductors in a metal raceway or limited styles of metal-clad cable from a panelboard to any receptacle or metal surface of fixed electrical equipment operating over 100 V in all health care facilities. But a separate grounding conductor is not required in a feeder conduit to such a panel. For feeders, the metal conduit is a satisfactory grounding conductor, as recognized generally in 250.118. But for all branch circuits to “receptacles and all ... fixed equipment ...” in “areas used for patient care,” neither metal conduit, jumpers with box clips (G-clips), nor a receptacle with self-grounding screw terminals [250.146(D)] may be used alone without the grounding wire run with the branch-circuit wires ([Fig. 517-1](#)), which must be in a metal raceway or in some styles of Type MC, Type MI, or Type AC cable (so-called BX). As required in **(A)**, those metal-clad cables must have “cable armor or sheath assembly” that “itself qualifies as an equipment grounding return path.” Type AC cable, Type MI cable, and Type MC cable with a smooth or corrugated continuous metal sheath all satisfy that grounding requirement. Type MC with a spiral-wrap metal sheath with two grounding conductors, one of which is insulated copper, has been a source of controversy. But the wording used in this section now makes it clear that the second ground return path must be through the metal raceway or cable armor. Use of two equipment grounding conductors in the spiral-wound Type MC cable does not satisfy the wording used here. However, the new style of interlocking-armor MC cable with a fully sized aluminum bonding conductor run outside the Mylar sheath and in contact with the cable armor would qualify for this purpose, as long as it was supplied with an additional green wire as part of the cable assembly.

Fig. 517-1. Grounding conductor run with branch circuit in metal raceway or cable must ground receptacles and equipment. (Sec. 517.13.)

The ground terminal of receptacles must be grounded to an equipment grounding conductor run in a *metal raceway or metal-covered cables*. Either metal raceway or metal cable must be used for circuits in patient care areas of hospitals, clinics, medical and dental offices, outpatient facilities, nursing homes, and residential custodial care facilities—*always* with an insulated *copper* equipment grounding conductor included in the raceway or cable. A new exception does clarify that the direct grounding connection language, with respect to connecting equipment to the equipment grounding conductor run in the raceway or cable, can be applied to a bonding pigtail from the receptacle, as long as the wire on the receptacle and the equipment grounding conductor running with the supply circuit directly connect to each other without relying on a bonding path through a metal box. This makes sense in the context that boxes and other enclosures containing receptacles are now expressly included in the patient care area enhanced grounding requirements.

This rule applies to “patient care spaces”—which, in hospitals, covers patient bedrooms and any other rooms, corridors, or areas where patients are treated, such as therapy areas or ECG areas. But for facilities other than hospitals, part **(B)(1)** of 517.10 excludes waiting rooms, admitting rooms, solariums, and recreation areas, as well as business offices and other places used solely by medical personnel or where a patient might be present but would not be treated.

The first exception is somewhat trivial and addresses a possible interpretation that there might be a problem with the branch-circuit equipment grounding conductor landing on the box, and then a bonding jumper running to the receptacle grounding terminal, because that would be an indirect connection. The critical return path performance is considered as upstream from the box and receptacle in combination, just as the wiring method is required to function with the redundant return path over its outer margin along with the wire next to the branch circuit conductors. This concept does

not apply to isolated ground receptacles. Here again, refer to the comprehensive discussion at 517.16.

Exception No. 2 to this rule clarifies the use of metal faceplates on wall switches or receptacles without actually connecting an “insulated copper conductor” to each faceplate. They are acceptable as grounded simply by screw connection to a grounded box or grounded mounting strap of a grounded wiring device.

Exception No. 3 excludes luminaires from the rule for grounding by an insulated copper conductor, provided the luminaire is mounted “more than 7½ ft (2.30 m) above the floor.” Although luminaires so located do *not* need an insulated grounding conductor, they must be fed by a conduit or cable that satisfies part (A) of this section. In other words, having gone to the bother of running a 250.118-compliant raceway, you can avoid running the redundant green wire in the conduit, as if that would be a significant concession.

Part (A) of this section emphasizes that a redundant metallic grounding path is required in patient care areas. Part (A) requires that *all* branch circuits supplying patient care areas must be run in a metal-enclosed wiring method—rigid metal conduit, IMC, EMT, or MI, MC, or AC cable—to provide a redundant metallic grounding path in parallel with the insulated copper ground wire required by part (B) in the wiring method. This rule emphasizes the need for high reliability of the ground-fault current return path as major protection against electrical shock.

517.14. Panelboard Bonding. Normal and essential electrical system panel-boards serving either the same general care or critical care patient location must have their equipment grounding terminal bars bonded together with an insulated, continuous copper bonding jumper not smaller than No. 10 AWG. Where more than one such panelboard supply a common patient care area, but are fed from separate transfer switches, the ground bus in each must be bonded together. Although required to be “continuous,” the wording of the last sentence in this rule recognizes terminating this conductor at ground buses and terminals as satisfying the requirement for a “continuous” conductor.

517.16. Use of Isolated Ground Receptacles. After being prohibited for the 2011 **NEC**, the 2014 **NEC** resurrected them, but not for use in patient care vicinities. The 2017 **NEC** clarified the requirements. If such a receptacle is installed anywhere within a patient care space (not patient vicinity), its equipment grounding conductor must be distinguishable from other equipment grounding conductors of the wire type, in accordance with 517.16(B). It must be a green wire with yellow stripes, which will land on the ground terminal of the receptacle. This contrasts with the equipment grounding conductor of a wire type, colored solid green that runs with branch circuit conductors, and which in this case will also arrive at the receptacle location, but only terminate on the wall of the box.

Prior to the 2011 **NEC**, these receptacles were permitted, and a note followed cautioning that for these receptacles, “the grounding impedance is controlled only by the equipment grounding conductors and does not benefit functionally from any parallel grounding paths.” The current prohibition within a patient care vicinity is a logical outcome of the concern expressed in the former note. This consideration also provides a valuable point of entry into the reasons that this article requires branch-circuit wiring methods that qualify, over their outer margins, as equipment grounding conductors. Testing was done at an older hospital wired generations earlier with rigid metal conduit in order to study how equipment grounding paths actually functioned on these systems. The test results were reported to the **NFPA** Electrical Section at the 1986 Annual Meeting at which the 1987 **NEC** was being voted on. The test consisted (in part) of removing the conductors from some branch-circuit

raceways and breaking open the walls and floors at various points on the conduits' path back to the panelboard. When this work was completed, 50 A of fault current was deliberately injected into the box at the end of the branch circuit, and then the current flowing over the conduit was measured at the various access points on the way back to the panel. The conduit did show 50 A just below the outlet point, but nowhere else. As the readings progressed from outlet to panel with a steady 50 A going into the grounding return system, the current observed in the conduit dropped steadily until, at the panel, it was down to not more than a fifth of what was going into the wall.

The reason for this is that there were hundreds of ways back to that panel and electricity being electricity, every available path was used. Every piece of reinforcing steel that the conduit happened to touch, every water pipe, and so on, got into the act. Even concrete is somewhat conductive depending on moisture content. Now none of these alternate paths was very good by itself and we would never want to qualify any of them in Art. 250. But they exist, and by the principle of impedances in parallel, where the reciprocal of the total impedance of the circuit is the sum of the reciprocals of all the component impedances, we know that a large number of parallel impedances, even if all quite high individually, produce a total impedance that is very low. In fact the final impedance is much lower than the conduit, or that of a copper wire, or even that of both together.

517.17. Ground-Fault Protection. At least one additional level of ground-fault protection is required for health care facilities where ground-fault protection is used on service equipment (see 230.95). Where the installation of ground-fault protection is made on the normal service disconnecting means, each feeder must be provided with similar protective means. This requirement is intended to prevent a catastrophic outage. By applying appropriate selectivity at each level, the ground fault can be limited to a single feeder, and thereby service may be maintained to the balance of the health care facility.

As shown in [Fig. 517-2](#), with a GFPE (ground-fault protection of equipment) hookup on the service, a GFPE hookup must be put on each feeder derived from the service. Note that the second-level requirement applies to health care facilities with critical care areas or utilizing life-support equipment. Questions have been raised about health care facilities taking up tenancy in a multiple-occupancy building with GFPE on its service. There is no question that if such a facility had this sort of critical power need, then a second level of GFPE would be required, presumably on each tenant main that was one step below the service, even though only one of the second-level GFPE devices had anything to do with a health care occupancy. However, many of these outlying medical offices do not have this degree of sophisticated care, and therefore do not trigger 517.17.

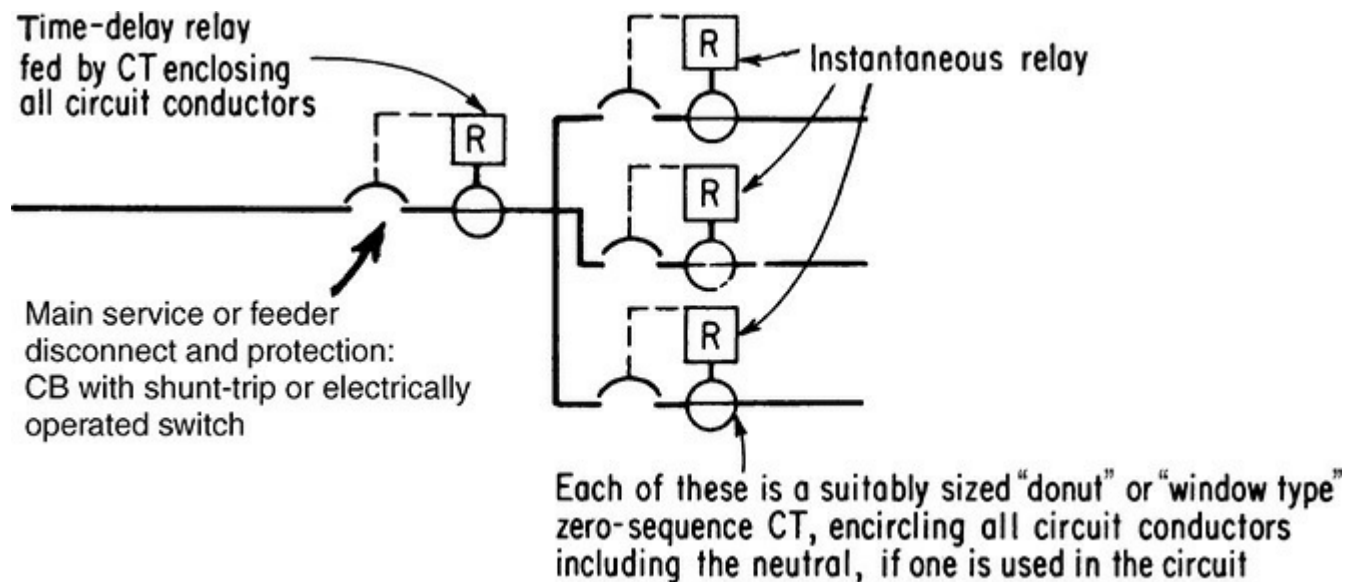

Fig. 517-2. GFPE on the service requires GFPE on main feeders also. (Sec. 517.17.)

The second paragraph is aimed at ensuring that essential systems are *not* isolated when the additional level of feeder GFPE is actuated. This requirement previously appeared as an FPN but now is included in the rule itself. Consequently, it is no longer advisory, but rather mandatory. Installation of GFPE on the load side of an emergency transfer switch is expressly prohibited, because if possible the fault should be cleared on the line side of the transfer switch. Closing a transfer switch into a fault may damage the switch and decrease the overall reliability of the system. However, the former prohibition against second levels of GFPE between the transfer switch and a standby generator, or on a voltage distribution not presently required to use GFPE, have been lifted. This should not be interpreted as a requirement to apply such protection, which is not an **NEC** requirement, but no harm results from lifting the prohibition. And part (C) requires that selection of the tripping time of the main GFPE be such that each feeder GFPE will operate to open a ground fault on the feeder, without opening the service GFPE. Instead of the former requirement for a six-cycle minimum separation, the **NEC** now creates a performance mandate for separation of the GFPE time-current characteristics in accordance with the recommendations of the manufacturer, consideration of required tolerances and operational timing so as to achieve complete selectivity. As shown, if the feeder GFPE relays are set for instantaneous operation, the relay on the service GFPE must have a delay such that it will only open in the rare event that the ground fault is between it and the downstream protective devices. A zone-selective GFPE system with a feedback lockout signal to an instantaneous relay on the service could satisfy the rule for selectivity.

Part (D) of this section calls for a test of the required GFPE when it is first installed. Such testing must demonstrate that the GFPE satisfies the rule of part (C) and provides "100 percent selectivity."

517.18. General Care (Category 2) Spaces. Two circuits must supply each bed used for inpatient care. A branch circuit supplying a patient bed location must not be part of a multiwire branch circuit. Given the common disconnect requirement in 210.4, a fault on one side of such a multiwire circuit would take out one or two other runs, depending on the distribution, reducing overall reliability. At least one of the circuits must be from the critical branch and one from the normal system, unless two circuits are available from the critical branch supplied through different transfer switches. If that arrangement is chosen, make certain it is correlated with the separation requirements in 517.31(C)(1). The receptacles, or the cover plates, at these bed locations that are

supplied from the critical branch must have a “distinctive color or marking,” and they must also indicate the identity of the panelboard and show the circuit number supporting them. But two branch circuits are not required for each patient bed in nursing homes, outpatient facilities, clinics, medical offices, limited care facilities, and the like. “Psychiatric, substance abuse, and rehabilitation hospitals” are also exempted from the branch-circuit and receptacle requirements for general care patient bed locations, including the requirement for panel and circuit identifying information.

As noted in part **(B)**, receptacles at patient bed locations in “General Care Areas” must be “listed hospital grade” and “so identified.” The minimum of eight required receptacles at each such bed location may be single or duplex types, or a combination of the two. (Two duplex receptacles constitute a total of four receptacles.) *All* receptacles at *all* patient bed locations, general care and critical care, must be “listed hospital grade” devices. There are now quadruplex receptacle devices that are rated hospital grade, and are an additional option in these locations. Psychiatric facilities as covered in exceptions to (B) are not included in the minimum requirements for receptacle placements.

As noted in part **(C)**, only tamper-resistant receptacles are permitted in pediatric locations. This rule requires that all 15- or 20-A, 125-V receptacles in pediatric locations be tamper-resistant. Tamper-resistant receptacles make it extremely difficult, if not impossible, to insert a pin, paper clip, or similar small metal object into a slot on the receptacle and make contact with an energized part. Obviously, the concern here is to protect infants or children from shock hazard as a result of playful or inadvertent tampering with the receptacle. Another option, seldom used, is a listed tamper-resistant cover.

These receptacles are similar to those required by 406.12 for dwelling units, but for these locations they must additionally carry a hospital grade rating. As in the case of devices in dwelling units, the UL information on these devices indicates that they are marked “TR” on the yoke where the mark will be visible with the faceplate removed.

517.19. Critical Care (Category 1) Spaces. Patient bed locations in general care areas (517.18) must be supplied by eight single or two duplex receptacles. However, critical care area patient beds must be provided with at least 14 receptacles (single or duplex or quadruplex devices totaling 14 points for connecting a cord plug cap). The two or more branch circuits to each critical care area patient bed location must include one or more from the critical branch and one or more from the normal system (Fig. 517-3). In both cases, at least two branch circuits must supply these receptacles. As in the case of 517.18, a branch circuit supplying a patient bed location must not be part of a multiwire branch circuit. Given the common disconnect requirement in 210.4, a fault on one side of such a multiwire circuit would take out one or two other runs, depending on the distribution, reducing overall reliability. In the case of general care areas, additional receptacles serving other patient locations may be served by these branch circuits, but in the case of critical care areas, at least one of these branch circuits is required to be an individual branch having no other receptacles on it except those of a single bed location. Here again, if the critical branch is supplying two (or more) circuits through multiple transfer switches, the normal system circuit is no longer required. However if that arrangement is relied upon, make certain it is correlated with the separation requirements in 517.31(C)(1). In addition, the receptacles connected to the emergency source must be identifiable as such and have their circuit number and panelboard ID visible on the faceplate or equivalent.

517.19. Both emergency system and normal system must supply branch circuits to critical-care bed location.

Fig. 517-3. Multipurpose patient care modules may incorporate a variety of the circuit, receptacle, and grounding requirements for patient care areas. In addition to a patient equipment grounding point and room bonding point, such a preassembled unit might include facilities for communication, patient monitoring, lighting, and lines for air, water, and medical gas. (Sec. 517.19.)

The 2017 **NEC** added a requirement that in addition to the circuit numbering and identification rule, any receptacle connected to either the critical branch or the life safety branch must have a distinguishing color to make it more quickly identifiable. Either the receptacle face or the faceplate (or both, presumably) must use this color. The **NEC** does not specify any particular color, but presumably whichever color is chosen it must be applied consistently throughout the facility. This requirement, for these receptacles, is essentially a duplication of 517.31(E).

As covered in part **(B)**, “hospital-grade” receptacles must be used at patient bed locations in critical care areas. Fourteen single or seven duplex receptacles (or any combination totaling 14 receptacles, including the possibility of one or more quadruplex receptacle(s) taking care of some of the six receptacles required) that are UL-listed as “hospital-grade” devices must be used at each patient bed location and must be so identified at each patient bed location in critical care patient areas. The best point to call a reference grounding point is the grounding bus in the distribution panel, which is the transition connection point between the branch-circuit grounding wires and the feeder grounding system. This is also, in effect, how the term is defined in 517.2.

As of the 2014 **NEC**, operating rooms now have their own unique receptacle requirements in **(C)** that parallel those of critical care bed locations generally, but that have significantly higher numbers of required hospital-grade receptacles. There must be at least 36 in the room divided between not less than two branch circuits, either laid out using single, duplex, or quadruplex receptacles, and at least 12, but no more than 24, need to be on the normal system or fed from a different transfer switch of the critical branch.

This set of requirements is for a room and not for a bed location. And a patient bed location includes a “procedure table of a critical care area,” which would include an operating table. Therefore, the literal text puts at least 14 receptacles at the operating table, with the remainder elsewhere in the room as specified by design.

Part **(D)** means that a “patient equipment grounding point” (defined as a “point for redundant grounding of electric appliances”) is *not* mandatory. Such a grounding point may be used, if desired, and connected as described in the rule. In its original application, years ago, the “patient equipment grounding point” was a special jack used to make a grounding connection to the metal enclosures of electrical medical equipment because, at the time, many power cords did not contain a grounding conductor. In addition, this was a carryover from procedures for operating rooms, where all metal surfaces had to be grounded to minimize static charge buildup. With today’s universal use of good 3-wire (grounding type) power cords and plugs or double-insulated equipment, there is no real justification for requiring this patient equipment grounding jack. Each three-contact receptacle, in effect, becomes a patient equipment grounding point.

When a patient equipment grounding point is used in a patient vicinity, it must be grounded to the ground terminal of *all* grounding-type receptacles in the patient vicinity by means of a minimum No. 10 copper conductor looped to all of the receptacles or by individual No. 10 conductors run from the patient grounding point to each receptacle.

Regardless of what additional methods are employed, in order to keep potential differences within the required limits, equipotential grounding is essential to the electrical safety of critical care areas. Some of the earliest equipotential grounding installations consisted of copper busbars run around the walls of patient rooms to which furniture and equipment were attached by means of grounding jumpers. Based on experience obtained through these early installations as well as the refinements produced by the **NFPA** Committee on Hospitals, the **National Electrical Code** now contains the requirements that correlate with the pertinent **NFPA** standards on the subject. At the same time, these requirements also permit the achievement of the desired end with a minimum of expenditure in labor and materials.

Objection has been raised to the concept of grounding every piece of exposed metal in sight. Doing this may actually increase the hazard. Because a shock occurs when a person touches two surfaces with a voltage difference between the surfaces, the fewer surfaces that are deliberately grounded, the better. Thus, a door frame or window frame that is not likely to become energized is not required to be grounded. It was not good safety engineering to propose that metal furniture in a patient's room be deliberately grounded. [Figure 517-4](#) shows the type of grounding and building points that past editions of the **Code** regulated, along with typical grounding hookups in older hospitals.

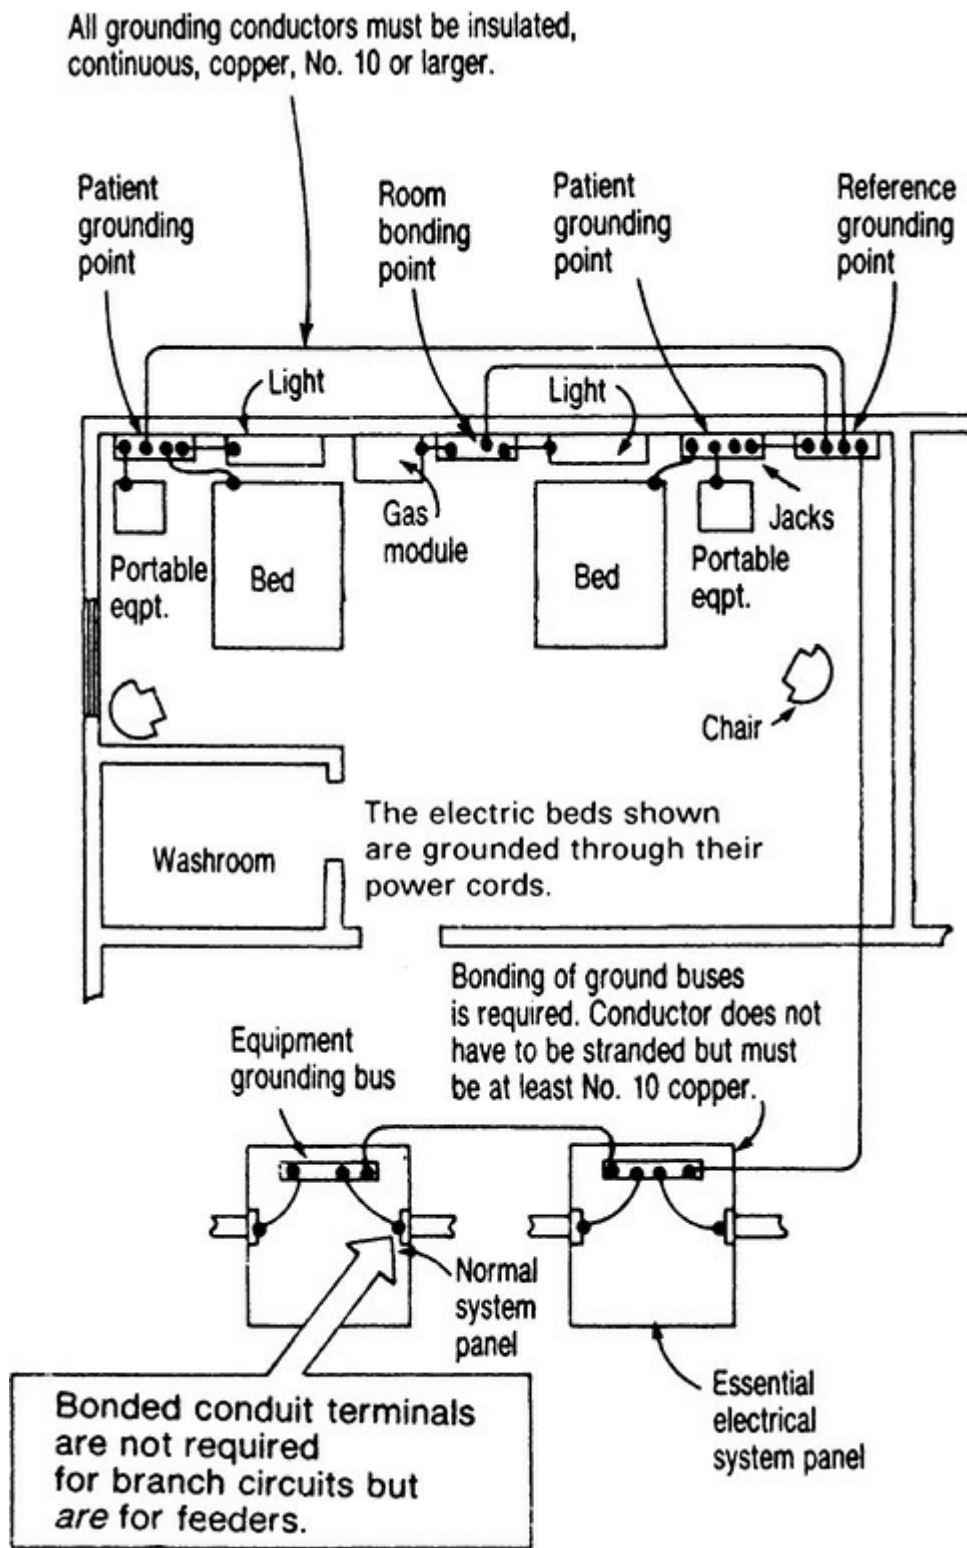

Fig. 517-4. The grounding techniques shown here were regulated by past editions of the **NEC** but are now optional at the patient bed locations. [Sec. 517.19(C).]

As required by part **(E)** of this section, a bonding-type connection is required for *feeder* metal conduit or metal cable (Type MC or MI) terminations, using a bonding bushing plus a *copper* bonding jumper from a lug on the bushing to the ground bus in the panelboard fed by the conduit (see illustrations in 250.92). Bonding locknuts or bonding bushings may be used on clean knockouts (all punched, concentric, or eccentric rings removed), and bonding may be provided by threaded connection to hubs or bosses on panel or switchboard enclosures. This is required for feeder conduits but not for branch-circuit conduits. And it seems clear that bonded terminals are required at both ends of each and every feeder to a panelboard that serves the critical care area (Fig. 517-5).

Fig. 517-5. Feeders to branch-circuit panelboards for critical care areas must be bonded. [Figure 517-4](#) covers rules on grounding and bonding for the patient vicinity of a critical care area, with feeder conduit bonding as in this photo. [Sec. 517.19(D).]

Part **(F)** makes use of an isolated power system for critical care areas a completely optional technique, simply noting that such systems are “permitted” to be used if the design engineer or the hospital-client wants them. This approach ties in with the deletion of the maximum potential difference of 100 mV “under conditions of line-to-ground fault” in a critical care area—which until

the 1978 **NEC** tended to make the isolated power system mandatory. Grounding of this optional power system must satisfy part **(G)**.

Part **(H)** covers receptacles that are intended for use by specific pieces of equipment. Those receptacles intended for special purposes—for example, mobile x-ray equipment—must have their equipment grounding conductor “extended” to the reference point within the branch-circuit panelboard that supplies the patient area.

517.20. Wet Procedure Locations. These locations, designated as such by the governing body of the hospital, are locations where certain medical procedures will be performed that involve copious amounts of fluids during the procedure, even though they are under cover and would generally meet the definition of a dry location. The reference to “wet” here is a medical procedure reference, and not an environmental description. Some surgeries, for example, involve extensive irrigation of the wound. The previous terminology “wet locations” was misleading and was revised for the 2008 **NEC**. Locations that are intended for protection would include hydrotherapy, dialysis facilities, selected wet laboratories, and special-purpose rooms where wet conditions prevail.

All receptacles (of any rating) *and fixed electrical equipment* at a wet location must “be provided with special protection against electric shock.” What follows are the two acceptable responses to achieve this special protection status as in prior Codes, but using different language, as extracted from **NFPA 99**. The first describes an isolated power system, and the second GFCI. The only exception eliminates the need for GFCI protection or supply from isolated power for “listed, fixed” therapeutic and diagnostic equipment.

517.21. Ground-Fault Circuit Interrupter Protection for Personnel. This rule correlates with the rules in 210.8(B)(1) and 406.3. These two Code sections deal with GFCI protection of 15- and 20-A, 125-V receptacles installed in new bathrooms and replacements made in existing bathrooms in occupancies other than dwellings. The intent of 517.21 is to exempt receptacles installed in critical care areas—whether new installations or where replacement is made in an existing installation—from being GFCI-protected where a toilet and basin are within the same room. Literally, the rules of 210.8(B)(1) and 406.3 would mandate GFCI protection for any 15- and 20-A, 125-V receptacles installed in such a location. *But* for any “critical care” patient bed location where the bathroom is separate from the care area, critical or general, GFCI protection *is* required for 15- and 20-A, 125-V bathroom receptacles.

517.25. Scope. Essential electrical systems are covered for hospitals, clinics, medical and dental offices, outpatient facilities, nursing homes, residential custodial care facilities, and other health care facilities for patient care. In any facility, there must be enough standby lighting and power to allow for an orderly cessation of procedures. This might be nothing more than battery-powered wall units for some illumination, but the concept must be addressed in all health care facilities.

517.26. Application of Other Articles. The definition of “life safety branch” in 517.2 no longer directly references Art. 700. That allowed this section to authorize variances from [Chap. 7](#) without contravening 90.3; with the restructuring of 90.3 that effort is no longer necessary, but does not change the intent. There are two principal areas of conflict between this article and Art. 700 that are now firmly resolved by this wording. Specifically, the conflict is between 700.5(D) that says an emergency system transfer switch must serve only emergency system loads, and 517.31(B) that expressly permits a single transfer switch at a small hospital (defined as not over 150 kVA of load on the essential electrical system). The second area involves the selective coordination requirements in

700.32, which are effectively set aside by 517.31(G).

517.29. Essential Electrical Systems for Hospitals and Other Health Care

Facilities. This section, along with 517.29(B), makes clear that essential electrical systems that are to be installed in hospitals, and other health care facilities as specified elsewhere that are using essential electrical systems to serve patients on electrical life support, must observe the rules of Part III of Art. 517.

517.30. Sources of Power. Essential electrical systems must have no fewer than two sources of power, each capable of supporting the system. The normal configuration is a normal utility source and a standby source of sufficient size, but other arrangements are recognized, including on-site generation as the normal source and recourse to a utility (or additional on-site generation) as the backup. Fuel cell systems, comprised of no fewer than N+1 units (N being sufficient for the demand) are permitted as a source if they are listed for emergency system use and meet the other requirements in 517.30(B)(2). The power components must be positioned to minimize risk of failure from disasters and other factors that could result in the simultaneous interruption of plural sources of supply.

517.31. Requirements for the Essential Electrical System. This section begins by identifying the three separate branches comprising the system (life- safety, critical, and equipment). It should be noted that the critical branch in hospitals comprises different equipment and connections than does the critical system in nursing homes. One subject of endless debate over past decades has been whether critical branch loads were to be covered by Art. 700 requirements, largely driven by the former grouping of the critical branch and the life-safety branch together in a subgrouping of the essential system called the “emergency system.” Essential electrical systems have three components, only one of which is directly comparable to Art. 700 (the life-safety branch). The other half of the former “emergency system” is the critical branch, which never did refer to Art. 700 within its definition, and was probably closer to Art. 701 (legally required standby) than Art. 700. Although it does have the same reconnection time of 10 s, it is not allowed to enter a common raceway with circuits on the life-safety branch, by 517.31(C)(1). This left very much in question whether other rules in Art. 700, notably including 700.32 per the inclusive language in 517.26, ever could have applied to the critical branch because 700.9 (B) expressly allows all Art. 700 circuits in common enclosures. However, the “equipment system” is plainly not Art. 700 or even Art. 701, with numerous permissions for delayed automatic or even manual reconnection to power. The 2014 **NEC** firmly ended these debates. The term “emergency system” is no more. Each load grouping (“Life-Safety,” “Critical,” and “Equipment”) is now followed by the same word in its title: “Branch.” The **NEC** drawings in Figs. 517-31(a) and (b) show three coordinate branches, each with its own wiring rules. To add further clarification, 517.31(A) requires that the separation between branches occurs, for anything but a small facility using a single transfer switch, at the transfer switches.

Both the critical branch and the life-safety branch must be divorced from each other and all other wiring and equipment. These circuits must not enter raceways, boxes, or cabinets that are common to other systems. In addition, it is common in large hospitals to subdivide the critical system among multiple transfer switches to increase reliability. Both 517.18(a) and 517.19(A) allow branch circuits fed through different transfer switches to create the diversity of supply required for receptacles under their control. This section now requires that when this is done, the branch circuits from different transfer switches must be “kept independent of each other.” This means separate raceways and boxes just as surely as it did, and still does, when circuits from both the normal system and the critical branch arrive at those bed locations. To correlate with this change, item (4) in 517.31(C)(1) now

limits the double circuit allowance to applications originating from the same transfer switch.

In 517.31(C)(3), although wiring of the life-safety and the critical branches is required to be installed in a “nonflexible metal raceway” or MI cable, (C)(3)(1) permits Schedule 80 PVC or RTRC-XW for such circuits that do not supply patient care areas. Only the Schedule 80 version of rigid PVC conduit may be used without concrete encasement. (C)(3)(2) says Schedule 40 PVC conduit and electrical nonmetallic tubing are permitted for other than branch circuits in patient care areas, where encased in no less than 2 in. (50 mm) of concrete. *But* note that, although such a raceway may be used for life-safety and critical-branch circuits, it is *not permitted* for such circuits that are “branch circuits serving patient care areas.”

Part (C)(3)(3) allows limited use of cable and flexible metal raceways to supply branch circuits in patient care areas, but don’t forget that 517.13 still applies to branch circuits, so the metal cable armor would have to be recognized for redundant grounding, and the flexible metal raceways would be limited to 1.8 m (6 ft) because otherwise they would lose their status as qualified equipment grounding conductors under 250.118. And this rule also formally recognizes flexible metal conduit and cable assemblies in prefabricated “headwalls” and where flexibility is needed, as well as fished application in existing facilities, and luminaires in rigid ceilings that preclude access to the wiring after the initial installation. Parts (C)(3)(4) and (C)(3)(5) cover cord-and-plug connections for utilization equipment, and recognize the use of conventional limited energy cabling for nurse-call and other signaling systems operating under Class 2 and Class 3 power limitations, and also data, communications, and other power limited systems within the reach of Part VI of the article, whether or not run in a raceway.

Part (D) addresses the sizing requirements for the overall essential electrical system notably including its standby source and requires it to be capable of picking up the connected load based on any combination of historical data, Art. 220 results, the actual load ratings of connected equipment, and cautiously applied demand factors. Unlike 700.4 and 701.4, this section does not recognize automatic load shedding as a strategy to bring load demand into line with the capacity of the standby source, and the concluding sentence expressly disallows the applicability of those sections.

Part (E) applies to receptacles throughout the hospital and not just in the patient bed locations described in 517.18 and 19. It requires a distinctive color on the receptacle faces or their faceplates at every outlet that makes it immediately apparent that the receptacle is supplied by the essential electrical system. Note that when the 2014 **NEC** eliminated the former terminology used here, “emergency system,” it broadened the applicability of this identification requirement to include receptacles on the equipment branch, including some that may be reenergized only following a delayed automatic or even a manual reconnection after a normal system outage.

Part (F), new to the 2014 **NEC**, covers a single feeder supplied from a generator as a standby supply source for the essential electrical system. The transfer switch does not need to be at the alternate source, and the single feeder permission extends from the alternate source to the point where the sources for the life-safety branch, critical branch, and equipment branches divide.

Part (G), also new as of the 2014 **NEC**, covers system coordination. This terminology intentionally differs from comparable terminology throughout the **NEC** that applies requirements for “selective coordination.” The latter term is now defined in Art. 100 and covers all overcurrent events capable of occurrence following the instant of energization. The requirement here in Art. 517 requires coordination for fault events for the period of time that extends beyond a tenth of a second. In this time

period, six cycles, it is comparatively easy to accomplish coordination of feeder- and branch-circuit levels in a distribution without resorting to fuses, or to using circuit breakers with undesirable frame size differentials.

Strict selective coordination accomplishes protection for an electrical event that has never been recorded in an occupied building in the history of the use of electricity in buildings. Refer to the in-depth discussion of this topic as part of the coverage of 700.32 in [Chap. 7](#) of this book as to why that is necessarily true. Unfortunately this sensible relaxation of coordination never would have come into the **NEC** voluntarily. The hospital industry, heavily impacted by the costs of compliance and well aware of the lack of observable benefit, put the amended rule in the *Health Care Facilities Code*, **NFPA 99**. The **NFPA** Standards Council, the ultimate arbiter in such things, decreed that this requirement related more to the performance of hospital electrical systems and not the essential installation criteria for those systems. As such, it can be extracted into the **NEC** but not substantively altered. This rule change was one of the single most important developments in the 2014 **NEC** cycle.

517.32. Branches Requiring Automatic Connection. Code diagrams 517-30 Nos. 1 and 2 in the Code book clarify interconnections and transfer switches required. Handbook [Table 517.1](#) summarizes the loads supplied by the hospital life-safety and critical branches, which must restore electrical supply to the loads within 10 s of loss of normal supply. A minor clarification in the 2017 **NEC**, partially in the interest of comfort at night, resulted in task illumination on the critical branch now being capable of switch control [517.34(B)].

Table 517.1 A Hospital Emergency System Must Serve These Loads (Sec. 517.32)

Life-Safety Branch	Critical Branch
<p>Lighting and receptacles and equipment for:</p> <ul style="list-style-type: none"> —Means of egress illumination —Exit and directional signs —Alarm and alerting systems <ul style="list-style-type: none"> • Fire alarms • Nonflammable medical gas piping • Mechanical controls for life safety —Communications for emergency use —Generator—set battery charger, lighting, together with accessory loads for a specific generator that are essential to keep it in operation —Transfer switch lighting, selected receptacles —Elevator cab lighting and communications —Automatic doors used for building egress 	<ul style="list-style-type: none"> —Isolating transformers in special locations —Critical care areas using anesthetizing gas, selected receptacles, equipment —Task illumination and selected receptacles in patient care areas in: <ul style="list-style-type: none"> • Nurseries • Medication preparation • Pharmacy • Acute nursing • Psychiatric beds (no receptacles) • Nurses stations • Ward treatment rooms —Additional specialized care —Nurse call systems —Bone, blood, and tissue banks —Telephone equipment areas —Task illumination, selected receptacles, and power for the following: <ul style="list-style-type: none"> • General care beds (one duplex per) • Angiographic labs • Cardiac catheter labs • Coronary care • Dialysis • Emergency rooms • Human physiology labs • Intensive care • Postoperative recovery rooms —Additional task illumination, receptacles, and selected power circuits as needed for effective operation; 1ϕ fractional hp motors permitted

517.35. Equipment Branch Connection to Alternate Power Source. This is where the equipment system comes in, comprised primarily of three-phase power loads. Ventilation systems for operating and delivery rooms were added under delayed automatic connection for the 2008 NEC. The 2014 NEC has added HVAC systems for telephone and data equipment rooms and closets.

517.40. Type 2 Essential Electrical Systems for Nursing Homes and Limited Care Facilities. An extensive informational note in 517.40 describes the different levels of care available in nursing homes, and the level (now referred to as a category) of care offered, and how that potentially affects essential electrical system design.

517.42. Essential Electrical Systems. This section covers nursing homes and limited care

facilities. In part (B), a single transfer switch may be used for the entire essential electrical system instead of using a separate transfer switch for each branch. One transfer switch may supply one or more branches of the essential electrical system in a nursing home or residential custodial care facility where the essential electrical system has a maximum demand of 150 kVA. Separate transfer switches are required only if dictated by load considerations. For small facilities, the essential electrical system generally consists of the life-safety branch and the critical branch. For larger systems, the critical branch is divided into three separate branches for patients, heating, and sump pumps and alarms. Code diagrams 517.42(a) and 42(b) illustrate typical installations. Part (E) requires nonlocking 125-V, 15- and 20-A receptacles to incorporate either an illuminated face or an indicator light on a receptacle connected to the essential electrical system so it will be obvious whether or not there is power at the receptacle location. This requirement was also supposed to apply in hospitals, but the amendment to then 517.30 was rejected by the **NFPA** Standards Council on a complaint from the **NFPA** 99 Committee that this was a performance requirement at variance from the applicable provisions in the other standard. The same committee may have failed to notice this amendment, because no complaint was filed.

517.43. Automatic Connection to Life-Safety Branch. Part (A) describes the switching arrangements for night transfer of corridor lighting. The rule is intended to ensure that some lighting will always be provided in the corridor regardless of the mode of operation.

517.44. Connection to Equipment Branch. This section details the loads requiring transfer from normal source to the alternate power source. In part (B)(2), elevator operation must not trap passengers between floors. This is now mandatory.

517.45. Essential Electrical Systems for Other Health Care Facilities. This section is increasingly important as health care decentralizes. If these facilities have critical care areas or patients on life support, then an essential electrical system as covered in 517.30 through 517.35 will be applied, or a battery system is permitted.

517.60. Anesthetizing Location Classification. The rules for flammable anesthetizing locations in the **NEC** are virtually obsolete. No hospital in the United States is using or has used ether and other such agents for many years. However, the rules have not been removed from the **NEC** because the **NEC** is used in other countries, and some of them are still using flammable anesthetics. [Figure 517-6](#) shows the classified hazardous locations of part (A).

Fig. 517-6. Two types of hazardous locations must be identified. (Sec. 517.60.)

Hazardous locations rules are separated from those for other-than-hazardous locations. A third category is also designated: “above-hazardous locations.” The Code covers wiring and equipment in three relations to anesthetizing locations: 517.61(A), within-hazardous; 517.61(B), above-hazardous; and 517.61(C), other-than-hazardous.

517.61. Wiring and Equipment. Part (A) calls for explosionproof wiring methods, in general, for such locations.

Part (A)(4) notes an extension of the hazardous boundary. 517.60(A)(1) defines the area of a flammable anesthetizing location as a Class I, Division 1 location from the floor to a point 5 ft (1.5 m) above the floor. The question then arises, “Is the seal required in the upper conduit entering the switch box on the wall of a hospital operating room as shown in Fig. 517-7?” The box is partly below and partly above the 5-ft (1.5-m) level.

Fig. 517-7. Boundary of Class I, Division 1 location may be extended. (Sec. 517.61.)

Part (A)(4) states that if a box or fitting is partially, but not entirely, beneath the 5-ft (1.5-m) level, the boundary of the Class I, Division 1 area is considered to extend to the *top* of the box or fitting. Therefore, the box or fitting is entirely within the hazardous area, and a seal is required in conduit entering the enclosure from either above or below, as shown in Fig. 517-7.

If the box or fitting is entirely *above* the 5-ft (1.5-m) level, a seal would not be required at the box or fitting, but conduit running to the box from the hazardous area would have to be sealed at the boundary, on the hazardous-location side of the box. If the box shown were recessed in the wall instead of surface-mounted, some means would have to be provided to make the seals accessible [501.15(C)(1)], such as removable blank covers at the locations of the seals.

Part **(A)(5)** calls for explosionproof receptacles and plugs within hazardous locations described in 517.60(A).

In part **(B)(1)** of this section, rigid metal conduit, electrical metallic tubing (EMT), and intermediate metal conduit (IMC) or Type MI or MC cable that has a continuous “gas/vaportight” sheath are permitted in “above-hazardous anesthetizing locations.” In “other-than-hazardous anesthetizing locations” [517.61**(C)(1)**], wiring may be in a metal raceway or cable assembly, but the cable armor must qualify as a ground return path per 250.118.

Hospital-Grade Receptacles

The **NEC** generally requires that “hospital-grade” receptacles (the UL-listed green-dot wiring devices) be used at patient bed locations in health care facilities. However, note that 517.61(B)(5) and 517.61(C)(2) of the Code also require use of “receptacles and attachment plugs” that are “listed for hospital use” *above* “hazardous” anesthetizing locations and *in* “other-than-hazardous” anesthetizing locations. As described, these rules require that all 2-pole, 3-wire grounding-type receptacles and plugs for single-phase 120-, 208-, or 240-V ac service must be marked “Hospital Only” or “Hospital Grade” and have a green dot on the face of each receptacle ([Fig. 517-8](#)). The relation between the phrase “listed for hospital use” and the phrase “Hospital Grade” is explained in the UL Guide Card information [see discussion at 110.3(B) for details], under the heading “Attachment Plug Receptacles and Plugs.” It says:

517.18(C). Receptacles in pediatric and psychiatric locations must have a type of construction that prevents improper contact

Fig. 517-8. Hospital-grade plugs and receptacles are required for anesthetizing locations. (Sec. 517.61.)

Receptacles for hospital use in other than hazardous (classified) locations in accordance with Art. 517 of the **NEC** are identified (1) by the marking "Hospital Only" (used to identify a specific grounding locking configuration rated 20 A, 125 V used for the connection of mobile x-ray and similar equipment) or (2) by the marking "Hospital Grade" and a green dot on the face of the receptacle. The identification is visible during installation on the wiring system or, in the case of the appliance outlet, after installation on the utilization equipment.

Of course, in the defined hazardous areas of flammable anesthetizing locations [517.60 and 517.61(A)(5)], receptacles must be explosionproof type, listed for Class I, Division 1 areas.

Underwriters Laboratories devised a special series of tests for wiring devices intended for hospital use. These tests are substantially more abusive than those performed on general-purpose

devices and are designed to ensure the reliability of the grounding connection in particular, when used in the hospital environment. Hospital-grade receptacles have stability and construction in excess of standard specifications and can stand up to abuse and hard use. Devices that pass this test are listed as “Hospital Grade” and are identified with these words and a green dot, both of which are visible after installation. UL listings include 15- and 20-A, 125-V grounding, nonlocking-type plugs, receptacles, and connectors. This class of device is acceptable for use in any nonhazardous anesthetizing location (Fig. 517-9). As noted in the exception to 517.61B)(2), receptacles above a hazardous location do not have to be totally enclosed and may be standard, available hospital-grade receptacles of the type that would be used to satisfy the rule of 517.61(B)(5).

Fig. 517-9. Although the NEC requires use of hospital-grade receptacles at patient bed locations and in “anesthetizing” locations, the ruggedness and high degree of connection reliability strongly recommend their use for such critical applications as plug-connection of respiratory or life-sustaining equipment.

As covered in part (C)(1), in anesthetizing locations that are not hazardous (no flammable agents used), Type AC cable is recognized along with Types MI and MC cable and rigid metal conduit, IMC, and EMT—but any such cable or raceway must contain an insulated-copper equipment grounding conductor and its outer jacket must be an approved grounding conductor. Note that, although the rule here does not specify a copper conductor, because an anesthetizing location is a patient care area, the copper wire is required by 517.13.

517.63. Grounded Power Systems in Anesthetizing Locations. Part (A) used to call

for a general-purpose lighting circuit, fed from the normal grounded service, to be installed in each operating room. And an exception used to recognize feed from an emergency generator or other emergency service that is separate from the source of the hospital's "Emergency System," as defined in 517.2. Figure 517-10 shows a layout where such an emergency supply (at lower right) is now the required source of supply to the lighting circuit in the operating room. Now, emergency illumination is required to be supplemented by at least one battery-powered emergency luminaire. This unit equipment (now formally defined in 517.2 as "Battery-Powered Lighting Units") is now permitted to be connected to the critical branch lighting circuit in the area, ahead of local switching. In the event of an extended normal power outage such units will run until their battery is discharged, at least 1½ h later; however, the lighting in the area will have been restored within 10 s by the emergency generator. Allowing these units to connect to the critical branch lighting circuit will avoid the pointless deep cycle discharge and long recharge time that would otherwise occur in the event of an extended normal system outage.

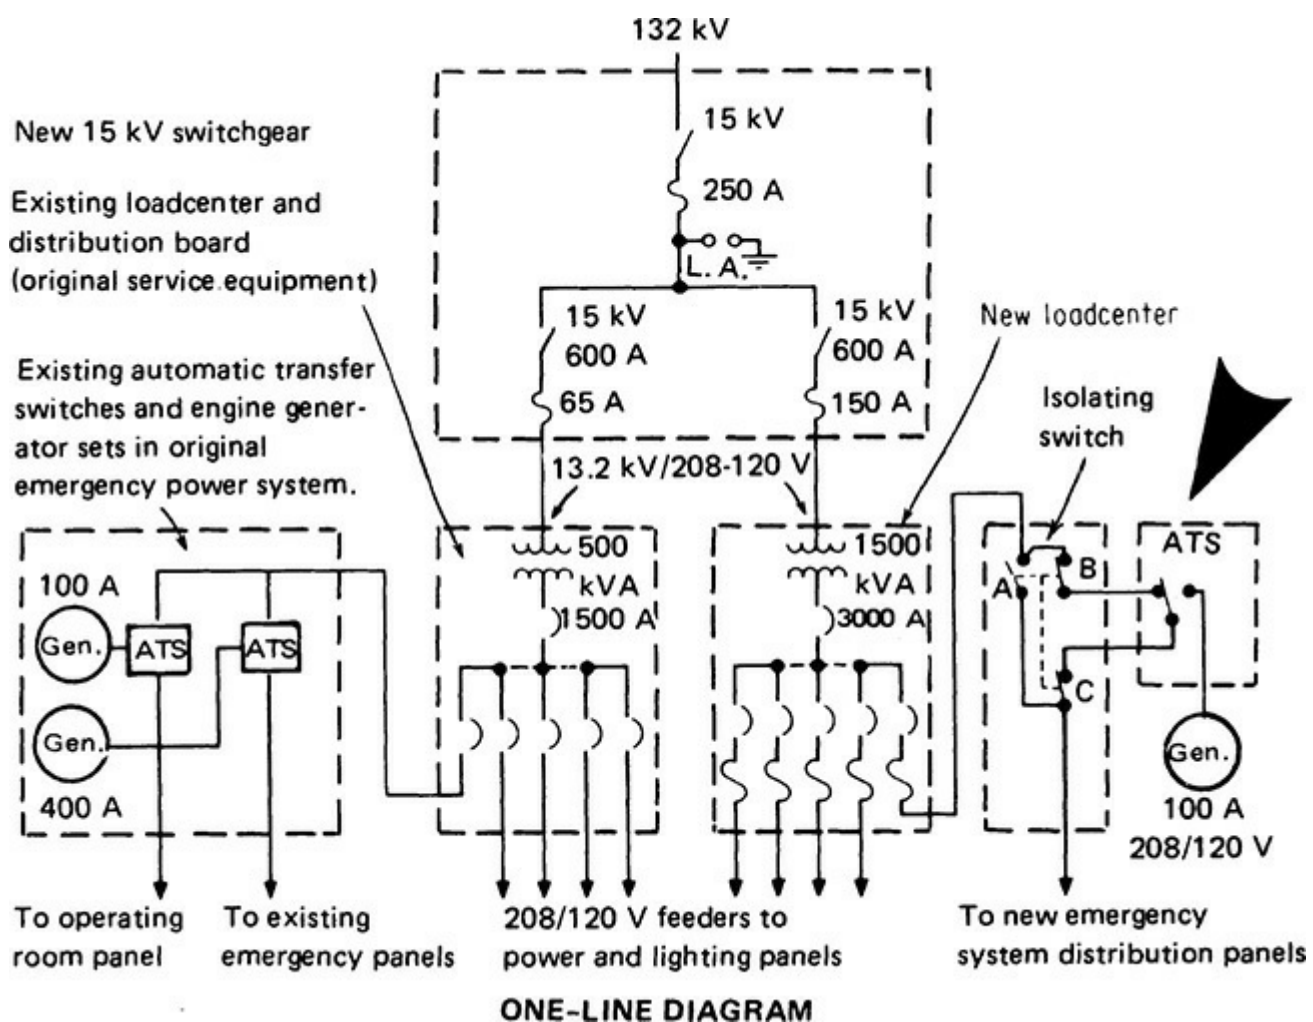

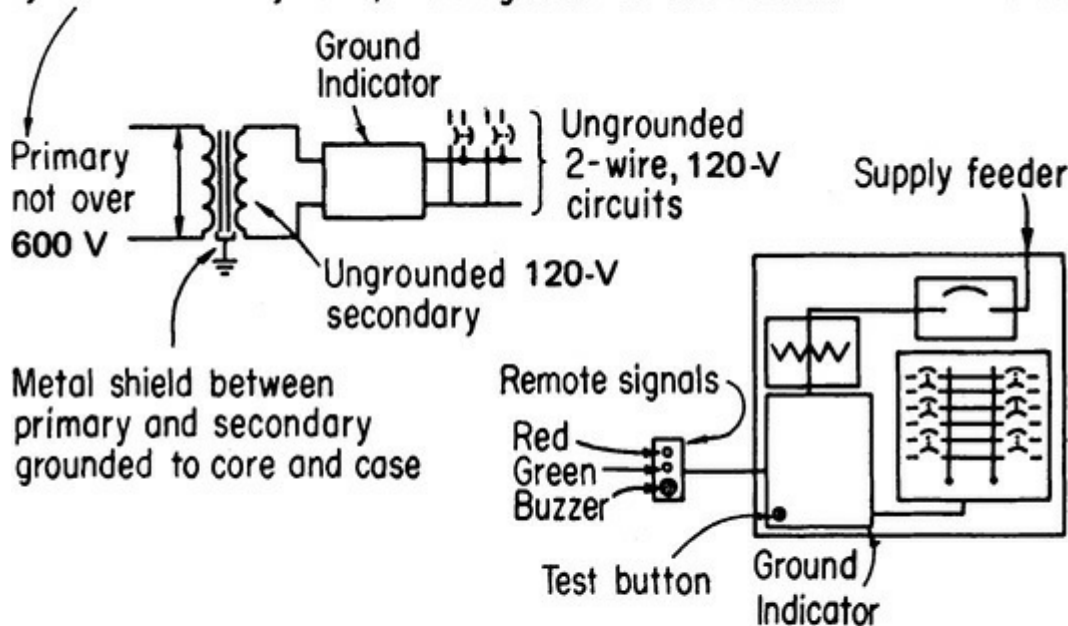

Fig. 517-10. General-purpose lighting circuits may be fed from the normal service, or from a separate alternate source. [Sec. 517.63(C).]

In part (F), an isolated power system (ungrounded operation with a line isolation monitor) is required only in an anesthetizing location with flammable anesthetics. Long ago, isolated power systems were required for locations with both flammable and nonflammable anesthetics. But in 1984, a revision was made in the former 517.104(A)(1) to change the phrase "anesthetizing" to "flammable anesthetizing" in this section. As a result, anesthetizing locations that do not use flammable

anesthetics (and as noted none do) don't require use of an isolated power system. 517.63(F) now makes the requirement for an isolated power system applicable only for anesthetizing locations where "flammable" anesthetics are used. For those cases where the anesthetizing location is used solely for nonflammable anesthetizing materials, an isolated power system is not mandatory in the **NEC** [although **NFPA 99** and 517.20(B) for some wet procedure areas still require it under some circumstances]. It is also used by design in many facilities.

Figure 517-11 shows the application of a completely packaged transformer loadcenter to provide power for the ungrounded, isolated circuits in hospital operating suites.

Supply can be made directly from two phase legs of 480/277-V system. On such systems, two stages of transformation are not needed

COMPLETE PACKAGED UNGROUNDED DISTRIBUTION CENTER FOR HOSPITAL OPERATING ROOM: Main CB, isolating transformer, ground indicator and CB panel for ungrounded circuits. For in-wall or floor mounting close to operating suite.

Fig. 517-11. Isolated power supply is required for circuits only in flammable anesthetizing locations. (Sec. 517.63.)

517.64. Low-Voltage Equipment and Instruments. Specific details are given for use of low-voltage equipment in an anesthetizing location. Figure 517-12 shows some of the rules. 517.160(A)(2) limits isolating transformers to operation with primary at not over 600 V.

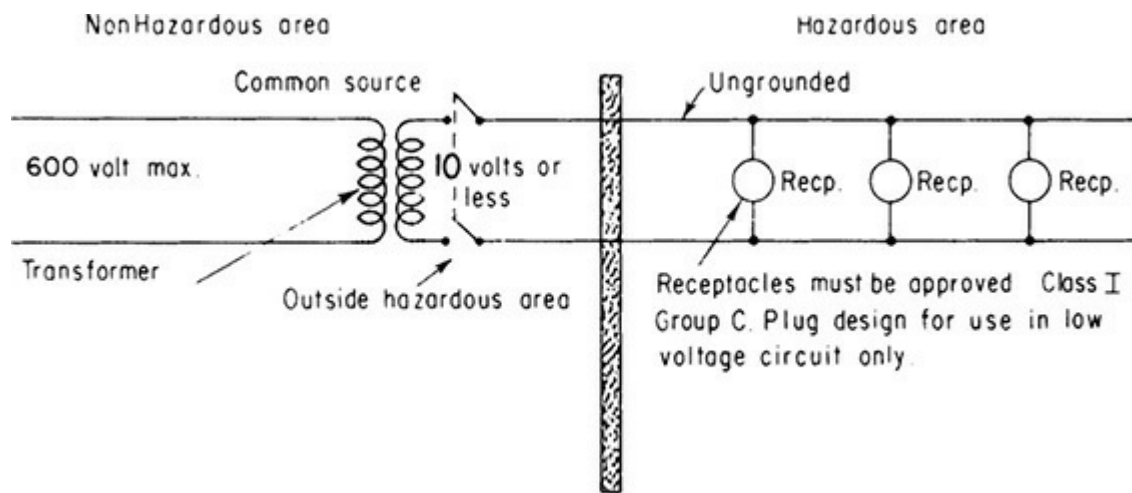

Fig. 517-12. Low-voltage circuits in anesthetizing locations must operate at 10 V or less or be otherwise approved. (Sec. 517.64.)

517.80. Patient Care Spaces. This section requires “equivalent insulation and isolation” to that required for patient care area power circuits, which has been interpreted as a requirement for equivalent mechanical protection, that is, raceways. For some time the raceway requirement has been debunked, but a new second paragraph here should decisively end all arguments. No special grounding requirements, no special mechanical protection requirements, and no special raceway requirement (unless required by [Chap. 7](#) or 8 of the **NEC**) apply. See also the discussion in this book at 517.31(C)(1).

517.160. Isolated Power Systems. Each isolated power circuit must be controlled by a switch that has a disconnecting pole in each isolated circuit conductor to simultaneously disconnect all power. That is in part **(A)(1)**. In addition, these circuits must not run within any raceway (or cable assembly or box or any other enclosure) that contains conductors that are not part of the isolated power system supplying those circuits. In fact, the literal text would even preclude conductors from two separate isolated power systems from running in a common raceway.

As covered in part **(A)(2)**, any transformer used to obtain the ungrounded circuits must have its primary rated for not more than 600 V between conductors and must have proper overcurrent protection. This Code rule used to limit the transformer primary to 300 V between conductors, which often required two stages of voltage transformation to comply with the rule, as shown in [Fig. 517-13](#). This diagram shows the circuit makeup used in a hospital to derive the 120-V ungrounded circuits, with transformation down from 480 to 240 V and then to 120 V. The ungrounded secondary system must be equipped with an approved ground contact indicator, to give a visual and audible warning if a ground fault develops in the ungrounded system.

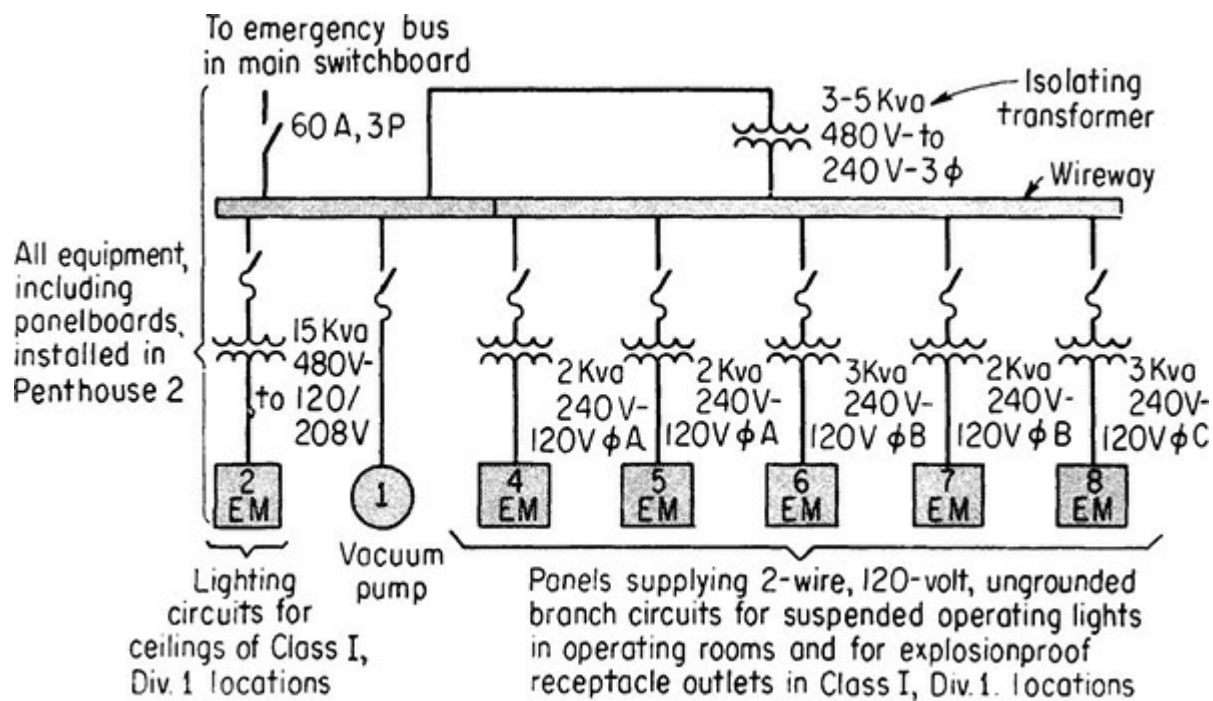

Fig. 517-13. Two-stage transformation was often needed for isolated circuits but is no longer necessary. (Sec. 517.160.)

Isolating transformers must be installed out of the hazardous area [part (A)(3)]. The ground indicator and its signals must also be installed out of the hazardous area. In an anesthetizing location, the hazardous area extends to a height of 5 ft (1.5 m) above the floor.

Fixed lighting fixtures above the hazardous area in an anesthetizing location, other than the surgical luminaire, and certain x-ray equipment may be supplied by conventional grounded branch circuits [517.63(B) and 517.63(C)].

Part (A)(5) requires isolated circuit conductors to be identified by brown and orange colors. Each wire must be striped with some color other than white, gray, or green so it will not be confused, for example, with the high leg on a center-tapped delta system, and that striping must run for the entire length of the conductor. Although these systems are ungrounded and therefore by definition have no grounded circuit conductors, there is still a standard protocol as to which color to use when connecting to the “white” side of a conventional 125 V receptacle. Use the striped orange wire for this side of the receptacle.

Part (B)(1) details a line isolation monitor and clarifies line isolation monitor alarm values, specifying 5.0 mA as the lower limit of alarm for total hazard current. Figure 517-14 shows the basic concept behind detection and signal of a ground fault. The diagram shows major circuit components of a typical ground detector/alarm system. Partial ground energizes current-relay A, opening contact A2 (energizing red light and warning buzzer). Pressing the momentary-contact silencer switch energizes coil C, opening contact C1 (disconnecting buzzer), and closing holding contact C2. When ground is cleared, contacts resume the position shown in Fig. 517-14. This equipment must be listed.

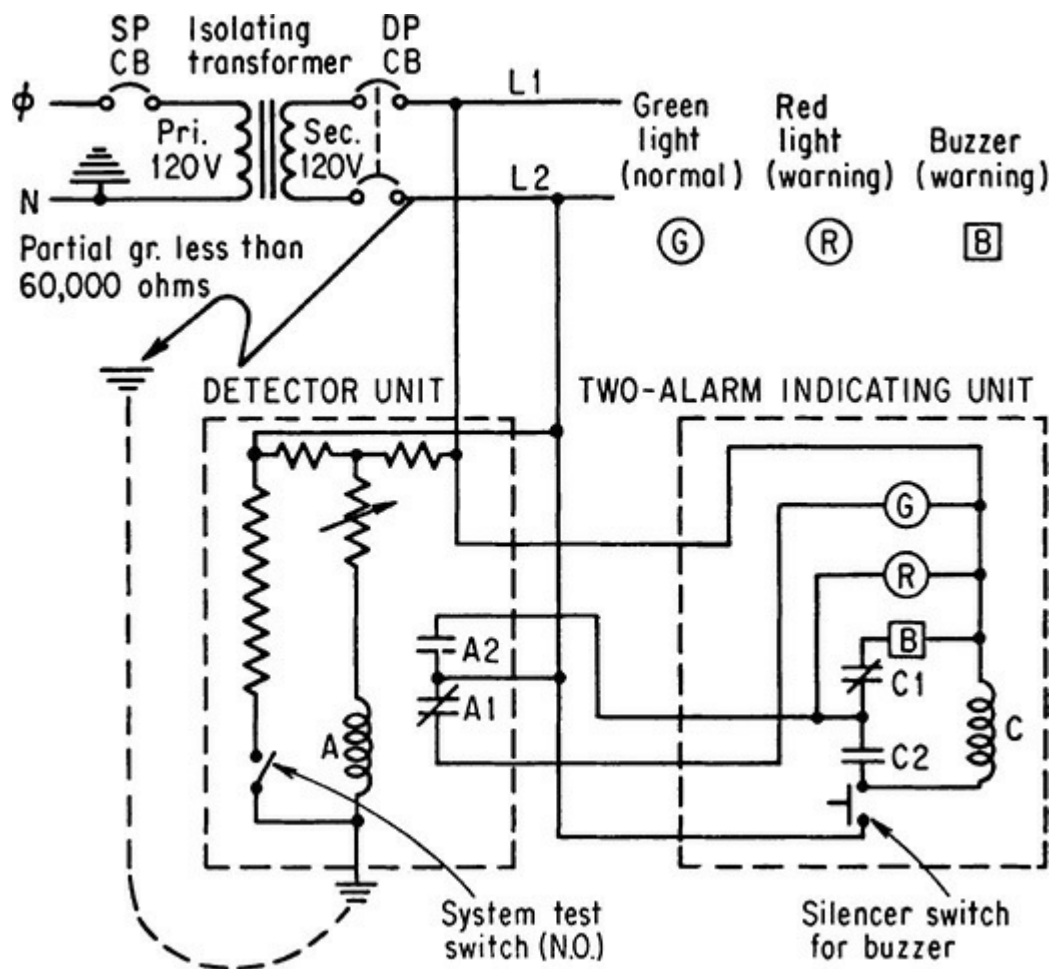

Fig. 517-14. Detection and alarm on ground fault is required for isolated power systems. (Sec. 517.160.)

The purpose of such a ground indicator is to provide warning of the danger of shock hazard and the possibility of a fault in the system due to accidental grounding of more than one conductor. If one conductor of an isolated system becomes grounded at one point, normal protective devices (fuses or CBs) will not operate because there is no return path and, therefore, no flow of short-circuit fault current. However, if an accidental ground subsequently develops on the other conductor, a short circuit will occur, with possible disastrous consequences, such as ignition of ether vapors by arc or a lethal shock to personnel.

ARTICLE 518. ASSEMBLY OCCUPANCIES

518.1. Scope. This article covers places of “assembly,” but does not apply to theaters, which are regulated by Art. 520. It covers any single indoor space (a whole building or part of a building) designed or intended for use by 100 or more persons for assembly purposes. That includes dining rooms, meeting rooms, entertainment areas (other than with a stage or platform or projection booth), lecture halls, bowling alleys, places of worship, dance halls, exhibition halls, museums, gymnasiums, armories, group rooms, funeral parlor chapels, skating rinks, pool rooms, transportation terminals, court rooms, sports arenas, and stadiums. A school classroom for less than 100 persons is not subject to this article. See 518.2. A supermarket with a rated occupancy load over 100 persons is not subject to this article because there is no assembly purpose and no likelihood of self-reinforcing panic during an emergency, as contrasted with the same number of people in an auditorium.

The clear differentiation given in this section points out that any such building or structure or part of a building that contains a projection booth or stage platform or even just an area that may, on occasion, be used for presenting theatrical or musical productions—whether the stage or platform is fixed or portable—must comply with the rules of Art. 520, as if it were a theater, and not Art. 518. A restaurant, say, that has a piano player for entertainment on Saturday night, could readily be classed as a theater and subject to Art. 520. This is covered in 518.2(C).

Article 518 directs attention “to a building or portion of a building” that would be used for the purposes outlined; therefore, you would have to determine how the occupancy is used.

A supermarket generally would not have a public assembly area. However, a department store could incorporate a community room for shows and similar audience functions. This room would be subject to Art. 518. The main areas of supermarkets and department stores, unlike theaters and assembly halls, have many aisles and exits that could be used in case of emergency evacuation of the building. It is these characteristics that permit conventional wiring methods to be accepted.

A proposal was once made to include supermarkets and department stores as “places of assembly,” but it was rejected.

Note that places of assembly covered by this article must be for 100 or more people. As a practical matter, questions of occupancy load belong with the local building official.

518.3. Other Articles. Part (B) permits exhibition hall wiring for trade shows and the like to use the temporary wiring in accordance with Art. 590, and also recognizes the use of dedicated cable trays for hard- and extra-hard-usage cords run in such trays. It also waives the GFCI protection rules for the temporary wiring that is necessarily widespread at exhibitions. However, all other GFCI rules do apply. For example, if an exhibit at a home-improvement trade show featured a wet bar, 210.8(B) (5) requires receptacles within 1.8 m (6 ft) of the sink to have GFCI protection. This section makes it clear that that requirement continues in force.

In addition, to provide that requirement at a trade show, it is very likely that the protection would be established at the end of an extension cord. When this happens the real possibility exists for a loss of neutral continuity. When this happens a conventional GFCI will fail on, because the internal electronics will have lost the voltage required to function. This is why 590.6(A)(2) requires GFCI “identified for portable use.” These devices have open neutral protection and disconnect in the event the neutral is open. This type of GFCI protective device is required to provide power in these cases. This is the practical solution and such devices are very much available; it is very unlikely that a field-assembled substitute, although allowed in this case, would be satisfactory.

518.4. Wiring Methods. The basic rule says that fixed wiring must be in a metal raceway, flex metal conduit, and nonmetallic raceways encased in *not less than 2 in. (50 mm) of concrete*, Type MI, MC or AC cable. Part (B) says that nonmetallic-sheathed cable, BX (Type AC cable), electrical nonmetallic tubing (ENT), and rigid nonmetallic conduit may be used in building areas that are *not* required by the local building code to be of fire-rated construction. Note that use of these methods no longer relates to the number of persons that the place holds, which was once in this rule. Another exception permits the use of other wiring methods for sound systems, communication circuits, Class 2 and 3 remote-control and signal circuits, and fire-alarm circuits.

Another allowance gives limited permission to use ENT and rigid PVC (and RTRC) conduits in smaller conference and meeting rooms in restaurants and in a variety of similar occupancies, provided the nonmetallic wiring is behind a thermal barrier providing at least 15 min of fire separation, such as conventional ½-in. drywall. It is also permitted above a suspended ceiling

assembled in compliance with a recognized fire rating protocol. Of course, if the suspended ceiling is air-handling, 300.22(C) would not allow such wiring methods within the plenum cavity ceiling.

ARTICLE 520. THEATERS, AUDIENCE AREAS OF MOTION PICTURE AND TELEVISION STUDIOS, PERFORMANCE AREAS, AND SIMILAR LOCATIONS

520.1. Scope. Where only a part of a building is used as a theater or similar location, these special requirements apply only to that part and do not necessarily apply to the entire building. A common example is a school building in which there is an auditorium used for dramatic or other performances. All special requirements of this chapter would apply to the auditorium, stage, dressing rooms, and main corridors leading to the auditorium but not to other parts of the building that do not pertain to the use of the auditorium for performances or entertainment.

520.2. Definitions. These are the specialized terms used in this article. Of note for the 2008 NEC is the new term (and technology) “Solid-State Sine Wave Dimmer.” This equipment produces current that varies with voltage over time, so both the current and voltage traces are in step. These dimmers do not draw harmonic currents from the neutral and the feeders and branch circuits they feed do not need to consider their neutrals to be loaded due to harmonic, nonlinear currents. They are also recognized in 518.5 for assembly areas.

520.5. Wiring Methods. Building laws usually require theaters and motion picture houses to be of fireproof construction; hence, practical considerations limit the types of concealed wiring for light and power chiefly to metal raceways. Only Type MI or MC cables may be used, or Type AC with an insulated equipment grounding conductor. Cables were long ago found unsuitable for circuits in theaters because they do not readily offer increase in the size of conductors for load growth. Many instances of overfusing dictated the value of raceways, which do permit replacement of larger conductors for safely handling load growth. Other wiring methods are permitted in areas for which the local building code does not require fire rating.

Much of the stage lighting in a modern theater is provided by floodlights and projectors mounted in the ceiling or on the balcony front. In order that the projectors may be adjustable in position, they may be connected by plugs and short cords to suitable receptacles or “pockets.”

There is an exception to the basic rule. Recording, communications, remote-control signaling, and fire alarm circuits may be installed using other wiring methods. And those installations described in parts (B) and (C) may also use other wiring methods.

520.6. Number of Conductors in Raceway. This rule is important because it removes the 30 conductor ceiling for waiving the mutual conductor heating limitations of 310.15(B)(3)(a). Therefore larger numbers of conductors can run within wireways and auxiliary gutters without a derating penalty. This arrangement is very advantageous for the large numbers of conductors, supplied by many different dimmers, that supply stage lighting that goes on and off as the lighting needs of a production change.

520.9. Branch Circuits. This section includes other important [Chap. 5](#) modifications of [Chaps. 1](#) through [4](#) rules (see 90.3), this one specifically waiving the 80 percent current limitation for receptacle loading on circuits with multiple receptacles or outlets that normally applies. For example,

each receptacle in a 20 A duplex receptacle or comprising multiple single 20-A receptacles on a 20-A circuit must not be loaded over 16 A under normal circumstances, but for theatrical applications every receptacle could be loaded up to the full 20 A as long as the receptacle rating was fully equal to the size of the overcurrent device. These receptacles typically operate for short loading periods that would not cause nuisance tripping of the overcurrent protection. It should be noted that the usual plugs and receptacles for this purpose are not of the usual NEMA configuration, but rather a linear arrangement of three unevenly spaced pins and sleeves for which the spacing polarizes the device.

The express permission in the first sentence “of any size” allows a receptacle circuit to supply stage lighting equipment of large current ratings even if it exceeds the 40- and 50-A limitations for lighting connections in 210.23. Normally, however, the loading will be subdivided through branch-circuit overcurrent devices that are lower than those sizes. Note also that 520.41(B) does not waive the enhanced lampholder requirements in 210.23 that apply to circuits rated above 20 A. This section grants permission to operate stage set lighting at 100 percent of a receptacle configuration, and also, for outdoor stage sets, to do without GFCI protection for such receptacles that would normally apply.

520.10. Portable Equipment Used Outdoors. Portable stage equipment not rated for use outdoors is permitted outdoors on a temporary basis, provided it is appropriately supervised and the general public is excluded from access.

520.21. General. The 2014 NEC has greatly modernized the coverage of stage switchboards. This section is completely rewritten, including a listing requirement and requiring all circuits supplied by the switchboard to have their overcurrent devices contained within it. This correlates with the definition, which includes the potential for dimmers and relays, and the result is that if the switchboard controls a circuit, it also includes the overcurrent device for that circuit. This work also correlates with the new part (D) of Sec. 520.26 that allows for a “constant power” type of stage switchboard that has no dimmers or relays. The former Secs. 520.22, 23, and 24 covered features for former switchboard designs that haven’t been necessary for over 40 years, and they have been deleted for correlation.

Major stage switchboards were commonly of the remote-control type. Pilot switches mounted on the stage board controlled the operation of contactors installed in any convenient location where space is available, usually below the stage. The contactors in turn controlled the lighting circuits.

The stage switchboard of many years ago was usually built into a recess in the proscenium wall, as shown in the plan view, [Fig. 520-1](#). After passing through the switches and dimmers, many of the main circuits were subdivided into branch circuits so that no branch circuit will be loaded to more than 20 A. Where the board was of the remote-control type, the branch-circuit fuses were often mounted on the same panels as the contactors. Where a direct-control type of board was used, and sometimes where the board was remotely controlled, the branch-circuit fuses were mounted on special panelboards known as *magazine panels*, which were installed in the space in back of the switchboard, usually in the location of the junction box shown in [Fig. 520-1](#).

Fig. 520-1. A plan view for an old-fashioned stage switchboard, some of which are still in use. Modern switchboards are not required to be on stage and may be set up in multiple locations. (Sec. 520.21.)

520.25. Dimmers. Figure 520-2 shows typical connections of two branch circuits arranged for control by one switch and one dimmer plate or section, dating back many decades. These few lines of explanation are for those who may become involved in an antique system. The single-pole switch on the stage switchboard was connected to one of the outside buses, and from this switch a wire ran to a short bus on the magazine panel. The magazine panel was similar to an ordinary panelboard, except that it contained no switches and the circuits were divided into many sections, each section having its own separate buses. One terminal of the dimmer plate, or variable resistor, was connected to the neutral bus at the switchboard, and from the other terminal of the dimmer a wire ran to the neutral bus on the magazine panel. This neutral bus had to be well-insulated from ground and separated from other neutral buses on the panel; otherwise, the dimmer would have been shunted and would have failed to control the brightness of the lamps.

Fig. 520-2. Branch circuits of lighting may be controlled by single dimmer in grounded or ungrounded conductor. (Sec. 520.25.)

While the dimmer was permanently connected to the neutral of the wiring system, this neutral was presumed to be thoroughly grounded and, hence, the dimmer was dead. A dimmer in the grounded neutral does not require overcurrent protection, as noted in part (A).

Figure 520-3 shows an autotransformer used as a dimmer. By changing the position of the movable contact, any desired voltage may be supplied to the lamps, from full-line voltage to a voltage so low that the lamps are “black-out.” As compared with a resistance-type dimmer, a dimmer of this type has the advantages that it operates at a much higher efficiency, generates very little heat, and, within its maximum rating, the dimming effect is not dependent on the wattage of the load it controls. These dimmers are seldom used today; contemporary dimming systems are digitally controlled.

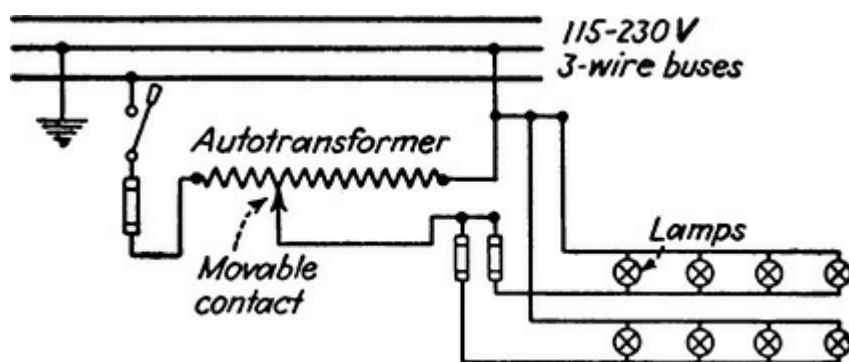

Fig. 520-3. Autotransformer dimmer must have grounded leg common to primary and secondary. (Sec. 520.25.)

Modern dimming systems use digital controls to control multiple dimmer racks with dozens of dimmers per rack and where necessary, multiple racks bused together with total capacities measured in hundreds of kilowatts. Each dimmer typically controls a single 20 A circuit.

520.27. Stage Switchboard Feeders. Part (A)(2) of this section covers the supply of patch panels, formally referred to in the **NEC** as intermediate stage switchboards. They receive power from dimmer banks operating at various voltage levels and distribute it out over the various available branch circuits as selected, allowing sets of luminaires to operate at one of the available dimmer settings in the main stage switchboard. For this reason there will be a number of feeders, one for each dimmer setting. In addition, there will be a common neutral return sized to the maximum unbalanced load, but it need not be larger than the primary stage switchboard neutral. If run in the form of parallel conductors, the usual rules for parallel conductors apply, including the obligation to represent the neutral in all parallel raceways, to use wires no smaller than 1/0 AWG, and to divide the load on the associated ungrounded conductors as equally as possible. The common neutral means that the originating switchboard must be fed with a single feeder.

As digital controls take over this industry, patch panels are becoming obsolete. Instead, the power is increasingly distributed from the primary stage switchboard, avoiding the intermediate layer in the distribution altogether. Because literally hundreds of dimmers can be located at a convenient location, and because they can be addressed electronically with multiprocessor support and controlled individually with ease, this is the direction the theater industry is moving. These dimmer

racks (switchboards) can be fed with a single feeder as in **(A)(1)**, or if of large size, fed with multiple feeders as in **(A)(3)**. In this case the switchboard must be prominently labeled with the disconnect location(s) and the number at each applicable location. Further, if the disconnects are from multiple switchboards, then the primary switchboards must include barriers to subdivide it in a manner that corresponds to the number of ungrouped remote disconnects that comprise its source of supply.

Part **(B)** used to require that all neutrals supplying these switchboards be counted as current-carrying conductors due to the harmonic loading produced by contemporary dimming systems. However, the advent of the new “solid-state sine wave 3-phase 4-wire dimming systems” made it possible for the 2008 **NEC** to waive this requirement, but only where the dimming is exclusively provided from such sources. If conventional dimming sources are used, in whole or even in part, then the neutrals must be counted as current-carrying.

Part **(C)**, which first entered the 1993 **NEC**, clarifies that switchboard feeders are permitted to be sized based on the maximum anticipated load, and not necessarily on the basis of every last watt that the dimmers can put out. There were many documented examples of inspection authorities making that insistence, which was completely unrealistic. To use this allowance the feeder must be protected at its ampacity (next higher standard size not allowed) and any egress or emergency lighting must be divorced from this feeder so it will be unaffected in the event it opens.

520.43. Footlights. A footlight of the disappearing type might produce so high a temperature as to be a serious fire hazard if the lamps should be left burning after the footlight is closed. Part **(C)** calls for automatic disconnect when the lights disappear.

There is no restriction on the number of lamps that may be supplied by one branch circuit. The lamp wattage supplied by one circuit should be such that the current will be slightly less than 20 A.

Individual outlets as described in part **(B)** are seldom used for footlights, as such construction would be much more expensive than the standard trough type.

A modern type of footlight is shown in [Fig. 520-4](#). The wiring is carried in a sheet-iron wire channel in the face of which lamp receptacles are mounted. Each lamp is provided with an individual reflector and glass color screen, or *roundel*. The circuit wires are usually brought to the wire channel in rigid conduit. In the other type of footlight, still used to some extent, the lamps are placed vertically or nearly so, and an extension of one side of the wire channel is shaped so as to form a reflector to direct the light toward the stage.

Fig. 520-4. Footlights must be automatically deenergized when the flush latch is closed down. (Sec. 520.43.)

520.44. Borders, Proscenium Sidelights, Drop Boxes, and Connector Strips.

[Figure 520-5](#) is a cross section showing the construction of a border light over the stage. This particular type is intended for the use of 200-W lamps. An individual reflector is provided for each lamp so as to secure the highest possible efficiency of light utilization. A glass roundel is fitted to each reflector; these may be obtained in any desired color, commonly white, red, and blue for three-color equipment and white, red, blue, and amber for four-color equipment. A splice box is provided on top of the housing for enclosing the connections between the border-light cable and the wiring of the border. From this splice box, the wires are carried to the lamp sockets in a trough extending the entire length of the border.

Fig. 520-5. Border lights must comply with **NEC** construction rules. (Sec. 520.44.)

Border lights are usually hung on steel cables so that their height may be adjusted and so that they may be lowered to the stage for cleaning and replacing lamps and color screens; hence, the circuit conductors supplying the lamps must be carried to the border through a flexible cable. The individual conductors of the cable may be of 14 AWG, though 12 AWG is more commonly used. Note that there is a special ampacity table in the **NEC** for listed extra-hard-usage cord connected to these luminaires.

This section also covers connector strips and drop boxes. A drop box has a number of receptacles mounted on it and connects through a multiconductor cable. A connector strip is a long metal wireway assembly (they are available in many lengths) with receptacles spaced along the strip, either directly on the strip or hanging as stage receptacle connector bodies from short-cord pendants. This equipment must be suitably stayed and supported, just as for border and proscenium lighting. It is also required to be listed as "stage and studio wiring devices." UL has no such classification exactly in the current Guide Card information [see discussion at 110.3(B) for details], but does show a "Stage and Studio Luminaires, Accessories and Connector Strips (IFDZ)" category whose products are being listed to the "Stage and Studio Luminaires and Connector Strips, UL1573" product standard.

The table governs the ampacity of extra-hard-usage multiconductor cords used for border lights, where they are not in direct contact with equipment containing heat-producing elements. The ampacities in this new table are identical to those in Table 400.5B in Column F (3 current-carrying conductors) for similar cords; however, where Table 400.5B begins at 8 AWG and goes up to 500 kcmil, this table begins at 14 AWG and goes up to 2 AWG. The ampacities below 8 AWG are proportionately reduced, but far higher than those in Table 400.5A which would otherwise apply to the smaller cords.

The table also sets the maximum overcurrent device ratings for each cord, which are identical to the values in Column A of Table 400.5A, that is, the traditionally determined cord ampacities for

cord with three current-carrying conductors. These values are far lower than the allowable cord ampacities. For example, 10 AWG 75°C rated cord has an ampacity of 41A and maximum overcurrent device rating of 25A. These cords often run in areas with comparatively high temperatures, and these restrictions add a safety factor for this as well.

The value of the higher ampacities comes where large numbers of these cables travel together in limited space, resulting in derating penalties. This frequently occurs in these applications. The new table helps here as well, resurrecting the old mutual conductor heating table break points with the 70 percent bracket applicable for 7-24 conductors, the 60 percent bracket for 25-42 conductors, and 50 percent for more. This table now appears in Annex B as Table B.310.15(B)(3)(11).

These more liberal factors are conditioned on at least 50 percent load diversity. This is normally the case for the same reasons that allowed the change in calculations for stage switchboard feeders in 520.27(C).

A new informational note provides a definition of diversity for the use of this table. It is the percentage of total current of all simultaneously energized conductors within the cable being calculated, divided by the sum of the ampacity ratings of all “circuits” in the cable. There are some problems with this wording, beginning with the fact that circuits do not have ampacity. For now this should be applied as the number of conductors that can potentially carry current. What is important is that this factor, should it calculate below 50 percent, is a significant constraint on how the table can be applied. Many stage applications rely on assemblies with large numbers of conductors, and the prospect of mandatory applications of large derating factors is a significant constraint. Note that this table was titled Table 520.44 in prior Codes, and is now being titled Table 520.44(C)(3) even though that particular reference has nothing to do with ampacity calculations and the table should be retitled 520.44(C)(2).

If the current-carrying conductors exceed 50 percent of the total, then the derating factors in Table 400.5(A)(3) would have to be applied in order to avoid overheating the cables and violating the ultimate insulation temperature restriction at the bottom of the table.

Under typical stage conditions, it should almost always be possible to stay within this table for calculations using extra-hard-usage cords in general. The allowances are limited to extra-hard-usage cord, which includes the stage cables (SC, SCE, and SCT). Part (C)(1) generally requires extra-hard-usage cord for this equipment. Note that the new stage lighting hoists listed as complete assemblies with integral cable handling systems, as covered in 520.2 and 520.40 as of the 2014 **NEC**, are exempt. These hoists use specially configured cables, often flat, for which this requirement is impracticable.

Part (C)(3) provides further practical assistance for wiring this equipment, beyond the allowable ampacity modifications. For drop boxes and connector strips, the usual multiconductor cord configurations do not contain a white wire for every colored wire, and stage personnel would prefer to use these cables and reidentify some of the colored conductors. Access to this equipment is generally limited to qualified personnel. Therefore, 200.6(E) Exception No. 1 and 250.119(B)(B) already allow, under these conditions, both grounded and grounding conductors within multiconductor cables to be established through color coding methods applied in the field. However, allowance from the inspection community has been uneven and so this subsection provides unequivocal field permission to alter the color code on these wires at their points of termination.

520.49. Smoke Ventilator Control. A normally closed-circuit device has the inherent safety feature that, in case the control circuit is accidentally opened by the blowing of a fuse or in any other

way, the device immediately operates to open the flue dampers.

520.50. Road Show Connection Panel (A Type of Patch Panel). This section effectively describes the interface between fixed stage wiring and portable stage switchboards as defined in 520.2 and covered in Sec. 520.53. Note that these provisions cover the construction of the connection panel and do not apply to wiring connected thereto. Part (A) requires the point where a circuit is connected to consist of an inlet that matches, by current and voltage, that of the receptacle supplied at the other end of the wiring outlet controlled by the panel. Part (B) requires that when a panel transfers power from the fixed switchboard in the building to that supplied by the portable switchboard, the transfer must include all circuit conductors including the grounded circuit conductor, and the transfer must be simultaneous with respect to all circuit conductors. Part (C) requires supplemental overcurrent protection for the supplied connections. Although this is normally provided in the supply switchboards, there are instances in old theaters where this cannot be relied upon, and the supplementary protection required here is important because as their name implies, these panels do not have a permanent address.

520.51. Supply. This section addresses the actual connection point for portable stage switchboards. These are often referred to as a “bull switch”; see the definition of this term in 530.2 for more information. The literal text calls for “power outlets” with the appropriate voltage and current rating. Be careful here because a “power outlet” in this context however, is not necessarily the equipment covered under this heading in the UL Guide Card information (guide card designation QPYV). Although the UL-covered equipment (typically enclosed assemblies incorporating receptacles and fused switches or circuit breakers) is certainly suitable for this application, it seems intended that this section also includes other connection methods including sequential interlocking connections of single conductors as covered in 520.53(K) and even direct connections to busbars, as covered in 520.53(H)(1). Although these latter references expressly cover only the load end of the feeder, the same feeder must have a supply connection. If the only possible connection were to an appropriately rated power outlet, then most of the motivation for special precautions and warning labels in 520.53(P) would disappear.

520.52. Overcurrent Protection for Branch Circuits. The portable switchboard is responsible for the overcurrent protection, but the usual limitations of 210.23 such as apply to receptacle loading at 80 percent do not apply to these circuits.

520.53. Construction. This section and the next cover the requirements for supplying portable switchboards (dimmer racks) used on stage, with this section focusing on the equipment. This equipment is covered by UL under the category “Power Distribution Equipment, Portable (Guide Card designator QPRW).” Part (A) requires a pilot light arranged to show the presence of power even if a main switch on the unit is in the open position.

Part (B) covers special rules for feeder neutral terminals. The neutral busbars and connecting supply terminal on a 3-phase 4-wire portable switchboard must “have an ampacity” not less than twice the “ampacity” of the largest ungrounded supply terminal. This oversizing allows these portable switchboards to be connected to single-phase systems where two phases will be connected to one phase line, potentially doubling the neutral current. If the portable switchboard has been specifically designed for field rearrangement from single- to three-phase and back again with the single-phase loading being left in balance when used, then the double size requirement is waived.

Part (C) covers single-pole separable connectors, which include three forms. This rule

specifically waives the normal strain relief rule in 400.14, and thereby meets the exception thereto. It also waives the unique configuration and marking rules in 406.7 and 406.8 because such devices are rated in amperes but can be used on many circuit configurations including parallel applications where there will be any of a number of Phase “A” and “B” and “C” and “N” conductors, etc. For parallel applications, there must be a prominent label advising of the internal parallel connections. A compliant installation where these are used must meet at least one of three design criteria. The first is that the connections are interlocked with the source such that the feeder is deenergized until the connections are complete. The second option uses listed sequential interlocking mechanisms to assure appropriate sequencing of connections, with equipment grounding first, neutral second, and phase conductors last, with the reverse order for disconnection. The final option is single connectors with no interlocking mechanism, in which case a label at the line connections must detail the correct connection sequence. Note that any such application must only be serviced by qualified individuals, as covered in 520.54(K).

Part (D) allows an outlet for a feed-through feeder connection to avoid local overcurrent protection if it is of the same rating as its supply counterpart. This is entirely unnecessary; if the supply side is properly protected then the load side will be as well, but it is also harmless. Unlike the other parts of these two sections, this alone is new for 2017.

In Part (E), specs cover conductors within portable stage dimmer switchboards, which must be stranded. Prior to the 2017 NEC, there were detailed rules covering the temperature ratings of conductors permitted in dimmer boards, based on the type of dimmer used. The rules recognized the difference in temperature of dimmers and permitted lower-rated conductors for solid-state dimmers. Those rules have been removed in favor of a comprehensive listing requirement in the parent language due to the sophistication involved in modern equipment.

520.54. Supply Conductors. Part (A) covers the general specifications for the feeder conductors to these units, which often are on casters to allow for easy repositioning. As such, the feeders must utilize a robust and flexible method of connection, and therefore require listed extra-hard-usage cord or cable. As in cases covered by 520.27(C), the supply ampacity must equal the load connected to the switchboard, and need not be sized in terms of its maximum capacity.

Part (B) requires that unless the switchboard is only using pure sine-wave dimmers, the neutral must be assumed as harmonically loaded and therefore required to be counted as current-carrying in terms of mutual conductor heating calculations.

Part (C) covers the use of single-conductor cable sets, provided the conductors are not smaller than 2 AWG. Single conductors do not experience mutual conductor heating and therefore have much higher ampacities than multiconductor make-ups. This makes them useful for these applications. For example, the ampacity of 2 AWG 75°C stage cable [from Table 400.5(A)(2)] is 170 A; if 75°C multiconductor cable were used, 520.54(B) would require counting the neutral on conventional dimmers, and therefore $(170 \text{ A} \div 0.8 = 213 \text{ A})$ a 3/0 AWG cable would be required. Such a cable weighs in at about 4.5 kg/m (3 lb/ft) and would not be practical for this use.

Parts (D) and (E) address tap rules for portable switchboards. They allow for smaller switchboards to be connected to larger sized power outlets covered in 520.51 without additional overcurrent protection. The feeders must not penetrate structural elements of the building, or run through doors or other traffic areas and must terminate at a single overcurrent device in the portable switchboard. This device must protect the feeder from overload by its size; no next higher standard size allowance applies here. If run as single conductors, the feeder conductors must not be bundled,

and the terminations must be approved. Specifically, **(D)** covers 3.0 m (10 ft) taps, and in addition to the foregoing the feeder conductor ampacity must be not less than one-quarter of the rating of the supply-side protection, and the feeders must be kept off the floor in an approved way. Part **(E)** covers 6.0 m (20 ft) taps, which must adhere to the same rules except the protection ratio of one-half is more conservative, and these taps must be elevated not less than 2.1 m (7 ft) above the floor, except at terminations.

Part **(F)** allows feeders to pass through holes in a wall if specifically designed for this purpose, and provided the feeder is not using one of the tap allowances in the prior two paragraphs. The hole must be fire-stopped if a fire rating applies to it. This allows for special shows to run off an outdoor generator that would otherwise overtax the existing stage distribution system in the building.

Part **(G)** requires protection against physical damage to these conductors. For example, there are rubber mats designed for this purpose if the feeder runs on a floor, and if mutual conductor heating is not problematic, raceway protection is another option.

Part **(H)** limits mated conductor pairings (as in plugs and connector bodies) for feeders to three per run up to 30 m (100 ft). In the common instance where there is such a connection at each end, the rule would set a minimum cord length of 15 m (50 ft) for at least one set of cords. If the run is longer, one additional interconnection is permitted for every 30 m (100 ft).

Part **(I)**, by specifically recognizing paralleled applications, also modifies 310.10(H)(1) to lower the threshold from 1/0 AWG to 2 AWG for these applications, although the equal length and the equal sizing rules still apply. In support of the principle that mutual conductor heating should not be a factor, the wording specifically prohibits bundling the single conductors, although they are to be grouped. The grounded conductors must be identified with at least 150 mm (6 in.) of marking at each end with white or gray, and the equipment grounding conductor (permitted to be not smaller than 6 AWG and otherwise sized by 250.122) the same way except the color is to be green. The ungrounded conductors must be identified by system if multiple voltage systems are present in the premises wiring.

Part (J)(1) duplicates the neutral marking rule in (C). The grounded conductors must be identified with at least 150 mm (6 in.) of marking at each end with white or gray. Part (J)(2) requires that the ampacity of a neutral on a multiphase system feeder to a portable stage switchboard must have an ampacity of 130 percent of the ungrounded conductors in cases where the feeder is run as single conductor cables. This rule only applies to single conductor uses, where the customary 125 percent increase in size for four conductors in a raceway or cable will not apply. This rule is due to the electrical characteristics of typical stage dimmer circuits and is not a response to the more general problem of harmonic currents. The U.S. Institute of Theatre Technology presented an analysis that the worst-case loading would occur when one phase was off, one phase was 100 percent loaded, and the third phase loaded to 55 percent; this would produce a 126 percent load on the neutral. For multiconductor cables, the harmonic content means the neutral is counted, resulting in a 125 percent factor already and this is judged sufficient to handle this loading. However, for single conductor cables, no such rule applies, so this section imposes a 130 percent factor. As in other comparable applications, the extra loading requirement is waived if the entire dimming system uses the new solid-state sine wave dimmers.

Part (K) requires portable stage switchboards to be connected by qualified personnel, and they must be conspicuously marked to indicate this requirement. An exception applies to smaller feeders 150 A and below using multipole receptacle outlets. The qualified personnel requirement applies to

routing conductors, as well as to making and breaking connections and to energizing and deenergizing the switchboards. The exception only applies where a multipole, permanently installed receptacle outlet has overcurrent protection not above its rating and where it is not accessible to the general public. Extra-hard-usage cord with an ampacity equal to the receptacle rating must be used. The concept is that if the only task is to plug a multiconductor cord into an appropriately located power outlet, the work can be left to an amateur.

520.61. Arc Lamps. This section requires that all arc lamp fixtures must be listed, including any associated ballasts and interconnecting cables and cord sets. The term “arc lamp fixture” is intended to include all fixtures that rely on an arc lamp as the source of light, whether carbon-arc or HID. The motivation for the current wording came from concerns about extremely high-energy lighting sources that are being used in stage settings. Some of these sources use 24,000 W lamps with 90,000 V ignition circuits.

520.65. Festoons. “Lanterns or similar devices” are very likely to be made of paper or other flammable material, and the lamps should be prevented from coming in contact with such material. Staggering the joints lessens the likelihood of a line-to-line arcing fault that could start a fire in such lamps. The second sentence incorporates the requirement for stranded wire to be used with insulation-piercing lampholders as has long appeared in 225.24 for comparable outdoor uses.

520.68. Conductors for Portables. The basic rule is for listed extra-hard-usage flexible cord. Stand lamps are permitted with hard-usage cord. As of the 2014 **NEC** hard-usage cord in lengths not over a meter are allowed to connect to a listed luminaire or to an inlet on the luminaire with a “luminaire-specific listed connector.” Luminaires operating at high temperatures are permitted with a 1.0 m (3.3 ft) connection typically consisting of some form of high-temperature fixture wire enclosed in a glass braid of some sort, and terminating in a pin-type stage plug. The braid is clamped by the plug housing and the luminaire connection, which provides a measure of strain relief. Paragraph 4 covers “breakout assemblies” and allows them to be made of hard-usage cord. They allow for one or multiple branch circuits to be taken out of a multiconductor cable that may have as many as 37 conductors within it. The use of hard-usage cord allows this to be done on a practical basis, and is appropriate given the conditions placed on their use. Limited to 20 A circuits, the branch cable cannot exceed 6.0 m (20 ft) and must be routed over its length attached to structure or other rigid supports. Note that this rule is not restricted to the supply of cord bodies, and that breakout plug assemblies are also available, in accordance with the same rules.

Part **(B)** allows cord ampacities and maximum currents to follow Table 520.44 unless they are in direct contact with “heat producing elements,” in which case the usual 400.5 provisions apply. The fixture wires used in accordance with 520.68(A)(3) use conventional Code ampacity provisions, which in this case would be Table 402.5. This code rule now makes an express reference to the 50 percent diversity parameter in Table 520.44(C)(3). A low diversity factor applied to the cords commonly used under these rules may be a significant design constraint. Review the commentary provided at the table location in this book for additional information.

520.69. Adapters. The “two-fer” (a male plug made up with a molded splice generally configured in a wye arrangement to feed two female receptacles) is a good example of the use of this section. The current and voltage ratings of the plug and the receptacles supplied must be identical, with no reduction in current rating to either branch. See the definition in 520.2 and also Sec. 520.67 for additional requirements. The conductors must be listed, extra-hard-usage cord. Alternatively, hard-usage cord with its overall length limited to 2.0 m (6.6 ft) can be used.

520.72. Lamp Guards. Lamps in dressing rooms should be provided with guards that cannot easily be removed to prevent them from coming in contact with flammable material.

520.73. Switches Required; 520.74. Pilot Lights Required. The luminaires and receptacles located adjacent to the mirrors and above a dressing table in a dressing room must be controlled by one or more wall switches located in the dressing room but equipped with pilot circuits brought out to a point near the dressing room door. This allows supervisory personnel to quickly determine if likely loads in the dressing areas are still connected. As of the 2017 **NEC**, the pilot lights needs to be equipped with LEDs or extended-life lamps, recessed or guarded, and carry a marking to show what its switch controls.

ARTICLE 522. CONTROL SYSTEMS FOR PERMANENT AMUSEMENT ATTRACTIONS

This article was new as of the 2008 **NEC**. It covers the unique wiring requirements of permanent theme parks and comparable attractions, such as Disney World. There are almost 500 of these parks now operating in the United States, and many others in different countries that also use the **NEC** for their electrical installation standard. It is a very unusual article in that it does not cover power circuits, only the controls for equipment connected to power circuits. As such it recognizes and provides an ampacity table for conductors as small as 30 AWG.

ARTICLE 525. CARNIVALS, CIRCUSES, FAIRS, AND SIMILAR EVENTS

525.1. Scope. The rules given here apply to the wiring of temporary power used to supply power to rides and amusements at circuses, and so on. However, it should be remembered that, unless otherwise modified by Art. 525, the requirements given in [Chaps. 1 through 4](#) also apply.

525.3. Other Articles. This article doesn't apply within permanent structures; Art. 518 and 520 apply instead. Art. 640 applies to audio signal and related wiring and equipment. Art. 680 (presumably focusing on Part **I** on general rules and Part **III** on storable applications, but the reference, to the entire article in violation of the whole-article reference prohibition in the **NEC** Style Manual, is extremely unclear) applies to attractions using contained volumes of water.

525.5. Overhead Conductor Clearances. Portable structures must not be placed under or within 4.5 m (15 ft) horizontally of overhead medium-voltage conductors, including utility primaries arranged on adjacent poles. This 4.5 m (15 ft) exclusion is to be applied from any point directly under the overhead conductors to a point on grade 4.5 m (15 ft) away, on both sides, all the way up to the level of the overhead conductor span. An example would be a standard 13.8 kV 3-phase utility primary run on cross-arms with a total span of 1.8 m (6 ft) between the outer phase wires [i.e., 900 mm (3 ft)] to either side of the actual pole line. No portion of any Ferris wheel, merry-go-round, portable ticket booth, or other "portable structure" shall be placed within 5.5 m (18 ft) of that pole line. The 4.5 m (15 ft) clearance also applies in any direction from overhead wiring at 600 V and below, except for the supply conductors to the structure.

525.10. Services. If in locations accessible to unqualified persons, service equipment must be lockable. It must be securely fastened to solid backing and protected from weather (unless

weatherproof).

525.11. Multiple Sources of Supply. If multiple power sources, such as two different generator wagons, supply adjacent portable structures, the equipment grounding conductors of both sources must be bonded together if the structures are separated by less than 3.7 m (12 ft). The size of the bonding conductor must not be less than the required size of an equipment grounding conductor that would be used (per Table 250.122) based on the largest overcurrent device supplying load in either of the two structures, but in any case not smaller than 6 AWG.

525.20. Wiring Methods. The principal wiring method for traveling carnivals is flexible cord. As presented in (A), for general use it should be listed for extra-hard service and for outside venues, listed for sunlight resistance and wet locations as well. Single-conductor cable is not permitted below 2 AWG, and splices are not permitted. Cord connectors must not be laid in traffic paths or within areas accessible to the public unless guarded. They must not be laid on the ground unless booted or otherwise made suitable for wet locations. They must be arranged so they do not create a tripping hazard, and they should be covered with low-profile matting that does not increase the tripping hazard. They can be pushed into a slit in the ground and then taken up because 525.20(G) waives 300.5 for these events. The conductors must only be spliced in boxes or in a comparable enclosure.

525.21. Rides, Tents, and Concessions. Each “structure,” which would include rides such as Ferris wheels, must have a disconnecting means within 1.8 m (6 ft) of the operator’s station at a readily accessible point while the ride is operating. A shunt trip device controlled from the operator’s console is acceptable for this purpose. Wiring in tents and concession stands must be securely supported and provided with mechanical protection if subject to damage. Lamps must be either mounted within a luminaire or equipped with guards.

525.22. Portable Distribution or Termination Boxes. If used outdoors, these boxes must be arranged to sit at least 150 mm (6 in.) above the ground, and of weatherproof construction. The overcurrent protection ahead of the box must not exceed the current rating of any included busbars. Where the box includes receptacles, overcurrent protection must be included within the box, rated not higher than the receptacles.

525.23. Ground-Fault Circuit Interrupter (GFCI) Protection. As covered in part (A), all 15- and 20-A, 125-V rated non-locking-type receptacles and equipment accessible to the general public must be provided with GFCI protection for personnel protection. There is no waiver for equipment incompatible with a GFCI, as in the recent past. The idea is that if a GFCI is nuisance tripping, the appliance should be repaired or replaced. There are many old popcorn popping machines and comparable equipment with an electrical resistance inserted into refractory material that is somewhat conductive until it heats up and drives the water out of the refractory insulation. Until that happens, a GFCI will nuisance trip. However, it is also true that modern equipment designs do not have this shortcoming. In part (B) the Code states that there is no need for locking-type receptacles to be GFCI protected. This rule, for “quick disconnecting and reconnecting” is aimed at the multiple connections of lighting strips and other connections on large rides. Receptacles qualifying under this waiver must not be accessible from grade. And (C) states that circuits supplying egress lighting are prohibited from employing GFCI protection.

The 2017 **NEC** added an additional part (D) to address widespread misunderstanding and improper use of conventional GFCI receptacles mounted in a box and fed using flexible cord,

especially at venues governed by this article. That practice is unsafe because if the neutral connection opens, the GFCI will fail closed, removing all shock protection from the energized side of the receptacle. There have been documented fatalities from this problem, which is why 590.6(A)(1) only allows GFCIs identified for portable use in such cases on construction sites. A GFCI for portable use has a drop-out relay built into it that opens both sides of the circuit if circuit voltage fails.

This new provision is carefully written to address branch circuits. Portable distribution equipment supplied by feeders (see Fig. 590-5 for an example) and equipped with multiple GFCI devices supported with circuit breakers so as to originate multiple protected branch circuits fully comply with the new rule.

525.32. Grounding Conductor Continuity Assurance. Each time portable electrical equipment is deployed, the continuity of the grounding system must be verified. This would presumably take place during the final stages of set-up at each venue. The electrical inspection community may need to stipulate timing and access so as to be able to judge compliance with this requirement.

ARTICLE 530. MOTION PICTURE AND TELEVISION STUDIOS AND SIMILAR LOCATIONS

530.1. Scope. Article 520 covers theaters used for TV, motion picture, or live presentations where the building or part of a building includes an assembly area for the audience. Article 530, however, applies to TV or motion picture studios where film or TV cameras are used to record programs and to the other areas of similar application, but where the facility does not include an audience area.

The term *motion picture studio* is commonly used as meaning a large space, sometimes 100 acres or more in extent, enclosed by walls or fences within which are several “stages,” a number of spaces for outdoor setups, warehouses, storage sheds, separate buildings used as dressing rooms, a large substation, a restaurant, and other necessary buildings. The so-called stages are large buildings containing numerous temporary and semipermanent setups for both indoor and outdoor views.

The Code rules for motion picture studios are intended to apply only to those locations where special hazards exist. Such special hazards are confined to the buildings in which films are handled or stored, the stages, and the outdoor spaces where flammable temporary structures and equipment are used. Some of these special hazards were due to the presence of a considerable quantity of highly flammable film, but this is rarely the case today since nitrocellulose film was discontinued in the early 1950s; otherwise, the conditions are much the same as on a theater stage and, in general, the same rules should be observed as in the case of theater stages. The rules in this article also amend provisions in Chap. 1 through 4 in ways that reflect some unusual load profiles and time factors that make possible special allowances.

530.11. Permanent Wiring. At one time, this section used the word *metal* between “approved” and “raceways,” in the first sentence. Because the word *metal* no longer appears in the rule, rigid nonmetallic conduit is, therefore, acceptable for use in motion picture and TV studios. In addition to raceways, Type MI and Type MC cables and Type AC cable with an insulated grounding conductor are also permitted.

In the exception, Class 2 and 3 remote-control or signaling circuits and power-limited fire-protective signaling circuits are exempted from the basic rule requiring permanent wiring to be in

raceways or certain cables. These circuits, along with communications and sound recording and reproducing circuits, are exempt from the basic rule.

530.12. Portable Wiring. Wiring that would be subject to physical damage needs to be extra-hard-usage cord; otherwise hard usage is permitted. Splices are permitted provided the load doesn't exceed the cable ampacity. Stage effect wiring can be either single or multiple conductor listed cord, provided it is protected from damage and secured to the scenery with cable ties or insulated staples. Splices are permitted only with listed devices on circuits not over 20A. For other equipment, cords that aren't suitable for extra hard usage are permitted if shipped as part of a listed assembly and protected at not over 20 A.

530.13. Stage Lighting and Effects Control. This section covers the use of "location boards" as defined in 530.2. They are a form of switchboard with fused switches or circuit breakers typically in the 200 A range protecting 3-wire circuits, so they can be used to source 200 A of line-to-neutral load on both ungrounded supply legs (total of 400 A). This equipment is usually mounted with casters and also often has a pulling eye in the upper surface so it can be hoisted to an elevated walkway. The common "deuce" board has two such switches, allowing it to supply double that amount of power. Usually contactors are arranged within the boards at a point where the board can be turned off or on all at once, or busbar by busbar. A local switch must be placed within 1.8 m (6 ft) of the board for each contactor, or a single switch that drops out all the contactors at once is also permitted. Today, it is common for these boards to be controlled at the stage level by incorporating suitable electronic controls that govern the switching activity within the board.

530.14. Plugging Boxes. At one time these were used on both ac and dc circuits; however they are unpolarized, which led to hazards when ac equipment designed with single-pole switching was connected. They were generally limited to dc applications, and effective with the 1987 **NEC**, ac connections are not permitted.

530.17. Portable Arc Lamps. At one time the only practical source of intensely white light in amounts large enough to illuminate studio sets came from drawing a dc arc between two carbon electrodes. The carbon electrodes would gradually burn back in the process, requiring them to be constantly advanced so the gap would remain constant. Early designs relied on manual supervision; later designs used mechanized methods to do the same thing. The current required for large-scale illumination was impressive, running on the order of 150A. The development of xenon filled high-intensity discharge lighting (introduced in 1954) made carbon arc light sources essentially obsolete by the 1970s, but many facilities still have the ac infrastructure in place. The xenon sources including their ballasts must be listed. These lamps operate with a color temperature of about 6200°K (about the same as the sun) and a color rendering index (CRI) only slightly below 100 percent.

530.18. Overcurrent Protection—General. Part (A) allows stage cables to be protected at 400 percent of their ampacity, and this percentage carries through in (B), (D), and (E). It is a short-time rating and is based on the time that the conductors are energized during production, generally on the order of 10 min and not over 20 min. Part (C) covers cable protection and roughly parallels 520.53(H)(5), covered extensively in this book, in order to address similar concerns. Note that the final sentence of the parent text at the beginning of the section specifically requires that conductors be sized in accordance with the load to be supplied. This sentence clarifies that although the overcurrent protection can be rated up to 400 percent of ampacity, it is never permitted to impose loads on conductors greater than normal Code rules permit. The 400 percent rule allows for flexibility of

arranging circuits, and does not justify overloading conductors. Studio equipment undergoes testing based on the higher overcurrent protection values permitted in this article.

530.19. Sizing of Feeder Conductors for Television Studio Sets. This section provides a table of demand factors that allow reductions in total feeder capacity for permanent studio and stage set lighting feeder loads. Portable feeders enjoy a blanket 50 percent demand factor.

530.21. Plugs and Receptacles. Part (A) covers ratings, which must not be less than the circuit voltage, and for ac circuits, the ampere ratings not less than the feeder or branch-circuit overcurrent device rating. Table 210-21(b)(2) does not apply. This is a similar allowance as in 520.9 for theatrical work. It allows fully rated and potentially fully loaded 20 A cord-and-plug-connected loads to plug into multioutlet 20 A branch circuits, which would otherwise be limited to 16 A by Table 210-21(b)(2). Some stage set lighting loads, such as 10,000-W 120-V luminaires, exceed 80 A.

Part (B) covers plugs and receptacles used in portable professional motion picture and television equipment, which can be interchangeable for ac or dc use on the same premises provided they are listed for ac/dc use and marked in a suitable manner to identify the system to which they are connected. Both types of power are commonly in use on the same premises in today's studios.

530.22. Single-Pole Separable Connectors. This section parallels 520.53(K), for which this book has complete coverage. Part (B) adds the ac/dc interchangeability principle in 530.21(B) to this location as well.

530.41. Lamps at Tables. This section, essentially unchanged for over 70 years, requires luminaire construction at film editing tables to be constructed in ways that make ignition of film scrap unlikely. This rule is rooted in the days of nitrocellulose film (a compound also known as guncotton), which is extremely flammable; however, it is unsuitable for color photography and has not been produced for almost 60 years.

530.51. Lamps in Cellulose Nitrate Film Storage Vaults. This section and the one following are another relic of another time, although some old prints are still archived. The goal is to keep all potential ignition sources away from the film. This film is so easy to ignite it has been known to spontaneously burst into flames and some spectacular (and horribly destructive) fires resulted as flames spread from reel to reel. These fires are extremely difficult to control because the nitrate component is a powerful oxidizing agent capable of sustaining combustion even under water. In addition, unless kept cool the film is chemically unstable because the nitrate component is also capable of forming nitric acid, which turns the film into a gelatinous mass. There have been many concerted efforts, largely successful, to convert the remaining old stock into modern film bases that do not have these problems.

530.61. Substations. This part of the article reminds us of the scale of motion picture sets and associated activities. The use of medium-voltage feeders to remote locations to support the large power demands during filming is often a necessary fact of life, with special allowances for work space reductions. The use of dc, still recognized here, is not as essential as it was during the time of carbon arc lighting. Here again, however, many facilities still operate dc distributions.

ARTICLE 540. MOTION PICTURE PROJECTION ROOMS

540.1. Scope. According to the definition of hazardous locations in Art. 500, a motion picture

booth is not classed as a hazardous location, even though even the old nitrocellulose film is highly flammable. The film is not volatile at ordinary temperatures, hence, no flammable gases are present, and the wiring installation need not be explosionproof but should be made with special care to guard against fire hazards.

540.2. Definitions. Figure 540-1 shows a *professional projector*, which is subject to lengthier and stricter requirements than those of nonprofessional movie projectors. The one shown, with ventilating duct work over the top of it, is a carbon-arc projector. A special form of high-intensity discharge lamp using a xenon gas fill has supplanted these older projectors, although some still exist in art houses. Refer to the discussion in the previous chapter (at 530.17) for more information on carbon-arc light sources.

Fig. 540-1. Professional projector. But note that Art. 540 applies to *both* professional and nonprofessional movie projectors. The article is divided into Part **III** on professional equipment and Part **IV** on nonprofessional units. (Sec. 540.10.)

540.10. Motion Picture Projection Room Required. Professional projectors must be installed in a projector booth, which as noted does not have to be treated like a hazardous (classified) location.

Figure 540-2 shows the arrangement of the apparatus and wiring in the projection room of a large but antique motion picture theater. This room, or booth, contains three motion picture projectors P, one stereopticon or “effect machine” L, and two spot machines S. This method of projection has been functionally obsolete for over 40 years having been supplanted by xenon arc discharge lamps, just as in the case of motion picture studio set lighting as noted in the commentary in the previous chapter at 530.17. However, arc-lamp projection is still used in some art houses and since this **NEC** article is largely still written around this technology, coverage in this book has been retained.

Fig. 540-2. Code rules cover many electrical details in a motion-picture projection room (or “booth”). (Sec. 540.10.)

The light source in each of the six machines is an arc lamp operated on dc. The dc supply is obtained from two motor-generator sets, which are installed in the basement in order to avoid any possible interference with the sound-reproducing apparatus. The two motor generators are remotely controlled from the generator panel in the projection room. From each generator, a feeder consisting of two 500-kcmil cables is carried to the dc panelboard in the projection room.

From the dc panelboard to each picture machine and to each of the two spot machines, a branch circuit is provided consisting of two 2/0 AWG cables. One of these conductors leads directly to the machine; the other side of the circuit is led through the auxiliary gutter to the bank of resistors in the rheostat room and from its rheostat to the machine. The resistors are provided with short-circuiting switches so that the total resistance in series with each arc may be preadjusted to any desired value.

Two circuits consisting of 1 AWG conductors are carried to the stereopticon or “effect machine,” since this machine contains two arc lamps.

The conduit leading to each machine is brought up through the floor.

540.13 specifies that the wires to the projector outlet should not be smaller than 8 AWG, but in every case the maximum current drawn by the lamp should be ascertained and conductors should be installed of sufficient size to carry this current. In this case, when suitably adjusted for the large pictures, the arc in each projector takes a current of nearly 150 A.

In addition to the main outlet for supplying the arc, four other outlets are installed at each projector machine location for auxiliary circuits. Outlets F are for foot switches that control the shutters in front of the lenses for changeover from one projector to another. Outlets G are for an 8 AWG grounding conductor, which is connected to the frame of each projector and to the water-piping system. From outlets C, a circuit is brought up to each machine for a small incandescent lamp inside the lamp house and a lamp to illuminate the turntable. Outlets M are for power circuits to the motors used to operate the projector machines.

Ventilation is provided by two exhaust fans and two duct systems, one exhausting from the ceiling of the projection room and one connected to the arc-lamp housing of each machine. (See [Fig. 540-1.](#))

A separate room is provided for rewinding films, but since this room opens only into the projection room, it may be considered that the rewinding is performed in the projection room.

Modern projectors have integral rectifiers that eliminate the need for remote dc generators, and also different light sources than the old dc arc lamps, as previously noted in this chapter and in the discussion at 530.17. A typical branch circuit for a modern xenon professional projector would run between 20 and 60 A on a 208Y/120V 4-wire branch circuit (5000 W being a common size). The projector sizing is based on the film and screen size, which in turn governs the size of the projector and the related requirements for the lamp house. This then eliminates the motor generator, making both building and electrical construction far simpler. Note, however, that even under the usual conditions where xenon arc lamps are used as the light source, the requirements in this section for all projection ports, etc. to be closed with glass or other approved material still apply.

540.11. Location of Associated Electrical Equipment. All necessary equipment *may* be located in a projector booth, but equipment which is not necessary in the normal operation of the motion picture projectors, stage-lighting projectors, and control of the auditorium lighting and stage curtain *must* be located elsewhere. Equipment such as service equipment and panelboards for the control and projection of circuits for signs, outside lighting, and lighting in the lobby and box office must not be located in the booth, although remote controls for auditorium lights and curtain and screen adjustments are allowed for obvious reasons.

Part **A** of this section includes enhanced precautions to be used around nitrocellulose film, which parallel and build on the ones in 530.52. As noted in the discussion at 530.51, this film is long obsolete, but if an old print is screened, the precautions are appropriate. Part **(B)** includes an exception essentially waiving the equipment segregation rules if only safety film (i.e., other than nitrocellulose) will be used and provided the projection booth is provided with signage both within

its confines and also on the door, clearly stating that only safety film is allowed in the room. Part (C) correlates these rules with Art. 700, including 700.21 that prohibits the placement of the only switch that can energize emergency lighting within a projection booth.

540.12. Work Space. The customary 750 mm (30 in.) of work space width about equipment that must be worked while energized also applies on each side of projection equipment, although the spaces to the sides may overlap where adjacent projection equipment is in use.

540.14. Conductors on Lamps and Hot Equipment. If equipment will be operating above 50°C (122°F) its supply conductors must be rated not less than 200°C (392°F). This could be a difficult requirement to meet if flexible cord is required for the application.

540.31. Motion Picture Projection Room Not Required. Assuming safety film is used, nonprofessional projectors do not require a projection booth. Such projectors must, however, be listed.

ARTICLE 545. MANUFACTURED BUILDINGS

545.1. Scope. This article covers prefabricated buildings delivered to a permanent foundation on flatbed trucks and put in place with a crane. They have no chassis framing and no running gear and therefore no capability to be towed. In this way they differ fundamentally from “Manufactured Homes” as covered in Art. 550.

545.4. Wiring Methods. Any Chap. 3 wiring method is permitted if otherwise permitted for the location. Where run in closed construction, cabled wiring is the equivalent of fished, and therefore a comparable allowance for securement only at the connectors. The cable size cannot exceed 10 AWG for this to be allowed.

545.10. Receptacle or Switch with Integral Enclosure. These are wiring devices without boxes, as permitted in 300.15(E).

545.13. Component Interconnections. When sections of a manufactured building must be mated in the field, the cabled interconnections (usually Type NM cable), need to be joined and there are listed devices that make up cable to cable and wire by wire within each cable, resulting in a field splice that is the equal of the cable as a whole. This section amends the usual requirements for a box at this point, and allows these devices to be used. Their track record is very good.

ARTICLE 547. AGRICULTURAL BUILDINGS

547.1. Scope. Any agricultural building without the environments covered in parts (A) and (B) must be wired in accordance with all other Code rules that apply to general building interiors. Article 547 covers *only* agricultural buildings with the dust, water, and/or corrosive conditions described in parts (A) and (B).

547.5. Wiring Methods. The wording leaves much of the determination of acceptability up to the inspection authority. But Type NMC cable (nonmetallic, corrosion-resistant—so-called barn wiring cable), UF, jacketed Type MC, or copper SE are specifically recognized for these buildings. PVC conduit and other nonmetallic or protected products including liquidtight flexible nonmetallic conduit would be suitable for the wet and corrosive conditions that prevail. The rule also accepts

wiring for Class II hazardous locations in locations covered by 547.1(A) in the scope (excessive dust).

Note that boxes and fittings must be both dust- and watertight in instances where corrosive and wet conditions warrant the attention. Flexible connections must use dusttight flex or liquidtight flex or cord. Also note that *nonmetallic* boxes, fittings, and so on, are exempt from the provisions of 300.6(D). If such components and cables are made from a *metallic* material, then the ¼-in. (6.35-mm) clearance called for in 300.6(D) would apply.

Part (F) of this section requires that in all locations within the scope of Art. 547, any equipment grounding conductor that runs underground, whether or not directly buried, must be insulated. The preference for copper grounding conductors in this section has been removed in the 2014 **NEC** based on an argument from an aluminum wire manufacturer that aluminum has equal or superior resistance to the corrosive effects of gases common to agricultural environments, such as ammonia. This section also covers GFCI requirements for receptacles, at 547.5(G). Refer to the discussion of equipotential planes at 547.10 for more information on this topic.

547.6. Switches, Receptacles, Circuit Breakers, Controllers, and Fuses. In this part, the description of the type of enclosure required corresponds to the following NEMA designations on enclosures:

Type 4: Watertight and dusttight. For use indoors and outdoors. Protect against splashing water, seepage of water, falling or hose-directed water, and severe external condensation. They are sleet-resistant but not sleet- (ice-) proof.

Type 4X: Watertight, dusttight, and corrosion-resistant. These have the same provisions as Type 4 enclosures, but in addition are corrosion-resistant.

The rule of this section seems to clearly call for NEMA 4X enclosures ([Fig. 547-1](#)).

NEMA Type 4X

Fig. 547-1. The Code rule seems to make use of this type of enclosure mandatory in agricultural buildings. (Sec. 547.5.)

Stainless steel NEMA Type 4X enclosures are used in areas that may be regularly hosed down or

are otherwise very wet, and where serious corrosion problems exist. Typical enclosures are made from 14-gauge stainless steel, with an oil-resistant neoprene door gasket.

Epoxy powdered resin-coated NEMA Type 4X enclosures are designed to house electrical controls, terminals, and instruments in areas that may be regularly hosed down or are otherwise very wet. These enclosures are also designed for use in areas where serious corrosion problems exist. They are suitable for use outdoors, or in dairies, packing plants, and similar installations. These enclosures are made from 14-gauge steel. All seams are continuously welded with no holes or knockouts. A rolled lip is provided around all sides of the enclosure opening. This lip increases strength and keeps dirt and liquids from dropping into the enclosure while the door is open.

547.9. Electrical Supply to Building(s) or Structure(s) from a Distribution Point.

Figure 547-2 shows a typical overhead distribution at a farm. The central pole is defined in 547.2 as the *distribution point* for the farm. Because this pole top is both the metering point and the service point for the utility, there will be a switch here, as shown in **Fig. 547-3**. The disconnecting means may be provided by the utility or by the owner, depending on local practice. The switch has no overload protective devices within it, thereby varying from the normal rule for services in **NEC 230.91**. The **NEC** classifies this device in 547.2 as a *site isolating device* to distinguish it from a service disconnect. Even if supplied and maintained by the utility, and therefore beyond the scope of the **NEC**, the **NEC** avoids needless duplication by recognizing it as a disconnecting means provided it meets the requirements in **NEC 547.9(A)**.

Fig. 547-2. Overhead distributions on farms usually involve one or more distribution points. (Sec. 547.9.)

Fig. 547-3. This is a site isolating device for a farm, showing the drops to the house and a barn. (Sec. 547.9.) (Adapted from *Practical Electrical Wiring*, 22nd ed., © Park Publishing, 2014)

Since it is not an actual service disconnect, it follows that the wiring that leaves this device still has the status of service conductors and must meet the wiring method and clearance requirements in Art. 230. Although nothing technically prevents a farm from establishing a conventional service at the distribution pole, and then routing conventional overcurrent-protected feeders to each building, the arrangement shown here is widely used for overall cost effectiveness. Note that although the switch is at the top of the pole, it can be operated from a readily accessible point through the permanently installed linkage shown in Fig. 547-3. In addition, a grounding electrode conductor must be installed at this point and run from the neutral block of the switch to a suitable electrode at the pole base.

Part (D) requires that if there are multiple distribution points, each location must have reciprocal labeling setting out the location of the other point(s) and the buildings or structures served by each.

Part (B) governs the wiring of the service conductors from the site isolating device to the various buildings that will be served directly, as shown in Fig. 547-2, and as detailed at the site isolating device by Fig. 547-3.

As a general rule the farmhouse can be supplied by a three-wire service, with its neutral grounded at the house just as if the utility had made a direct termination. The farmhouse must not, however, share a common grounding return path with the barn. If it does, as in the case of a common metallic water piping system, the house (1) has to be supplied with a four-wire service, and (2) have all instances of electrical contact between the neutral and the local equipment grounding system removed.

Although the barn, arguably, could also be wired like the house (three-wire), a three-wire hook-up would mean that the neutral and the equipment grounding system in the barn would be bonded together at the barn disconnect. That in turn would mean the neutral, in the process of carrying current across its own resistance, would constantly elevate the voltage to ground of all barn equipment by some finite amount relative to local ground, especially from the perspective of farm animals where they stand. The feet of livestock, being in close contact with moisture, urine, and other farm chemicals, are conductively rather well-coupled to local earth. Most livestock are much more sensitive to voltage gradients than are people. A potential difference in the range of a fraction of a volt can take a cow out of milk production, which no farmer can afford.

The NEC addresses this in two ways. First, it establishes the unique rules on farm distributions being covered here. Second, it establishes an equipotential plane for these environments, covered in 547.10. The service to the barn is normally wired four-wire, and that is (1) customary because of the reasoning discussed in the previous paragraph, and (2) mandatory unless there are no parallel grounding return paths over water systems, etc., a necessary condition to comply with NEC 250.32(B)(1) Exception No. 1. There is an additional condition [see 547.9(B)(3)] attached to the four-wire scheme that is unique to agricultural buildings. The separate equipment grounding conductor must be fully sized. That is, if the run to the barn is 3/0 AWG copper for a 200-A disconnect, and the neutral is 1/0 AWG copper (both sized on the basis of load), the equipment grounding conductor is not 6 AWG as normally required by NEC Table 250.122; nor is it 4 AWG, the size for a grounding conductor on the supply side of a service using 3/0 AWG wires; nor is it 1/0 AWG, the size of the neutral. It must not be smaller than the largest ungrounded line conductor, or 3/0 AWG. When this wire arrives at the barn, it must arrive at a local distribution with the neutral completely divorced from any local electrodes or equipment surfaces requiring grounding.

547.10. Equipotential Planes and Bonding of Equipotential Planes. Due to the

sensitivity of livestock to very small “tingle” voltages, the **NEC** now requires an equipotential plane in livestock (does not include poultry) confinement areas, both indoors and out, if they are concrete floored and contain metallic equipment accessible to animals and likely to become energized. These areas must include wire mesh or other conductive elements embedded in (or placed under) the concrete floor, and those elements must be bonded to metal structures and fixed electrical equipment that might become energized, as well as to the grounding electrode system in the building. The bonding conductor must be solid copper, not smaller than 8 AWG. In the case of dirt confinement areas, the equipotential plane may be omitted. For outdoor areas the plane must encompass the area in which the livestock will be standing while accessing equipment likely to become energized.

Remember that the grounding system to which equipotential planes should be connected is usually (refer to the discussion on 547.9) electrically separated from neutral return currents. The idea is to minimize voltage gradients. Due to the well-grounded environment, the **NEC** also requires [see 547.5(G)] all general-purpose 15- and 20-A, 125-V receptacles in the area of an equipotential plane to have GFCI protection. This GFCI protection requirement also applies to similar receptacles in all damp or wet locations, including outdoors, and for dirt confinement areas whether indoors or out. Prior to the 2017 NEC, the wording of 547.5(G) effectively excluded receptacles that were other than “general purpose” from the GFCI requirement, which allowed single receptacles for such functions as electric fencing power controllers to avoid the coverage. That wording has been changed and the requirement now applies to all such receptacles.

ARTICLE 550. MOBILE HOMES, MANUFACTURED HOMES, AND MOBILE HOME PARKS

550.1. Scope. The provisions of this article cover the electric conductors and equipment installed within or on mobile homes and manufactured homes, and also the conductors that connect mobile homes and manufactured homes to a supply of electricity. But the service equipment that is located “adjacent” to the mobile home is covered in Art. 550 and all applicable Code rules on such service equipment—as in Arts. 230 and 250—must be observed.

550.2. Definitions. The difference between a mobile home and a manufactured home is that although both buildings have a chassis and are designed to move on running gear, the mobile home is not intended to be placed on a permanent foundation. Most buildings in this category today are manufactured homes, produced with the expectation that they will ultimately rest on a permanent foundation. A manufactured home is not a manufactured building covered in Art. 545.

They also enjoy a protected regulatory status, because the federal Department of Housing and Urban Development (HUD) has determined that they are a solution to the lack of housing. Therefore, acting under the supremacy clause in the U.S. Constitution with authority delegated by a congressional enactment, HUD has decreed that what passes muster under its regulations regarding the manufacture of these homes will be accepted by local enforcement agencies. This is why the version of the **NEC** that applies to any particular manufactured home is usually not synchronized with local adoption of the **NEC**.

The definition for “manufactured home” clarifies when the service equipment may be hung on the dwelling. The service may *never* be installed on, or in, a mobile home. But where a manufactured home meets the requirements of 550.32(B), which include provisions for a permanent foundation (and

almost all do), it may be supplied by a service that is installed adjacent to or even on or in the manufactured home. Notice that the last sentence in the definition makes all rules for “mobile homes” applicable to “manufactured homes” as well.

550.4. General Requirements. Part (A) covers mobile homes that are not for residential purposes, such as construction trailers and the like. Such buildings need not comply with the rules regarding the number and capacity of circuits, but they must comply with the other applicable rules, including the requirement in 550.32(A) that the service not be mounted in or on the trailer (mobile home).

550.10. Power Supply. Part (A) requires that the power supply to the mobile home be a feeder circuit consisting of not more than *one* 50-A rated approved mobile home supply cord, or that feeder circuit could be a permanently installed circuit of fixed wiring (Fig. 550-1). An exception correlates with allowances for these dwellings to be supplied directly with service wiring if they meet the definition of a “manufactured home.”

Fig. 550-1. Service equipment for a mobile home lot consists of disconnect, overcurrent protection, and receptacle for connecting *one* 50-A (or 40-A) power-supply cord from a mobile home parked adjacent to the service equipment. (Sec. 550.10.) Note that the single-conduit support for the receptacle enclosure violates 314.23(F).

Part (B) covers use of a cord instead of permanent wiring. The power-supply cord to a mobile home is actually a feeder, and must be treated as such in applying Code rules. The service equipment must be located adjacent to the mobile home and could be either a fused or a breaker type in an appropriate enclosure or enclosures, with not more than 50-A overcurrent protection for the supply cord (or 40 A, as in the exception). The equipment must be approved service-entrance equipment with an appropriate receptacle for the supply cord, installed to meet Code rules the same as any installation of service equipment. The panel or panels in the home are feeder panels and are *never* to

be used as service-entrance equipment, according to 550.10 and 550.11(A). This means that the neutral is isolated from the enclosure and the equipment grounding goes to a separate bus for that purpose only. As a result, there must be an equipment grounding conductor run from the service-entrance equipment to the panel or panels in the home. This is true whether there is cord connection or permanent wiring.

In some areas, mobile homes are permanently connected as permitted in paragraph (D). Accordingly, local requirements must be checked in regard to the approved method of installing feeder assemblies where a mobile home has a calculated load over 50 A. In many such cases, a raceway is stubbed to the underside of a mobile home from the panelboard. It is optional whether the feeder conductors are installed in the raceway by the mobile home manufacturer or by field installers. When installed, four continuous, insulated, color-coded conductors, as indicated, are required. The feeder conductors may be spliced in a suitable junction box, but in no case within the raceway proper.

550.11. Disconnecting Means and Branch-Circuit Protective Equipment. As shown in Fig. 550-2, the required disconnect for a mobile home may be the main in the panelboard supplying the branch circuits for the unit. Details of this section must be observed by the mobile home builder.

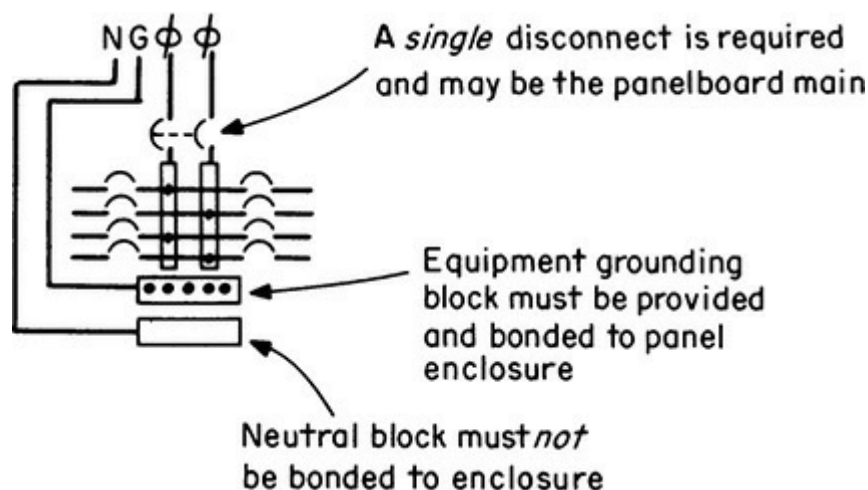

Fig. 550-2. A “panelboard,” not “service panelboard” may be used *in* mobile home. (Sec. 550.11.)

550.12. Branch Circuits. The manufacturer of the mobile home must ensure this minimum circuiting.

550.13. Receptacle Outlets. These rules generally line up with comparable rules in Art. 210, but one cycle behind. As changes occur in Chap. 2, this article tends to be updated in the next cycle. For example, the disallowance of a snap-switch controlled receptacle to meet a placement rule in 210.52, a 2008 **NEC** change, is still not correlated with this article. On the other hand, the requirements for GFCI protection [see (B)] now correlate properly with comparable requirements in 210.8(A), including all sinks coverage and dishwashers as well. Part (F)(1) correctly correlates with 406.9(C). Part (E) for the heat tape receptacle outlet, however, is unique to this article. The heat tape outlet (“pipe heating cable”) must now have GFCI protection, and it must be arranged so tripping the GFCI protection would be obvious to the occupant. Accordingly the outlet must go on an interior circuit arranged with all other outlets on that circuit on the load side of the GFCI protective device. A bathroom, but not a small appliance, branch circuit could be chosen for this purpose. Note that the

GFCI protection, provided by a residual current device, also effectively complies with 427.22. Small-appliance branch circuits can only serve their intended outlets as covered in 550.12(B), so this correlates with [Chap. 2](#). Note also that 550.12(B) makes no amendments to [Chap. 2](#) in this regard. This section makes no provisions for tamper-resistant receptacles; however, the expansion of coverage in 406.12 to mobile homes may cure that if the jurisdictional question is resolved. Refer to the discussion at 406.12(1).

550.15. Wiring Methods and Materials. Part (H) governs under-chassis wiring that is exposed to weather. Previous Code editions required such wiring, including a hard-wired supply from an underground distribution, to be heavy wall steel conduit for the portion that was exposed to weather. There was an exception for nonmetallic conduit, but only where it closely followed the frame. Now Schedule 80 PVC and RTRC-XW (the forms designed for exposure to damage) can extend from direct burial at least 450 mm (18 in.) below grade (Table 300.5 requirement for such circuits) to a factory-intended termination point. These methods and also EMT and MI cable can also be used where protected by framing. The actual text was simplified, and now simply requires a raceway approved for wet locations and for resistance to physical damage if located where susceptible.

In the exception to part (D), the smaller-dimensional box mentioned would usually be a box designed for a special switch or receptacle, or a combination box and wiring device. This application is recognized in 300.15(E) and 334.30(C). Such combinations can be properly evaluated and tested with a limited number of conductors and connections and a specific lay of conductors to ensure adequate wiring space in the spirit of 314.16.

550.16. Grounding. The white (neutral) conductor is required to be run from the insulated busbar in the mobile home panel to the service-entrance equipment, where it is connected to the terminal at the point of connection to the grounding electrode conductor.

The green-colored conductor is required to be run from the panel grounding bus in the mobile home to the service-entrance equipment, where it is connected to the neutral conductor at the point of connection to the grounding electrode conductor.

The requirements provide that the grounded (white) conductor and the grounding (green) conductor be kept separate within the mobile home structure in order to secure the maximum protection against electric-shock hazard if the supply neutral conductor should become open.

A common point of discussion among electrical authorities and electricians is whether the green-colored grounding conductor in the supply cord should be connected to the grounded circuit conductor (neutral) outside the mobile home—say, at the location of the service equipment. The grounding conductor in the supply cord or the grounding conductor in the power supply to a mobile home is always required to be connected to the grounded circuit conductor (neutral) outside the mobile home on the supply side of the service disconnecting means, but *not* in a junction box under the mobile home or at any other point on the *load side* of the service equipment (pedestal).

550.18. Calculations. This section provides the rules for making load calculations for mobile homes. These provisions generally track the provisions for comparable loads in other dwelling occupancies. For example a 12 kW range is an 8 kW load. However, for a home on a 40-A cord and no air-conditioner, 15 A per leg must be allowed for a future air-conditioning load. Part (C) allows the optional calculations in 220.82 to be used without amendment, but interestingly does not recognize the somewhat more forgiving provisions of 220.83 to be used for existing units.

550.25. Arc-Fault Circuit-Interrupter Protection. This section now requires adherence to 210.12, so it is now fully in line with the rest of the Code. However, even this version of AFCI, may or may not reflect current HUD 3280 rulemaking and therefore what is being shipped in interstate commerce. Refer to the discussion at 550.2 for more information on this point.

550.30. Distribution System. The mobile home park supply is limited to nominal 120/240-V, single-phase, 3-wire to accommodate appliances rated at nominal 240 V or a combination nominal voltage of 120/240 V. Accordingly, a 3-wire 120/208-V supply, derived from a 4-wire 208Y/120-V supply, would not be acceptable.

550.31. Allowable Demand Factors. While the demand factor for a single mobile home lot is computed at 16,000 VA (unless the 550.18 result for the typical home provided results in a larger number), it should be noted that 550.32(B) requires the feeder circuit conductors extending to each mobile home lot to be not less than 100 A. Table 550.31 provides demand factors for a mobile home lot with multiple units connected to a common service or feeder.

550.32. Service Equipment. The service equipment disconnect means for a mobile home must be mounted with the bottom of its enclosure at least 600 mm (2 ft) above the ground, because some very low mounted disconnects are subject to flooding and are difficult to operate. But the disconnect must not be higher than 2.0 m (6 ft 7 in.) above the ground or platform (Fig. 550-3). For mobile homes that are actually mobile and not mounted on a permanent foundation as covered in part (B) of this section, the service equipment must not be placed on the home, and the final connection must be through a feeder as covered in 550.33. Part (B) covers what has become the more usual condition, where the home is located on a permanent foundation with no intention of relocation. Note the requirement in (7) for a red warning label advising site electricians not to make service connections until a grounding electrode is installed and connected properly.

Fig. 550-3. Mobile home service disconnect must comply with minimum mounting height rule. (Sec. 550.32.)

ARTICLE 551. RECREATIONAL VEHICLES AND RECREATIONAL VEHICLE PARKS

551.1. Scope. Some states have laws that require factory inspection of recreational vehicles by state inspectors. Such laws closely follow **NFPA 1192-2008**, *Standard for Recreational Vehicles*. This standard contains electrical requirements in accordance with part (I) of Art. 551. It also contains requirements for plumbing and heating systems.

551.20. Combination Electrical Systems. As explained in the last exception of part (B), “momentarily” operated electric appliances do not affect converter sizing. This exception excludes from calculation of the required converter rating any appliance that operates only momentarily (by a momentary contact switch) and cannot have its switch left in the closed position. Such appliances draw current for only momentary periods and do not have to be counted as load in sizing the converter rating.

551.30. Generator Installations. Part (B) requires a transfer function for safety, and adds the requirement that an automatic transfer switch be listed for either emergency systems or optional standby systems. Note that if the alternate source of power is some other system, such as an inverter, the same requirement applies, as covered in 551.33. It was noted that the previously acceptable methods involving relays were susceptible to a welded-contact type of failure where the connection to the utility side could have been maintained. Part (E) places an enclosed transfer switch on the same footing as a panelboard relative to the allowable length of supply conductors (18 in.) into the vehicle.

551.41. Receptacle Outlets Required. This section is primarily of interest to RV manufacturers. In addition to requirements that enhance placement requirements for countertops for obvious reasons in these cramped spaces, the 2014 NEC added a requirement for a receptacle meeting 406.9(B) for wet locations, and within the outer perimeter of a rooftop deck in cases where that deck is accessible from inside the RV.

551.42. Branch Circuits Required. This rule coordinates the rules on branch circuits to those of 551.45 on the panelboard. Note that if the branch circuits exceed five, the minimum supply becomes 50 A from a 120/240-V source (or 208 V, reflecting the allowance for three-phase distributions in RV parks). A sixth circuit is allowable if all it does is supply a power converter and the total load profile still agrees with the load as originally designed for the five circuits. Power converters are commonly available and allow for powering interior lights and some other loads at 12 V dc.

551.45. Panelboard. Note that Part (B) amends the normal workspace distances, reducing the width from 752 mm (30 in.) to 600 mm (24 in.) and the depth from 914 mm (3 ft) to 750 mm (30 in.). The metric differences between the two 30-in. spacings constitute another amendment, because unlike 110.26, this section uses hard conversions throughout (see 90.9 for more information on this topic). If the panel faces an aisle, the workspace in one of the required dimensions can be reduced to 22 in. if the panel front is not recessed more than 2 in. from the finished surface (or over 1 in. of the backside of a flush door enclosing it). In addition, this section does not require the dimensions to be applied before the RV is set up. This allows for panels in “side-out” RVs to be obstructed during travel, provided the proper clearances are provided when the vehicle is fully expanded on site.

551.46. Means for Connecting to Power Supply. Note that the configuration of the 125-V 30-A, 2-pole 3-wire grounding plug and receptacle is unique to the RV industry, and is incompatible with the standard NEMA 5-30 configuration for this voltage, amperage, and number of poles. Part (E) correlates with 551.77, assuring that properly configured RVs can park at properly configured RV parks with a minimum of cord travel.

551.47. Wiring Methods. RV wiring is chiefly of interest to their manufacturers and will not be considered at length here. For just one of many examples in a long section, part (P) covers the rules for wiring side-out provisions (previously mentioned here at 551.45).

551.71. Type Receptacles Provided. RV parks must meet certain minimum receptacle

allotments, which in turn have a bearing on the number of sites that will go into the load calculations to determine the overall service size for the park. To begin with, every RV site with an electrical supply must have a 20-A 125-V 2-pole 3-wire grounding receptacle outlet. As covered in part (A), this must be installed in recreational vehicle site supply equipment. This terminology is defined in 551.2 and includes overcurrent protection and disconnecting provisions for the site. Because this equipment is not for use in dwelling and has an overall NEMA 3R rating, these receptacles, which must be GFCI protected in accordance with part (F), are exempted from tamper- and weather-resistance as would otherwise be required by 406.9 and 406.12.

Part (B) covers what is still the majority of RV hook-ups, the special 30-A 125-V receptacle shown in Fig. 551-46(C)(1). At least 70 percent of the sites with power must accommodate these supply ratings. Part (C) covers the NEMA 14-50 configuration (50-A 125/250-V 3-pole 4-wire grounding) receptacles which are in ever increasing demand, now running at 30 percent of all new units shipped, according to RV industry sources. The requirement for powered existing sites is that 20 percent of them have this configuration, and for any new sites developed the number rises to 40 percent. The informational note at the end of the section reminds designers that sites intended for “seasonal” use may approach 100 percent demand for 50-amp. connections by customers. A final requirement is that any site with one of these receptacles must also have a 30-A 125-V receptacle with it. The panel is trying to avoid an incentive to use bogus adapters that allow a 30-A. 125-V RV to plug in to a 50-A. receptacle due to what would be an oversized overcurrent device ahead of it.

Part (D) covers tent sites with 125-volt 15- or 20-amp. receptacles. These locations can be excluded when making the percentage calculations for the 30- and the 50-amp receptacles covered in (B) and (C). Part (E) covers additional receptacles for outdoor activities apart from the vehicle. These receptacles are permitted, but not mandatory.

551.72. Distribution System. As these parks increase in both area and power density, the incentive from the perspective of both the utility and the owner to employ three-phase distributions increases as well. For the first time, this section explicitly recognizes 208-volt circuits (with neutral, inaccurately described as “1-phase”) from a wye system. Informational notes point to the issues of voltage drop (and calculation considerations) on long RV park feeders; ironically, the line-to-neutral voltage drop on a three-wire supply fed from two legs of a wye system is much higher than the same load fed from a single phase distribution, for which the neutral disappears for voltage drop purposes on equally loaded hot legs. Of course, this can be counteracted by feeding sites in groups of three.

551.73. Calculated Load. The load on a site is based on the highest rated receptacle. As of the 2017 NEC, for 50-A sites, use 12,000 VA; for 30-A sites, use 3600 VA; for 20-A sites, use 2400 VA; and for the dedicated tent sites with a 20-A 125-V receptacle use 600 VA. Add the results together and then apply the demand factor from Table 551.73 that matches the total number of powered sites. If one powered location can serve two vehicles, use the two highest-rated receptacles in the summation.

551.75. Grounding. Part (B) squarely addresses a frequent topic of discussion. Largely informed by the revision to the definition of “structure,” the RV pedestal does not require a grounding electrode unless it is service equipment. An auxiliary electrode may be installed but is not required.

551.77. Recreational Vehicle Site Supply Equipment. This is where to find how to place the equipment, which differs, based on whether or not the site is a pull-through site.

ARTICLE 552. PARK TRAILERS

552.2 Definition. A park trailer is a unit that is built on a single chassis mounted on wheels and has a gross trailer area not exceeding 37 m² (400 ft²) in the set-up mode. The article has no independent provisions or demand factors for the placement of these units in a group, although 552.47 does have a procedure for determining the rated load of any given unit. These calculations, as in the case of many other provisions in this part of the article, parallel comparable requirements for both mobile homes and for recreational vehicles. Here again, there are no requirements in this article that interface the loads in these units with other loads in the location where they are connected. For example, if a park trailer is set up at an RV park, how does its load relate to Table 551.73? Absent any demand factor allowances, and there are none, it must be taken at 100 percent. In addition, there are no rules for the feeder supply to the trailers, leaving open the question of whether direct connections are required or whether cord connections are permitted.

Gradually other rules are periodically correlated; as of the 2011 cycle, for example, 552.59(A) requires outdoor receptacle outlets to meet the weather-resistance rules and in-use cover rules in 406.9, and outdoor switches must comply with the weatherproof cover or enclosure rules in 404.4, depending on the installation.

ARTICLE 553. FLOATING BUILDINGS

553.1. Scope. This article covers the electrical system in a building—either residential (dwelling unit) or nonresidential—that floats on water, is moored in a permanent location, and has its electrical system supplied from a supply system on land. The rules apply to any floating building and are not limited only to floating “dwelling units.”

553.4. Location of Service Equipment. The service-disconnect means and protection for a floating building must not be mounted on the unit. This ensures the ability to disconnect the supply conductors to the floating building in an emergency, such as in a storm, in the event that it is necessary to move the unit quickly (Fig. 553-1).

Fig. 553-1. Service equipment for a floating building must be on the dock, pier, or wharf.

A major 2011 **NEC** change requires low-level GFPE/GFCI (the actual wording only says ground-fault protection) as a part of the main overcurrent protective device feeding the floating building, with a trip setting not above 100 mA. As an alternative, “ground-fault protection” can be provided on each and every branch circuit and feeder circuit. The change was motivated by documentation of 50 deaths from leakage currents “on and around marinas.” Note that this issue is far more important in fresh water exposures. Fresh water has a much higher resistance than salt water, and as a consequence the voltage gradient in the vicinity of a fault is much steeper, to the point of being many volts across the width of a human body. A very few volts, especially with water in the ears, can bring on enough disorientation to cause drowning. Salt water has such low resistance that such a steep gradient across the width of a body is almost unheard of.

There are obvious major issues with this requirement. The proposal was offered by a manufacturer who just happens to have such a device. What does it actually do? It would appear to be a residual current device set to trip at 100 mA. This is higher than the usual setting for low-level GFPE used to protect heat tape and snow-melting cables, and far higher than usual GFCI settings, so it would be ineffectual at actually preventing an electrocution. It would function more as a “maintenance required” annunciator, hopefully tripping before someone was in the wrong place at the wrong time and got injured or worse. If it tripped, one supposes it would motivate major maintenance to be performed in order to reduce the leakage below the trip setting.

The 100 mA set point is obviously far too high to prevent an electrocution, but it is also far too low for its intended applications. There are many large floating buildings with services running over 1000 A and occupying considerable ocean front in major harbors, how could this be applied in those locations? Could every feeder and branch circuit be wired with the GFCI alternative? The same rule applies to marinas, there are likewise large marinas with service in the mid four figures, and undoubtedly in some cases with service taken at medium voltage.

Careful discussion with the local authority having jurisdiction is obviously called for in this instance, because a rule-making procedure may be required in order to modify or delete this requirement.

553.7. Installation of Services and Feeders. For obvious reasons the wiring between land and the floating building must be flexible, and this section makes that clear in (A). Although flexible raceways are permitted, extra-hard-usage flexible portable power cable with its fine conductor stranding is the most resilient. Such cord must be marked “sunlight-resistant” and for “wet locations.” If cord is used, however, the stranding will not terminate correctly in conventional mechanical lugs. According to UL data, a termination for that type of stranding must use a lug marked with the class of stranding and the number of strands, and generally only a few hydraulically crimped lugs has been available for this purpose. Recently some mechanical solutions have come on the market, so this problem is well on its way to being solved. Review the discussion regarding 110.14 and Fig. 110-8 in [Chap. 1](#) for more information.

553.8. General Requirements. A green-colored, insulated equipment grounding conductor must be used in a feeder to the main panel of a floating building. For conductors larger than 6 AWG, the color can be applied afterward in accordance with the usual rules in 250.119. This equipment grounding conductor must be run to the panel from an equipment grounding terminal (or bonded neutral bus) in the building’s service equipment on land.

ARTICLE 555. MARINAS, BOATYARDS, AND COMMERCIAL AND NONCOMMERCIAL DOCKING FACILITIES

555.1. Scope. This article covers both fixed and floating piers, wharfs, and docks—as in boat basins or marinas. As of the 2017 **NEC**, it covers these facilities of any size and in any location or occupancy, from a large ocean facility to a dock for a small boat at a single-family dwelling, and the article is retitled accordingly. In [Fig. 555-1](#), branch circuits and feeder cables run from panelboards in the electrical shed at the left, down, and underground into a fabricated cable space running the length of the pier shown at the right, supplying shore-power receptacle pedestals (arrows) along both sides of the pier.

Fig. 555-1. This is one part of a 406-boat marina where shore power is supplied to moored boats from receptacle power pedestals (arrows) supplied by cables run under the pier from a panelboard in the shed at the left. (Sec. 555.1.)

555.2. Definitions. The “electrical datum plane” is a horizontal plane that serves as the reference level for any rules governing height above water level. It is absolutely essential that this be determined before proceeding with other requirements. It is 606 mm (2 ft) above normal high water, except that on a floating pier, it is 762 mm (30 in.) above the water and also 305 mm (12 in.) above the floating pier.

555.3. Ground-Fault Protection. This is a major change as of the 2011 **NEC** and raises serious questions as to technical validity and workability. The same requirement applies to floating buildings. Review the discussion at 553.4. The 2017 **NEC** has doubled down on the issue and now requires protection at the 30 mA level (in marinas, not yet for floating buildings). This would be the traditional GFPE level so these devices are readily available. The requirement extends to the overcurrent devices that “supply the marina, boatyards, and commercial and noncommercial docking facilities.” On the literal text, this rule applies to any circuit, whether or not it ventures anywhere near equipment that might generate a voltage gradient in the water, and it applies whether or not the water is fresh water. Salt water is sufficiently conductive that a hazardous voltage gradient is a virtual impossibility. Presumably the most effective solution is to place it on each shore power circuit. Because defective equipment on visiting boats is the likely source of most loss experience to date, in that way only the miscreant boat is inconvenienced.

555.7. Location of Service Equipment. As in the case of floating buildings, service

equipment must remain on shore where floating docks or other facilities are supplied.

555.9. Electrical Connections. All connections must be at least 305 mm (1 ft) above a fixed or floating pier, and simultaneously above the datum plane. For floating piers, however, connections using sealed methods identified for submersion are permitted provided they are enclosed in approved junction boxes.

555.12. Load Calculations for Service and Feeder Conductors. This is an unusual load calculation in that it is entirely based on the current ratings of the power receptacles installed for each slip. If two (or more) receptacles are provided at a slip, the one whose configuration translates into the largest kVA load profile is the one used to enter the table. If the slips have kilowatt-hour meters, a reduction in electrical demand of 10 percent is assumed (through the use of a 0.9 multiplier). Note that on the literal text, the meters need not be read or used to bill the boat owners in order to achieve this presumed reduction in load. In addition, the neutrals must not be further reduced under the terms of 220.61(B); this demand factor table is the only permitted calculation for all circuit conductors.

The 2011 **NEC** clarified the appropriate application of the receptacle count in the left hand column of the demand factor table as being the number of shore power receptacles and no others. Apparently some had added local convenience receptacles into the count, artificially increasing the presumed load diversity and thereby reducing the demand factor to be applied.

555.13. Wiring Methods and Installation. The rules here present various options that are available for the circuiting to the loads at marinas and boatyards. This section recognizes any wiring method “identified” for use in wet locations. Examples of wiring methods that are recognized by the **NEC** for use in wet locations are as follows:

1. Type PVC or Type RTRC conduit.
2. Type MI cable.
3. Type UF cable.
4. Corrosion-resistant rigid metal conduit—which is taken to mean either rigid aluminum conduit or *galvanized* rigid steel conduit. The use of the word *corrosion-resistant* is not intended to require a plastic jacket on galvanized rigid steel conduit, although such a jacket does provide significantly better resistance to natural corrosion, such as rusting.
5. Galvanized IMC.
6. Type MC (metal-clad) cable.
7. Extra-hard-usage portable power cable, such as Type W, where listed for both wet locations and sunlight resistance, has tremendous ability to flex because of its fine stranding. Take care to observe the UL termination limitations on fine-stranding at terminations, as covered in [Chap. 1](#) at 110.14. If these cables are used, a corrosion-resistant junction box must be provided with permanently installed terminal blocks to facilitate the termination of the flexible cord and the feeder extensions. Alternatively, a listed power outlet box with suitable terminal bars or blocks built in can be used.

In the design and construction of a marina it is usually necessary to compare the material and labor costs involved in each of those methods. Emphasis is generally placed on long, reliable life of the wiring system—with high resistance to corrosion as well as high mechanical strength to withstand impact and to accommodate some flexing in the circuit runs. The need for great flexibility in running the circuits under the pier and coming up to receptacle pedestals and lighting poles is often extremely

important in routing the circuits over, around, and below the many obstructions commonly built into pier construction. And that concern for flexibility in routing can weigh heavily as a labor cost if a rigid conduit system is used.

Any of the recognized types of cable offer the material-labor advantage of a preassembled, highly flexible “raceway and conductor” makeup that is pretested and especially suited to the bends, offsets, and saddles in the circuit routing at piers, as shown in [Fig. 555-2](#). Cable with a metal armor can offer a completely sealed sheath over the conductors, impervious to fluids and water. For added protection for the metal jacket against oils and other corrosive agents, the cable assembly can have an overall PVC jacket.

Fig. 555-2. PVC-jacketed metal-clad cable—with a continuous, corrugated aluminum armor that is completely impervious to any moisture and water and resistant to corrosive agents—is used for branch circuits and feeders under this marina pier. (Sec. 555.13.)

555.15. Grounding. The purpose is to require an insulated equipment grounding wire that will ensure a grounding circuit of high integrity. Because of the corrosive influences around marinas and boatyards, metal raceways and boxes are not permitted to serve as equipment grounding conductors. The preference for copper grounding conductors in this section has been removed in the 2014 **NEC** based on an argument from an aluminum wire manufacturer that aluminum has equal or superior resistance to the corrosive effects of gases common to marine environments.

555.19. Receptacles. [Figure 555-3](#) shows typical configurations of locking- and grounding-type receptacles and attachment plugs used in marinas and boatyards. A complete chart of these devices

can be obtained from the National Electrical Manufacturers Association or wiring-device manufacturers. Locking-type receptacles and caps are required to provide proper contact and assurance that attachment plugs will not fall out easily and disconnect onboard equipment such as bilge pumps or refrigerators. Shore-power receptacles for boats must be rated at least 30 A.

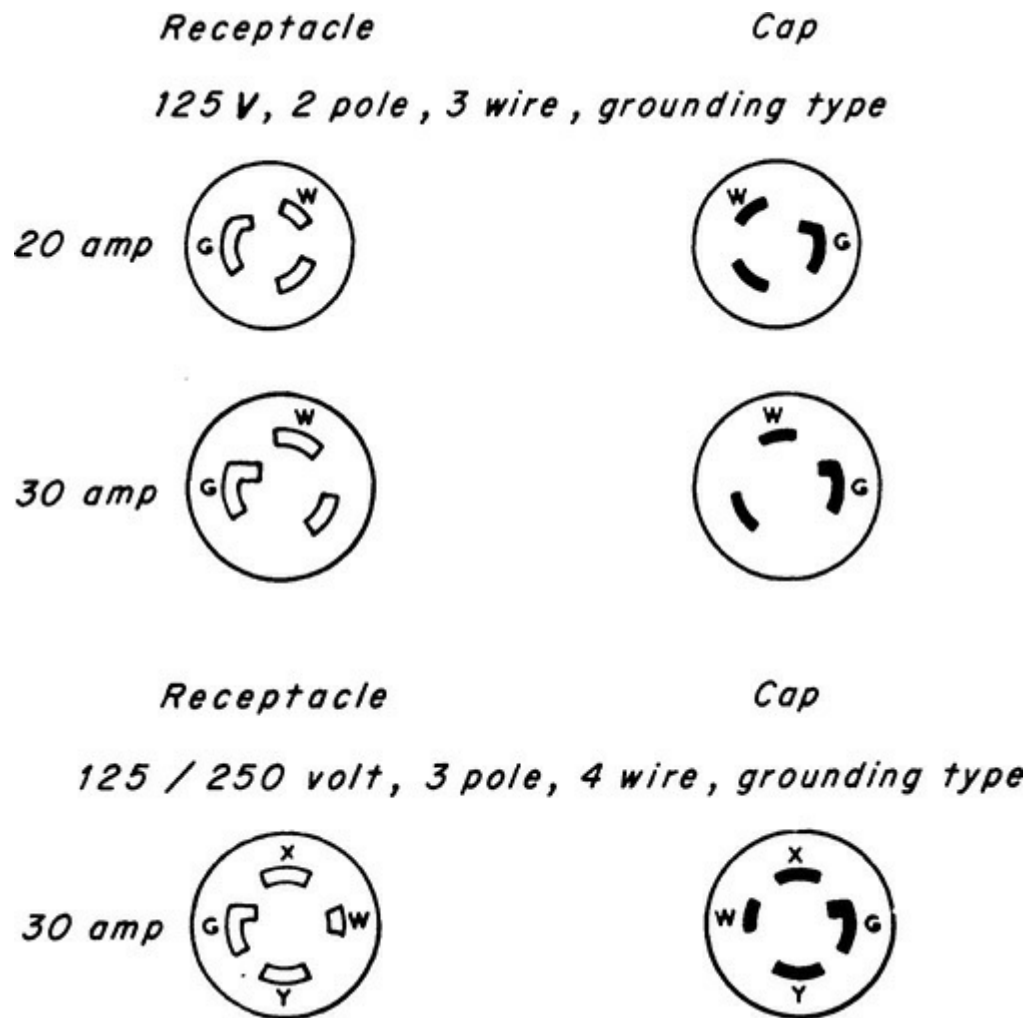

Fig. 555-3. These types of connections provide shore power for boats. (Sec. 555.19.)

As covered in part **(A)(3)**, each single receptacle must be installed on an individual or multiwire branch circuit, with only the one receptacle on the circuit. As shown in [Fig. 555-4](#), a receptacle pedestal unit (two mounted back to back at each location) contains receptacles providing plug-in power to boats at their berths along the pier, with CB protection and control in each housing. As required by **NEC 555.19**, each receptacle must be rated not less than 30 A and must be a single locking- and grounding-type receptacle. There is no requirement for ground-fault circuit interruption on these receptacles. (However, at a marina, any 15- or 20-A, 120-V receptacles that are *not* used for shore power to boats must be provided with GFCI protection.)

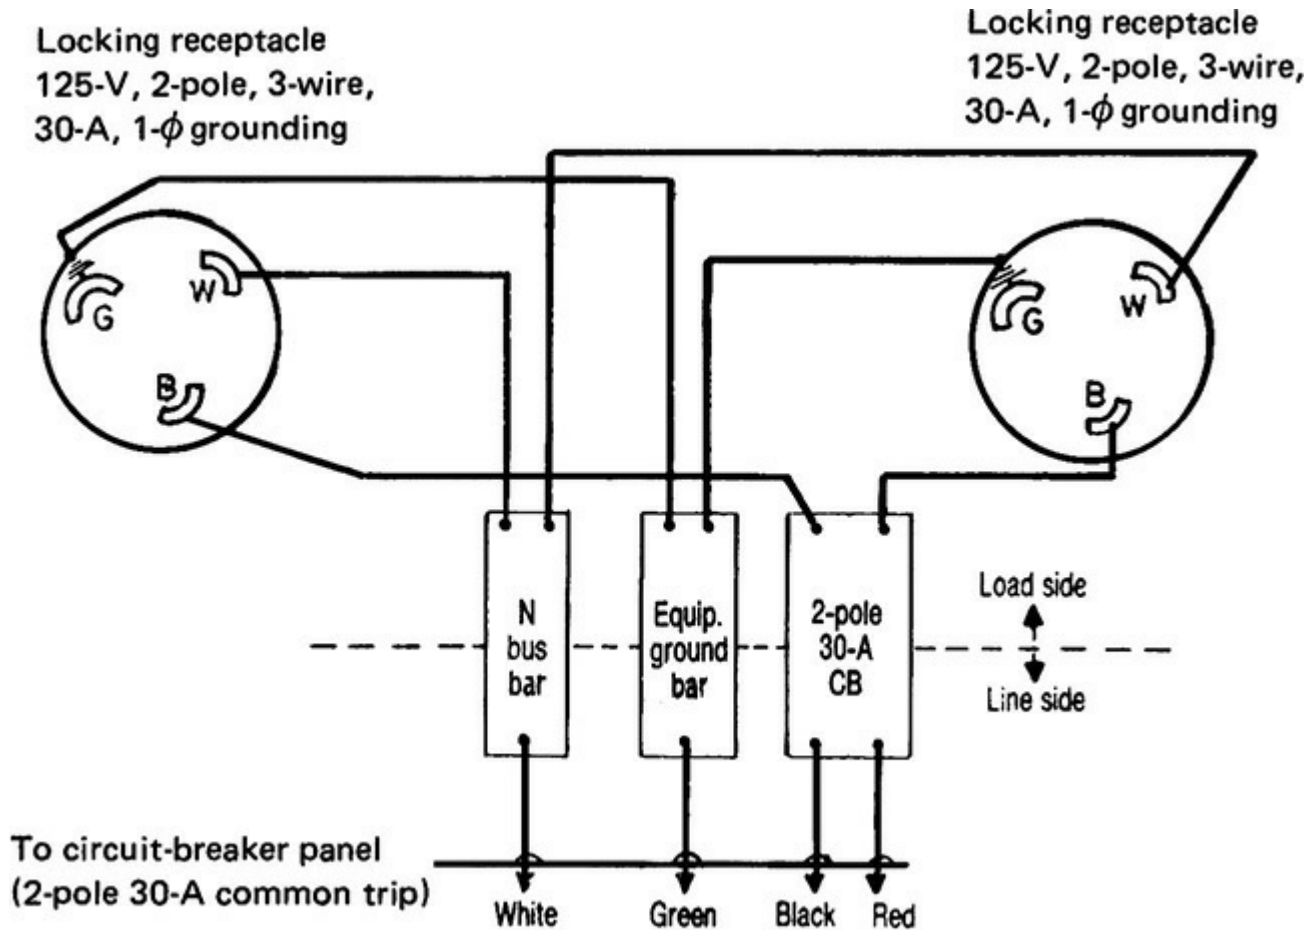

Fig. 555-4. Receptacle providing shore power to each boat is contained in a “power pedestal” and is a locking and grounding type. (Sec. 555.19.)

Also, as required by **NEC 555.19(A)(3)**, each individual receptacle in the pedestal unit is supplied by a separate branch circuit of the voltage and current rating that corresponds to the receptacle rating. At each pedestal location, a separate bare, stranded No. 6 copper conductor (arrow) is available as a static grounding conductor bonded to all pedestals and lighting fixtures. The inset in [Fig. 555-4](#) shows one receptacle wiring arrangement. Hookup details at pedestal units vary with voltage ratings, current ratings, and phase configuration of power required by different sizes of boats—from small motorboats up to 100-ft yachts. Note also that each shore power receptacle must be wired in conjunction with a properly marked disconnecting means not over 762 mm (30 in.) away, as covered in 555.17.

555.21. Motor Fuel Dispensing Stations—Hazardous (Classified) Locations. This material has been relocated in the 2014 **NEC** to 514.3(C), (D), and (E).

555.22. Repair Facilities—Hazardous (Classified Locations). This is the key to bringing Art. 511 requirements to bear on motorboats being serviced at a dry dock or comparable facility.

555.24. Signage. Permanent signs must be posted “at all approaches” to a marina facility to the effect that electrical currents might be in the water that present a shock hazard (see **NEC** for exact text). Refer to the discussion at 555.3 and 553.4 for more information. Here again, note that this is a nonexistent hazard at a salt water facility.

ARTICLE 590. TEMPORARY INSTALLATIONS

590.1. Scope. Although a temporary electrical system does not have to be made up with the detail and relative permanence that characterizes a so-called permanent wiring system, the specific rules of this article cover the only permissible ways in which a temporary wiring system may differ from a permanent system. Aside from the given permissions for variation from rules on permanent wiring, all temporary systems are required to comply in all other respects with Code rules covering permanent wiring ([Fig. 590-1](#)).

Fig. 590-1. Temporary wiring is not an “anything goes” condition and must comply with standard Code rules to prevent a rat-nest condition, which can pose hazard to life and property. (Sec. 590.1.)

590.3. Time Constraints. In part (A), the words *maintenance* and *repair* indicate that the less rigorous methods of temporary wiring may be used and that all rules on temporary wiring must be observed wherever maintenance or repair work is in progress. This expands the applicability of temporary wiring beyond new construction, remodeling work, or demolition.

Part (B) recognizes use of temporary wiring for seasonal or holiday displays and decorations, as shown in [Fig. 590-2](#).

Fig. 590-2. Temporary wiring techniques are permitted for 90 days for such “experimental” work as energy demand analysis. (Sec. 590.3.)

Part (C) of this section permits temporary wiring to be used for other than simple construction work. Such wiring, as covered in this article, may also be used during emergency conditions or for testing, experiments, or development activities. As the proposal for this Code rule noted:

Were it not permissible to use temporary wiring methods for testing purposes, it would be impossible to check, before placing in service, many electrical installations. Likewise, emergency conditions would remain without electric power and lighting until permanent installation could be made.

However, part (D) of this section is aimed at ensuring that the equipment and circuits installed under this article are really temporary and not a backdoor to low-quality permanent wiring systems.

590.4. General. Although part (A) requires a temporary service to satisfy all the rules of Art. 230, part (B) recognizes the use of temporary feeders that are conductor “cable assemblies” used as open wiring (Fig. 590-3), multiconductor cable assemblies (Type NM, UF, etc.), or multiconductor cord or cable of the type covered by Art. 400 for hard-usage or extra-hard-usage flexible cords and cables, which are not acceptable for use as feeder or branch-circuit conductors of permanent wiring systems.

400.12 specifically prohibits the use of such cords and cables “as a substitute for the fixed wiring of a structure.” As shown in [Fig. 590-4](#), prewired portable cables with plug and socket assemblies are available for power risers in conjunction with GFCI-protected branch-circuit centers, or cables can be run horizontally on a single floor to suit needs. GFCI breakers may be used in temporary panelboards interconnected with cable and feeding standard receptacles in portable boxes, as shown in [Fig. 590-5](#). The 2017 **NEC** added Type SE cable to both (B) and (C), feeders and branch circuits as permitted, including running in a raceway underground.

Fig. 590-3. The exception to 527.4(B) permits temporary feeders to be run as open individual conductors supported by insulators spaced not over 10 ft (3.0 m) apart where used during emergencies or testing. (Sec. 590.4.)

Fig. 590-4. Temporary feeders may be cord assemblies made especially for such use. (Sec. 590.4.)

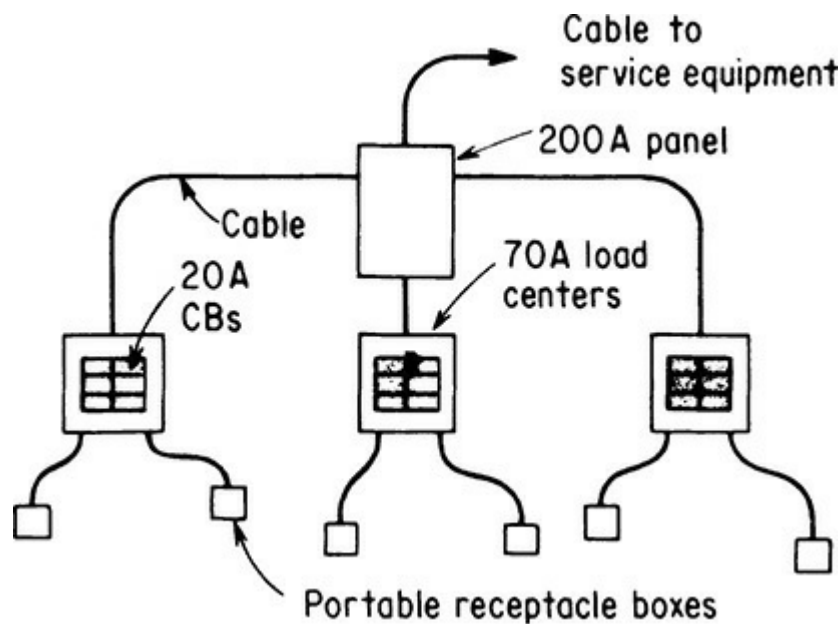

Fig. 590-5. Distribution for temporary power may utilize cable or raceway feeders. (Sec. 590.4.)

590.4(C) requires temporary branch circuits to consist of multiconductor cable assemblies (Types NM and UF) or cords or cables covered in Table 400-4, provided that they originate in a panelboard, switchboard, motor control center, fused switch, or “an approved power outlet,” which is one of the manufactured assemblies made for job site temporary wiring. As shown in Fig. 590-6, the temporary

branch circuits for receptacle outlets may be part of a manufactured temporary system, which consists of cable harnesses and power centers (or outlets). Several variations of protection may be provided by such portable receptacle boxes, as shown in Fig. 590-6. Box 1 may have GFCI protection for its own receptacles without providing downstream protection. Box 2 may have the same protection as box 1 and in addition have GFCI protection for its 50-A outlet, thus providing protection for box 3. With this arrangement, box 1 will sense the ground fault from the worker at upper left and will trip, allowing boxes 2 and 3 to continue to provide power. Or all three boxes could receive GFCI protection from a permanently mounted loadcenter feeding the 50-A receptacle outlet at upper left. In this case, the ground fault shown would interrupt the power to all boxes. It should be noted that use of a GFCI breaker may be viewed as a violation for temporary power applications because it does not have the same characteristics—that is, “open neutral” and “reverse phasing” protection—as do listed temporary power GFCI devices.

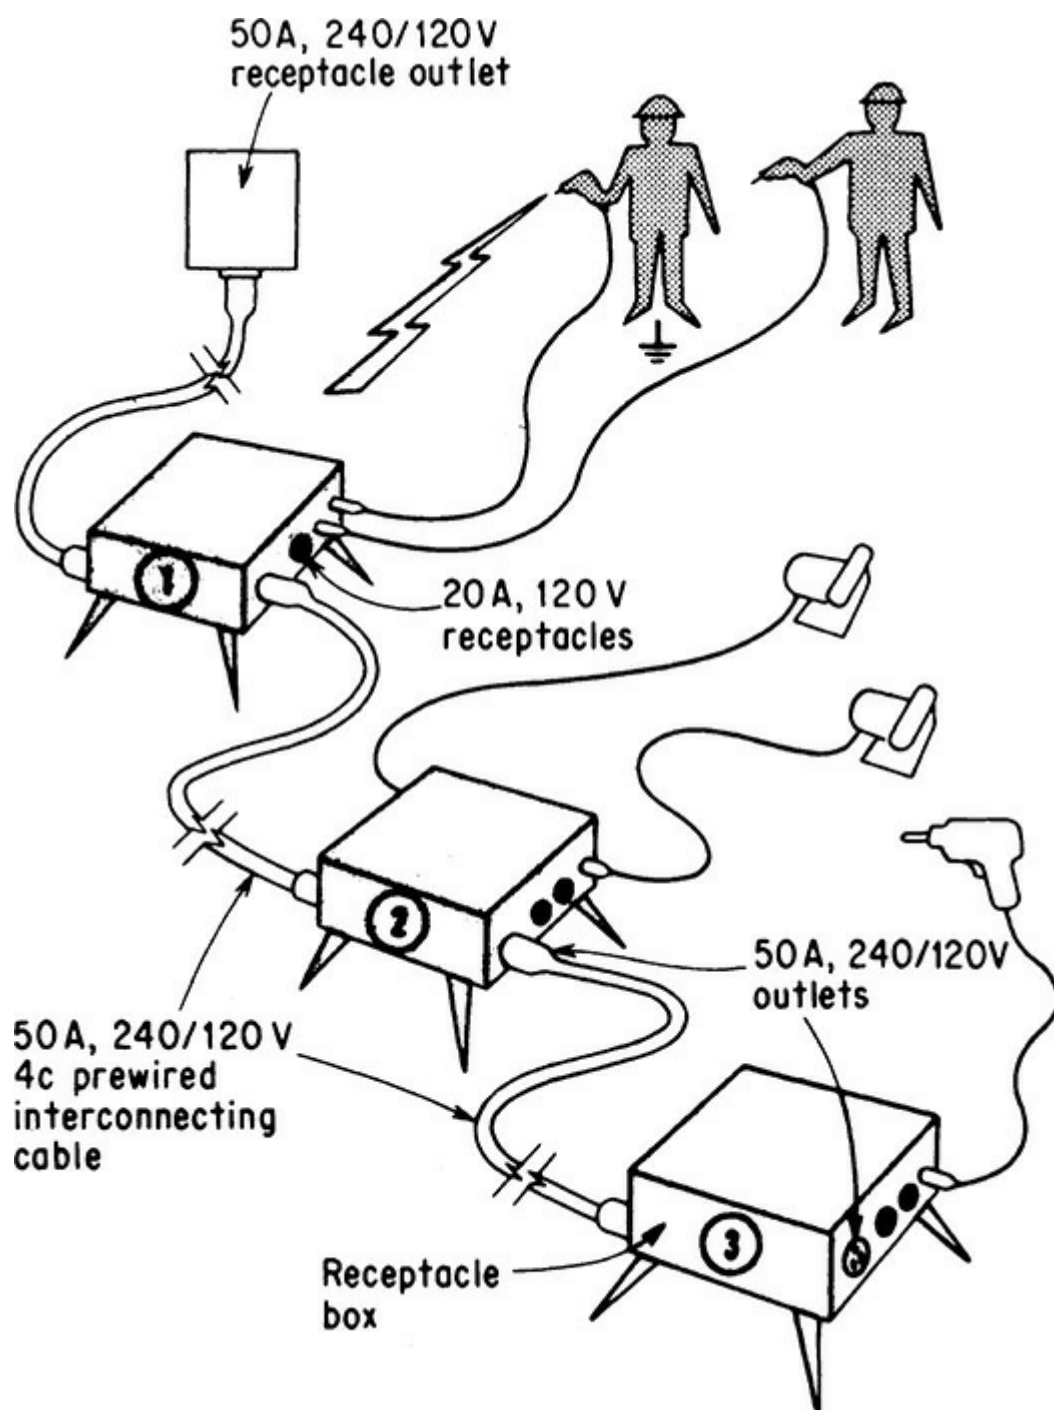

Fig. 590-6. Temporary branch circuits may be part of a manufactured system. (Sec. 590.4.)

590.6 makes it clear that only receptacles used under temporary job conditions require GFCI protection. The implication is that the nonmetallic-sheathed cable runs and pigtail connections traditionally associated with temporary power on the job site would not win awards for neatness and safety, but that once the permanent feeders and panelboards are in place and energized, the shock hazard is considerably reduced.

However, as long as portable tools are being used in damp locations in close proximity with grounded building steel and other conductive surfaces, the possibility of shock exists from faulty equipment whether it is energized from temporary or from permanent circuits.

Standard panelboards used for temporary power fitted with GFCI circuit breakers for the protection of entire circuits satisfies the rules of 590.6, but may be a violation of 110.3(B) because breaker type GFCI devices listed for permanent installation would not satisfy the UL requirements for temporary power use. However, the many varieties of portable power distribution centers and modules have been developed with integral GFCI breakers protecting single-phase, 15- and 20-A, 120-V circuits. Other circuits (higher amperage, higher voltage, and 3-phase) are also required by the **NEC** to have GFCI protection, or the Assured Equipment Grounding Conductor Program, described in 590.6(B), may be used. A variety of cord sets are also available for use with GFCI-protected plug-in units to supply temporary lighting and receptacle outlets.

While a manufactured system of cable harnesses and power-outlet centers costs more than nonmetallic-sheathed cable runs and pigtail sockets, it is completely recoverable, and its cost can be written off over several jobs. From then on, with the exception of costs for setup and removal, storage, and transportation, much of the temporary power charges included in bids could be profit.

In previous Code editions, part **(C)** of this section required temporary wiring circuits to be “fastened at ceiling height every 10 ft (3.0 m).” But now, if such circuits operate at not over 150 V to ground and are not subject to physical damage, the fourth sentence in this paragraph permits open-wiring temporary branch circuits to be run at any height “supported on insulators at intervals of not more than 10 ft (3.0 m)” where used for other than “during the period of construction” as covered in part **(A)** of 590.3. Open wiring must not be laid on the floor or ground.

In the interest of greater safety, part **(D)** prohibits the use of both receptacles and lighting on the same temporary branch circuit on construction sites. The purpose is to provide complete separation of the lighting so that operation of an overcurrent device or a GFCI due to a fault or overload of cord-connected tools will not simultaneously disconnect lighting ([Fig. 590-7](#)). In addition, all receptacles used for temporary power and located in wet locations must comply with the weather-resistance and the in-use cover requirements of 406.9(B)(1).

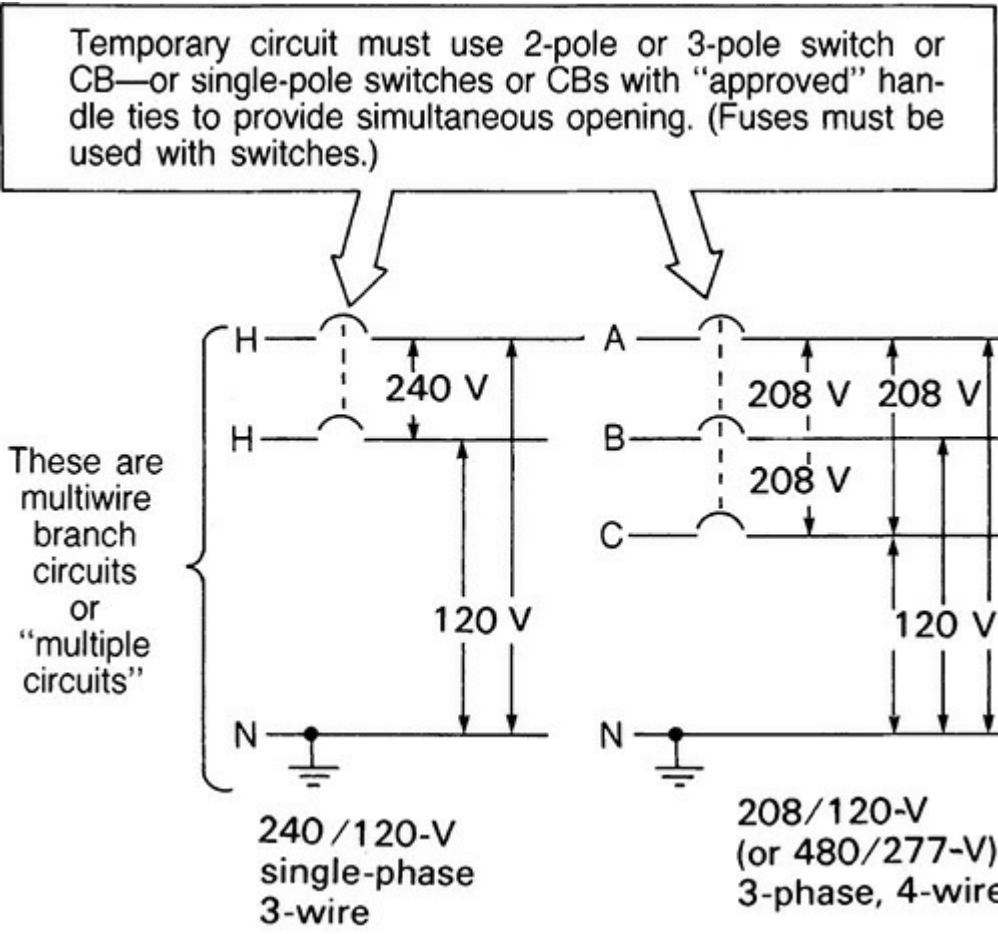

Fig. 590-7. This rule prevents loss of lighting when a defective, high-leakage, or overloaded Code-connected tool or appliance opens the branch-circuit protection of a circuit supplying one or more receptacles. (Sec. 590.4.)

According to part (E), every multiwire branch circuit must have a disconnect means that

simultaneously opens all ungrounded wires of the temporary circuit. At the power outlet or panelboard supplying any temporary multiwire branch circuit (two hot legs and neutral, or three hot legs and neutral), a multipole disconnect means must be used. Either a 2-pole or a 3-pole switch or circuit breaker would satisfy the rule, or single-pole switches or single-pole CBs may be used with approved handle ties to permit the single-pole devices to operate together (simultaneously) for each multiwire circuit, as shown for the multiwire lighting circuit in [Fig. 590-7](#).

Part (F) requires lamps for general lighting on temporary wiring systems to be “protected from accidental contact or breakage.” Protection must be provided by a suitable fixture or lampholder with a guard ([Fig. 590-8](#)). OSHA rules also require the use of a suitable metal or plastic guard on each lamp. As shown in [Fig. 590-9](#), commercial lighting strings provide illumination where required. Splice enclosure is equipped with integral support means, and a variety of lamp-guard styles provide protection for lamp bulbs.

Fig. 590-8. A lampholder with a guard is proper protection for a lamp at any height in a temporary wiring system (above). Unguarded lamps at any height constitute a Code violation (right). (Sec. 590.4.)

Special watertight plugs and connectors provide insurance against nuisance tripping caused by weather conditions on construction sites.

Fig. 590-9. Temporary lighting strings of cable and sockets are available from manufacturers. Note the multiconductor cable makeup; festoon lighting strings are not permitted. (Sec. 590.4.)

Part **(F)** requires grounding of metal lamp sockets. The high level of exposure to shock hazard on construction sites makes use of ungrounded metal-shell sockets extremely hazardous. When they are used, the shell must be grounded by a conductor run with the temporary circuit.

In part **(G)**, splices or tap-offs are permitted to be made in temporary wiring circuits of cord or cable without the use of a junction box or other enclosure at the point of splice or tap ([Fig. 590-10](#)). But this new permission applies only to nonmetallic cords and cables. A box, conduit body, or terminal fitting must be used when a change is made from a cord or cable circuit to a raceway system or to a metal-clad or metal-sheathed cable. The enclosure can generally be omitted with a major proviso: the equipment grounding continuity must not be compromised. This can be accomplished with nonmetallic wiring methods easily, and even with metallic wiring methods provided listed fittings are used to secure the cable sheath and maintain continuity.

Fig. 590-10. Splices may be used without boxes for cord and cable runs on construction sites. (Sec. 590.4.)

Regulations in part **(H)** require protection of flexible cords and cables from damage due to pinching, abrasion, cutting, or other abuse.

Part **(I)** calls for the use of proper fittings to secure cables that enter enclosures containing receptacles and/or switches.

Part **(J)** requires cable assemblies and cords to be supported at intervals that assure protection from physical damage. You can use staples, cable ties, straps, or other fittings that don't damage the cable. The idea here is to allow a greater support interval than would be covered in the applicable article, because this is just for temporary applications.

Be careful! The 2014 **NEC** inserted a far-reaching prohibition against running any cable assemblies or flexible cords "installed as branch circuits or feeders" on the floor or on the ground. Although this language goes on to specifically exempt extension cords from its reach, it will definitely require the common applications of large SER cable assemblies to be supported so as to not run across a floor. This will have a definite impact on job costs. In addition, the boundary between an "extension cord" and a feeder or branch circuit is not always clear-cut on construction sites. For example, 50-A flexible cord assemblies connecting the distribution boxes in [Fig. 590-6](#), although they connect and disconnect like extension cords, may very well be interpreted as feeders within the meaning of this rule. The supporting substantiation for the rule clearly intended the extension cord wording to only apply to the load side of GFCI protection, although the **NEC** text is silent on that point. OSHA regulations also do not allow feeders to be laid on the ground. Consultation with the inspector will be crucial to avoiding severe financial consequences during construction.

Vegetation, however, is prohibited from being used as temporary support of overhead runs of branch-circuit or feeder conductors. The only exception is holiday decorative lighting, which is permitted to run from tree to tree provided there is some tension take-up mechanism or other approved arrangement that will prevent tree movement from damaging the temporary lighting strings.

590.5. Listing of Decorative Lighting. Here the Code makes it absolutely clear that any

manufactured decorative lighting used for temporary installation *must* be listed *and* so labeled on the product. And this would include a proper listing for the application. That is, where used outdoors such lighting must also be listed for outdoor use or wet locations, etc. Note that 410.160 imposes the identical requirement.

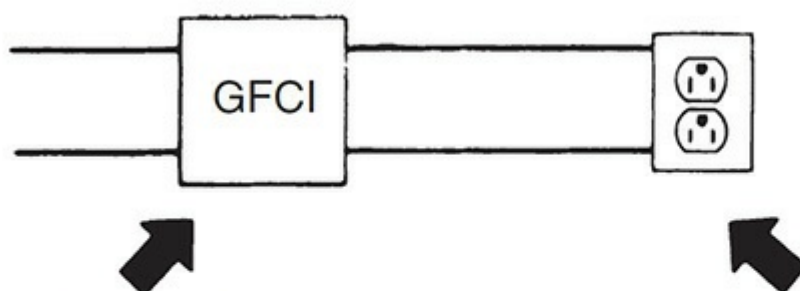

590.6. Ground-Fault Protection for Personnel. This section covers the rules that concern GFCI protection for all receptacles supplied from temporary wiring systems.

Part (A) is a construction site GFCI requirement that applies to temporary power provided for receptacle outlets, whether from a utility or on-site generator source, that is used by personnel to construct, demolish, remodel, maintain, or repair buildings or structures, or perform similar work. This analysis will use the term “construction activities” as a shorthand reference to the preceding list of qualified activities. The requirements for GFCI protection apply to 125-V, single-phase, 15-, 20-, and 30-A receptacle outlets as specifically described in three-numbered paragraphs itemized below.

Industrial occupancies with qualified maintenance and supervision are permitted to use the assured equipment grounding conductor program. However, that permission is strictly limited to those specific receptacle outlets that supply equipment having a design that is incompatible with GFCI protective devices, or that supply power to equipment that, if suddenly disconnected, would create a greater hazard than that addressed by the shock protection inherent to the GFCI device. The substantiation for this exception (originated in the 2002 **NEC**) pointed to small 120-V MIG welders as examples of the first problem, and magnetic-based drills and vacuum-held coring drills during operation as examples of the second problem.

Paragraph (1) applies to receptacle outlets that are not part of the permanent wiring on site (Fig. 590-11) and are used for construction activities, such as receptacles in a spider box. Any such receptacles must “have” GFCI protection for personnel at all times when they are being used. Reversing the content of the 2011 **NEC**, the 2014 **NEC** now expressly permits listed cord sets or devices incorporating GFCI protection identified for portable use to supply temporary loads fed from a receptacle not considered part of the permanent wiring. (Fig. 590-11). However, the permission to use the portable use devices does not excuse compliance with the basic requirement that temporary receptacles in use as part of the construction project must have GFCI protection.

BASIC RULE

Ground fault circuit interrupter protects personnel by opening circuit on ground; may be in branch circuit CB or in the receptacles

All 15-, 20-, or 30- amp, single-phase, 125-volt receptacle outlets *which are not part of permanent wiring of building or structure and are used for temporary power must be GFCI-protected*

Fig. 590-11. GFCI protection on construction sites for receptacles in use that are not part of the permanent wiring of the building or structure. Listed GFCI cord sets or devices identified for portable use are now, as of the 2014 **NEC**, permitted to be used. [Sec. 590.6(A)(1).]

Paragraph (2) applies to receptacle outlets that are part of the permanent wiring for the building, but are being used for construction activities. GFCI protection must be provided, but a portable GFCI device or cord set that is “identified for portable use” is permitted so as to avoid changing out receptacles or circuit breakers (**Fig. 590-12**).

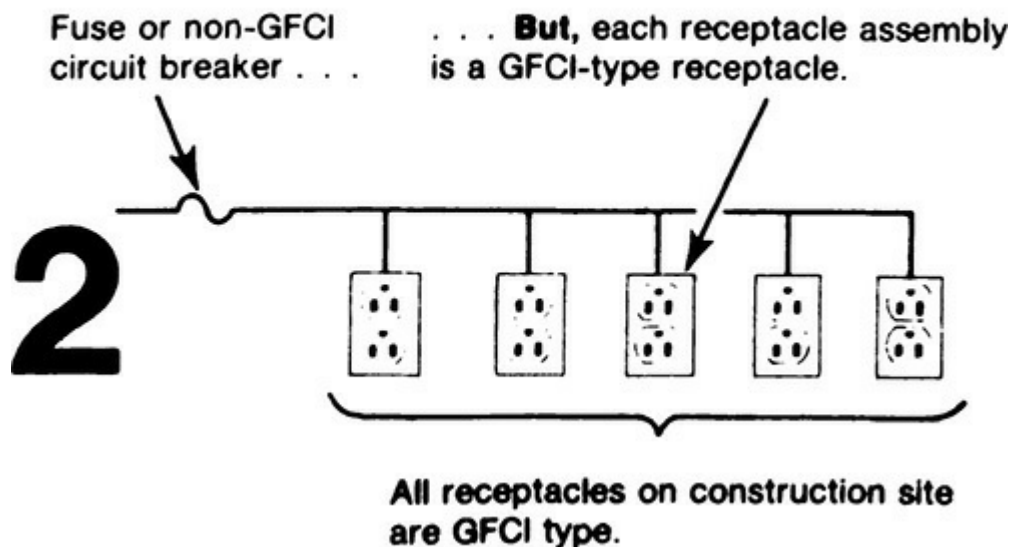

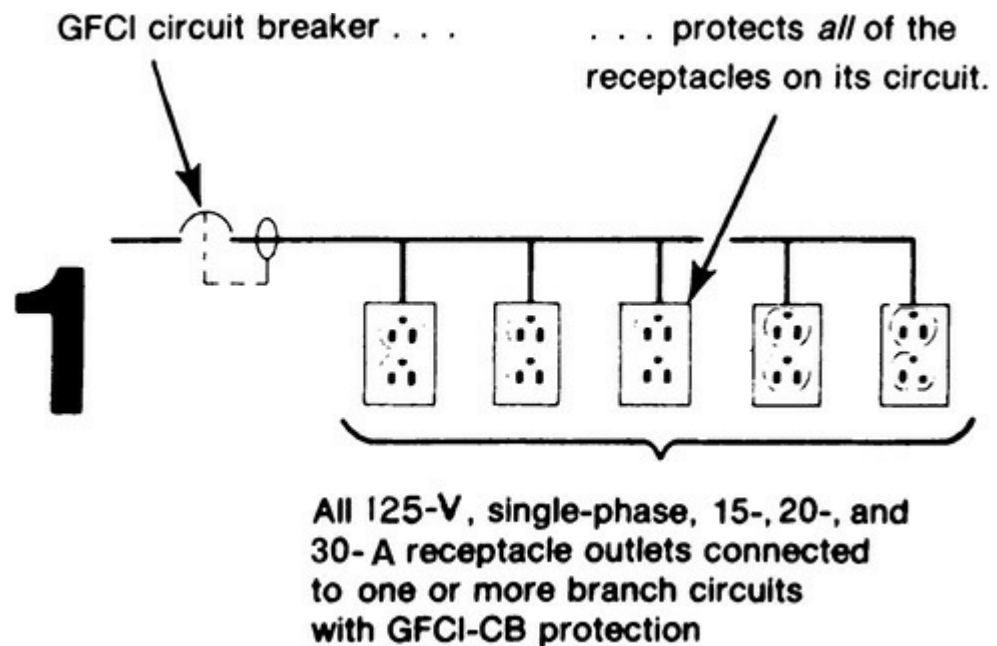

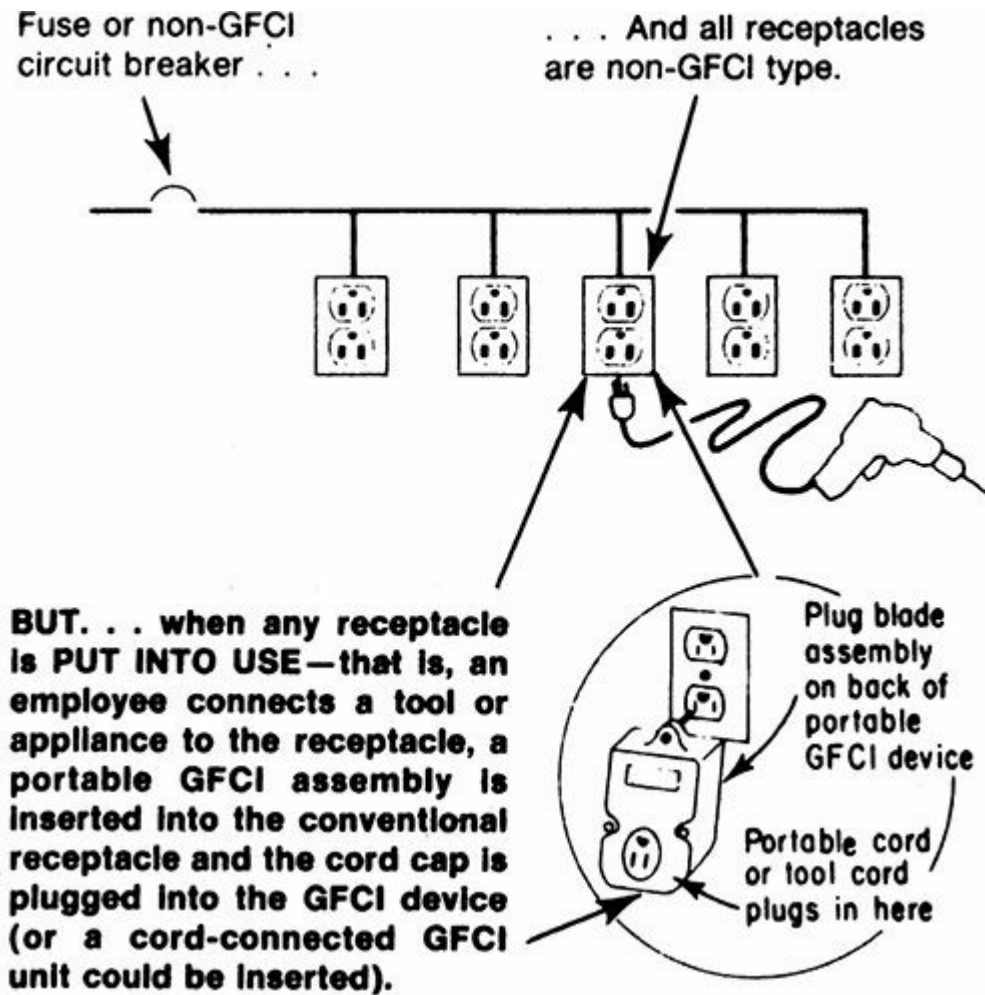

Fig. 590-12. Two ways to satisfy the basic rule on personnel shock protection at *temporary* receptacles on construction sites that are part of the permanent wiring of the building or structure subject to construction activities. [Sec. 590.6(A)(2).] Listed GFCI cord sets or devices identified for portable use can also be used. That means they will have internal circuitry that opens all poles of the device if the grounded circuit conductor is open for any reason. Conventional GFCI devices for permanent connection in a panel or at an outlet do not have this feature, and will fail closed (energized) if the grounded conductor opens because their circuitry will not have the 120 V they need

to work. This is why making a short extension cord with an ordinary GFCI receptacle in a box does not comply with this requirement.

Both paragraphs only directly apply to receptacles that: [Paragraph **(1)** “are in use by personnel”] or are [Paragraph **(2)** “used for temporary electric power”]. For either paragraph the Code wording clearly limits required GFCI protection to receptacles that are actually being used at any particular time. Receptacles not in use do not have to be GFCI-protected. This means that portable GFCI protectors may be used at only those permanently installed outlets being used ([Fig. 590-13](#)). There is no need to use GFCI breakers in the panel to protect all receptacles or to use all GFCI-type receptacles. This might seem to seriously confuse the task of electrical inspection. If all cord-connected tools and appliances are unplugged from receptacles when the inspector comes on the job, then none of the receptacles is “in use” and none of them has to have GFCI protection, and there is no Code violation. Most inspectors can see through such foolishness.

These 15A receptacles are fed by a temporary branch circuit without ground-fault protection ahead of them.

Wherever personnel are using cord-connected tools they plug in this portable ground-fault circuit interrupter having protected receptacles on its face for connection of the tools.

Fig. 590-13. Portable GFCI devices may be used to satisfy GFCI rule, but only when plugged into receptacles that are permanently installed. The drawing at the top, presumed to show receptacles that are permanently installed, shows a portable GFCI applied correctly. The violation for lack of GFCI protection at the temporary receptacles in the bottom drawing cannot be cured with portable GFCI devices. (Sec. 590.6.)

The 2008 **NEC** added the requirement that GFCI protection must apply “to power derived from an electric utility company or from an on-site-generated power source.” Paragraph **(3)** now carries the generator portion of that requirement in the **NEC**. Now all receptacles for construction activities that are a part of a 15-kW or smaller portable generator must have listed GFCI protection for personnel. Such portable generators must also provide listed GFCI protection for 125/250-V receptacles if they provide them. Note also that for portable generators that will operate in damp or wet locations, 15- and 20-A 125- and 250-V single-phase receptacles that are “part” of the generator must have the weather-resistance and the in-use cover features required in 406.9.

GFCI receptacles don't provide meaningful protection on ungrounded circuits, and if the generator neutral is not bonded to the frame, then the generator output circuits are functionally ungrounded. For this reason, the recently released UL Standard on Portable Engine Generator Assemblies (UL 2201) requires all 15-kW or smaller portable generators to have bonded neutral connections. This makes them suitable to supply GFCI receptacles that will actually trip on a ground fault, and therefore agrees with the new rules in this paragraph. This change is extremely controversial in the generator community. Refer to the discussion in this book at 250.34 on portable generators for more information on this point. Because of the large numbers of generators without bonded neutrals, Paragraph **(3)** also allows portable-use GFCI protective devices to be used on all generators manufactured or rebuilt prior to Jan. 1, 2011. There are further developments in this area, covered in some depth in this book in the commentary regarding the new Sec. 445.20.

Part **(B)** extends the requirements to all receptacles other than those for construction activities [as defined in the discussion at **(A)** for these purposes]. That includes 3-phase and phase-to-phase receptacles of any current value temporarily installed. Alternately, the Assured Equipment Grounding Conductor Program explained in the remainder of this section may be used.

As of 2013, some manufacturers are making new classes of GFCIs available. They use a 20 mA trip threshold, which will not cause ventricular fibrillation but can be enough to cause the muscles to lock on to the faulted equipment. They work on the principle that if there is a suitable equipment grounding return path in parallel with the person being shocked, then the fault will be cleared before permanent damage is done. In effect the ground trip is the let-go protection. UL anticipated these by creating the relevant categories in the 2009 edition of the standard. For example, a Class C device can be used on circuits not over 300V to ground (e.g., 480Y/277V). These circuits must use an EGC at least equal in size to the circuit conductors and the device must trip if the ground opens. There are also Class D devices for 600V systems.

The 2017 **NEC** recognized this option by adding, as a new **(B)(2)** “Special purpose ground-fault circuit-interrupter protection for personnel” or “SPGFCI.” This is the first time this technology has made it into the **NEC**, and undoubtedly it won't stop here. They are covered in UL Standard 943C.

Still another option for avoiding use of GFCI protection on temporary wiring systems is given in part **(B)** of this section for other than 15-, 20-, or 30-A, 125-V receptacles. GFCI protection at the higher ampere and voltage ratings of receptacles may be omitted totally if a “written procedure” is established to assure testing and maintenance of “equipment grounding conductors” for receptacles, cord sets, and cord-and-plug-connected tools and appliances used on the temporary wiring systems (Fig. 590-14). In effect, the **NEC** accepts such an equipment grounding conductor program as a measure that provides safety that is equivalent to the safety afforded by GFCI protection. GFCI protection is not required for other than the 15-, 20-, and 30-A, 125-V receptacles if all the following

conditions are satisfied:

A written procedure must cover testing of...

... all cord-connected tools and equipment

Continuity tester to assure connection of equipment grounding conductor

... and all receptacles, cord sets, and extension cords.

Continuity tester or ohmmeter to check connections and assured grounding continuity

15-, 20-, and 30-A locking plugs and receptacles are also covered under the assured grounding program.

Fig. 590-14. Assured grounding program eliminates the need for GFCI.

Note: The assured equipment grounding program may *only* be used on 15-, 20-, and 30-A, 125-V receptacles in industrial establishments. (Sec. 590.6.)

1. The inspection authority having jurisdiction over a construction site must approve a written procedure for an equipment grounding program.
2. The program must be enforced by a single designated person at the construction site.
3. “Electrical continuity” tests must be conducted on all equipment grounding conductors and their connections. The requirements on making such tests are vague, but they do call for:
 - a. Testing of fixed receptacles where there is any evidence of damage.
 - b. Testing of extension cords before they are first used and again where there is evidence of damage or after repairs have been made on such cords.
 - c. Testing of all tools, appliances, and other equipment that connect by cord and plug before they are first used on a construction site, again any time there is any evidence of damage, after any repair, and at least every 3 months.

Obviously, these rules are very general and could be satisfied in either a rigorous, detailed manner or a fast, simple way that barely meets the qualitative criteria. The electrical contractor who has responsibility for the temporary wiring on any job site is the one to develop, write, and supervise the Assured Equipment Grounding Program, where that option is chosen as an alternative to use of GFCI protection. This whole **NEC** approach to use of either GFCI or an Assured Equipment Grounding Program directly parallels the OSHA approach to the matter of receptacle protection on construction sites.

It should be noted that the Assured Equipment Grounding Program described in part **(B)** is one of the most frequently cited violations during OSHA inspections. Implementation is a bureaucratic nightmare and is rarely successfully executed.

Chapter Six

ARTICLE 600. ELECTRIC SIGNS AND OUTLINE LIGHTING

600.1. Scope. In the case of signs that are constructed at a shop or factory and sent out complete and ready for erection, the inspection department must require listing and installation in conformance with the listing. In the case of outline lighting and signs that are constructed at the location where they are installed—the so-called skeleton tubing covered by Part II—the inspection department must make a detailed inspection to make sure that all requirements of this article are complied with.

Rules governing the installation of electric signs vary widely from jurisdiction to jurisdiction. In some cities, inspection departments inspect signs in local shops as well as performing installation site inspections. Likewise, in some cities, the electrical inspector conducts the sign inspection alone. In others, a sign inspector will review plans for proposed signs for compliance with local ordinances, and the electrical inspector will then do the field inspection in conjunction with the sign inspector. Contact the building department in the municipality having jurisdiction to establish the exact procedure that must be followed.

600.2. Definitions. This section contains a number of definitions that are critical to the proper application of the Code rules for electric signs and outline lighting.

600.3. Listing. All electric signs, section signs, and outline lighting, whether fixed, mobile or portable, and all retrofit kits applied for similar purposes must be listed unless exempted by special permission. However, field-installed skeleton tubing is not required to be listed if installed per **NEC** rules, and outline lighting need not be listed as a system if it consists of listed luminaires wired using [Chap. 3](#) methods. Required markings and listing labels must be visible to the installer and servicer, but need not be visible on the outside after the installation is completed. The 2014 **NEC** notably includes a requirement, directed at manufacturers, that essentially all products within the scope of Art. 600 must be marked to say that “field-wiring and installation instructions are required.” The intended purpose is to put installers firmly on notice to abide by 110.3(B) and follow the directions. The only exception to this rule is for portable, cord-connected signs.

600.4. Markings. As of the 2017 edition, this section addresses signs retrofitted from fluorescent lamps to tubular-style LED strips. After the retrofit procedure, the sign may have characteristics that will cause a conventional fluorescent lamp to fail violently if mounted in the lamp sockets now wired for the LED replacements. Sign retrofits done in this matter must have a marking applied that alerts service personnel to the retrofit, identifies the equipment manufacturer and the installer, and provides a suitable warning label in accordance with 110.21(B) advising not to attempt the substitution of fluorescent lamps for the LED strips.

600.5. Branch Circuits. In part (A), the Code mandates that any commercial occupancy that is

“accessible to pedestrians” must be provided with one outlet for the purpose of supplying an electric sign, which must be accessible. Additionally, this section requires that the branch circuit supplying this outlet be a dedicated circuit, with no other loads supplied. The wording of this section requires that a sign outlet be installed for every ground-level store—even if an outdoor electric sign is not actually installed or planned. Note that no limit is placed on the number of outlets that may be connected on one circuit for a sign or for outline lighting, except that the total load should not exceed 16 A where incandescent or fluorescent lighting loads are to be supplied. A 30-A maximum is established for branch circuits supplying neon tubing. However, the minimum size for this circuit is 20 A. Note that for a mall-type environment, the wording is for “each entrance” so the outlet could be on the central hallway.

Where the loads to be supplied are “continuous loads,” that is, where in normal operation, the load will continue for 3 h or more, the load should not exceed 80 percent of the branch-circuit rating. Given that commercial lighting is generally considered to be a “continuous load,” circuits and OC devices used to supply and protect such loads must be sized on the basis described for continuous loading, and 600.5(B) removes all doubt by classifying this load. That is, the conductors must have current-carrying capacity that is at least 125 percent of the continuous load, before derating. And the OC device must also have a long-time trip rating of at least 125 percent of the rated lighting load. This effectively translates into a 16-A maximum lighting load and No. 12 copper conductors for a 20-A circuit, and 24 A using No. 10 copper on a 30-A circuit. See 210.19(A), 210.20(A), and 240.4(D).

Part **(B)** indicates the minimum ratings for the required sign circuit. The 20-A branch circuit for sign and/or outline lighting for commercial occupancies with ground-floor pedestrian entry—required by part **(A)**—may supply one or more outlets for the purpose, but not any other loads. The intent is that the required, dedicated 20-A circuit supply one or more outlets intended for electric signs. However, if the intended sign is to be made of neon tubing, the rating could be 30 A (and no more).

As noted in part **(C)**, the wiring method used to supply signs must conform with the requirements of parts **(1)**, **(2)**, and **(3)**.

In part **(C)(1)**, the Code requires that the wiring method used to supply the sign—which may be any of the wiring methods recognized in [Chap. 3](#) suitable for the type of location in which the sign is installed—must be terminated either in the sign, in a box provided with the sign, or in a typical junction/outlet box or conduit body. In part **(C)(2)**, the Code recognizes the use of signs and electric-sign transformer enclosures as raceways to supply adjacent signs and associated equipment. And part **(C)(3)** mandates that metal poles used to support electric signs comply with the rules for poles used to support lighting, as covered in 410.30(B). (See [Fig. 600-1](#).)

Fig. 600-1. Commercial buildings must have outdoor sign outlet. (Sec. 600.5.)

600.6. Disconnects. This section is somewhat difficult to understand and expect consistent interpretation of because the parent language at the subsection level provides an unclear context for the three parts that follow. The major point of disagreement turns on whether it is sufficient to comply with any one of the three location rules. Each of the three carries mandatory language.

Taking the last one (3) first, it is clear that there must be a disconnect in sight of a sign controller remote from the sign, that the disconnect must be ahead of the sign as well as the controller, and that disconnect must have a lock-open capability. The next case is (2), which requires a sign ahead of the disconnect, and if the sign is configured in such a way that part of it is out of the line of sight from the disconnect, then that disconnect must also have a lock-open capability, such as where a multisection sign extends around the corner of a building.

The **NEC** has applied these concepts in a very consistent way since sign disconnects first appeared as Rule 3807 of the 1928 edition. For almost 90 years, signs have been required to have disconnects, either in sight or remote with a locking feature. The parent text of the section, which provides the general requirements for disconnection, dictates that they must be externally operable, control no other load, and open all legs of a multiwire circuit simultaneously. Every instance of the term “disconnect” is handled grammatically as singular in number.

This was the context into which the 2014 **NEC** placed 600.6(A)(1), renumbering the previous options as (2) and (3). It either required or covered, interpretation being required, a disconnect at the physical location of the sign itself, at the point where the electrical supply circuit for the sign enters

the sign enclosure, or its supporting pole. And by the term “enclosure,” the intent is a reference to the outer margin of the sign itself, and not any electrical enclosure within the sign body. The rule does address very large signs, some larger than houses, that are supplied by multiple feeders running in [Chap. 3](#) raceway wiring methods supporting different parts of what is technically a single sign.

Following discussions with panel members during the 2014 **NEC** cycle and reviewing the supporting substantiation, it was apparent at the time that the panel intended the first requirement to supersede the existing options and to apply to all signs. However, it was also the case that the second and third options were not removed, nor was any prioritizing language inserted to follow the subsection title, “Location.” All three numbered items, based on the literal text, had to be regarded as compliant, and there was no basis to require multiple disconnects.

Three years later (2017 **NEC**), the literal text is still unclear, but the context has improved considerably. There is now parent language ahead of the three options stating “shall be permitted to be located” in reference to the three options. The sentence, however, does use the conjunction “and” instead of “or,” potentially suggesting all of the options need to be installed. The substantiation supporting the 2017 **NEC** language is very helpful here, because it comes from the the major trade organization of professional sign installers, and the intent is very clear:

The current text of the rule does not specify that the subsections are choices for the disconnect location. Texts added to identify the subsections that follow are separate, alternate rules for the location of the sign’s disconnecting means. “Shall be permitted” effectively conveys the rule is allowed as an option/choice for the location of the disconnecting means as intended by the additional text in (A).

In addition to this substantiation, there is also a highly significant group of text changes within all three of the options. For options (2) and (3), when they are out of sight of the sign, a warning label meeting the requirements of 110.21(B) must be inserted where it will be visible during service work, and it must spell out the location of the disconnect. This is even true of the first option (right at the sign), which carries that language in its exception addressing very large signs with internal panelboards located remotely. If items (2) and (3) were superseded by (1), that language would not have been necessary.

Option (1) is particularly directed at very large signs, and to that end now carries an exception directed at extremely large signs with a panelboard within them. The panel can be remote from the entry point, but the feeder wiring must be in a raceway or metal jacketed cable with a warning label applied that advises that the enclosed wiring may be energized.

It is now clear that enforcing authorities should not attempt to prioritize (A)(1) and disallow any other location for the required disconnect. The technical merit for such an interpretation is compelling. A close examination of instances cited in the supporting substantiation for the 2014 **NEC** change demonstrates that the conclusion reached was fallacious and, on the contrary, that strict adherence to the provisions of (A)(2) would have been fully sufficient to address the problems cited. If a worker does not choose to avail himself or herself of reasonable provisions for disconnecting a sign and keeping that disconnect locked open as appropriate, the responsibility for the consequences of a failure does not rest with the **NEC**. However, as always, the final decision rests with the authority enforcing the Code. Figure 600-2 depicts the disconnecting means that should be within sight of the sign, outline lighting, or remote controller, as covered in part **(A)(2)**. The phrase “within sight” is clearly defined in Art. 100, and it is well understood that it means the same thing as the phrase “in sight from,” which specifies that it shall be visible and not more than 50 ft (15.0 m) distant

from the other. Some signs are comprised of sections as part of a listed unit (see the “Section Sign” definition in 600.2) and those sections may in some cases be placed where they continue around the corner of a building. In such cases, part of the sign will be “out of the line of sight” from other sections, and the disconnect must be capable of being locked in the open position. Note that section signs must be marked to indicate that field wiring and installation instructions are required.

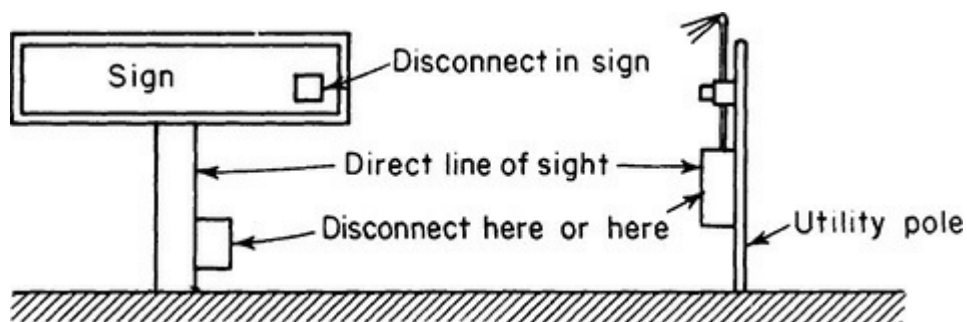

Fig. 600-2. An “in-sight” disconnect may be *in* the sign or visible from the sign. (Sec. 600.6.)

Figure 600-3 illustrates the conditions recognized by part (A)(3), which allows the disconnecting means to be located within sight of the controller where the signs are operated by electronic or electromechanical controllers located external to the sign. Note that any sign disconnect located within sight of the controller must be capable of being locked in the OFF or OPEN position, as specified in part (A)(2)(3).

Fig. 600-3. Controller disconnect location may vary, but disconnect must be lock-open type. (Sec. 600.6.)

With respect to part (B), any switching device controlling the primary of a transformer that supplies a luminous gas tube operates under unusually severe conditions. In order to avoid rapid deterioration of the switch or flasher due to arcing at the contacts, the device must be rated for inductive loads or have a current-rating of at least twice the current rating of the transformer it controls. General-use ac snap switches, as covered in 404.14, are rated for inductive loads and will handle motor loads up to 80 percent of their rating, making them suitable for this application provided a permanent provision has been made for locking them open. There are handy-box and square-box raised covers available with factory mounted escutcheons around the toggle slot that will accept padlocks.

The question of what constitutes “operated by electronic or electromagnetic controllers” frequently arises in the context of modern energy management systems that turn signs on and off along with other building lighting. The purpose of the disconnect rule is to provide maintenance personnel with a secure means to ensure that the equipment they are working on is disconnected and that it will stay that way until they are ready to reenergize it. By long usage and custom, a maintenance disconnect is unique to its equipment. No one would seriously suggest that because a service disconnect could be locked in the OPEN position, all **NEC** requirements for disconnects of specific loads were met. Any maintenance worker on any downstream equipment would feel compelled to work the downstream equipment hot rather than inconvenience the enterprise to that extent. Therefore, if the energy management system operates a contactor for a sign among other control devices for other loads, this section requires that contactor to be in sight of a disconnect, that disconnect will be capable of being locked open, and a second disconnect would not be required at the sign location. On the other hand, if the contactor operated a lighting panel for which the sign was one load among many, then a local disconnect for the sign must be installed, and apply the warning signs now required within the sign enclosure that will clearly indicate where the disconnect can be found. This principle has also been reinforced and the requirement clarified through the added wording “and controls no other load” to the parent wording of 600.6.

600.7. Grounding and Bonding. The general principles in this section agree with the grounding principles in Art. 250, but there are specific provisions that are unique to this article, particularly with respect to neon signs that operate at high voltage and very low current. Part **(A)** addresses equipment grounding connections to sign parts that may be exposed to line voltage and follow the usual rules for equipment grounding connections. Specific language forbids the use of metal building parts as an equipment grounding return path, reiterating 250.136(A). Small metal parts, such as the metal feet on tubing support clips, do not require bonding connections, and remote metal parts in a section sign powered by a Class 2 power supply need not be bonded either. Although skeleton tubing does not have metal parts over the length of the tubing, if it is enclosed in a metal housing or has a transformer enclosure or such items as metal tubing receptacles, then those items also fall within the equipment grounding provisions.

Part **(B)** addresses bonding and addresses neon signage with provisions that are unique throughout the **NEC**. Flexible metal conduit is permitted in total accumulated lengths of up to 30 m (100 ft) as a bonding conductor, although the run from the transformer to the first termination will not exceed 6 m (20 ft) per 680.32(J)(1). The currents are very small, and the performance of this wiring method in this context was investigated by a testing laboratory. If the wiring to the sign is in a nonmetallic wiring method such as PVC conduit, the bonding conductor must run outside the conduit, with the spacing governed by the frequency of the power supply ([Fig. 600-4](#)). For transformers with no change in frequency, the spacing from conductor to conduit must be at least 38 mm (1½ in.), and for electronic power supplies with frequencies over 100 Hz, the spacing must be at least 45 mm (1¾ in.). This reduces the voltage gradient between the GTO cable and the bonding conductor, and in doing so, it reduces the likelihood of damaging corona discharge. Metal raceways distribute the ground plane equally around the cable, and are also shorter, as noted in [Fig. 600-4](#). Research showed that most of the damage occurs in the initial cable run from the power supply.

Fig. 600-4. Many unique bonding requirements apply to neon installations. (Sec. 600.7.)

The **NEC** does address, courtesy (originally) of Las Vegas, the wiring of signs in fountains. Most of the requirements are in 680.57, covered later in this chapter. However the bonding requirements are here, in that the metal piping system, required to be bonded by 680.53, is permitted as the bonding connection required here. If the piping is nonmetallic, then a connection must be arranged to the equipment grounding conductor. This section also addresses the increasing use of LED and other sign components that can function within Class 2 power limitations. Here 600.7(B)(1) Exception waives the bonding requirements for “remote” metal parts of a section sign or outline lighting system from any need to be connected to an equipment grounding conductor. Presumably, “remote” means remote from the power supply and not from the first display component of the sign itself, but this is not completely clear.

600.10. Portable or Mobile Signs. This rule applies to outdoor portable or mobile signs that are plug-connected. The rule calls for manufacturer provided GFCI protection in or within 12 in. (300 mm) of the plug cap at the end of the supply cord from the sign to protect personnel from potential shock hazards. Documentation for the need for this new rule cited six accidents—three deaths and three shocks—due to ground faults in such outdoor signs that were plug-connected but in which there was no grounding connection or a failed grounding connection. Note that the product standard requires that this integral protection include open-neutral protection, as discussed in the previous chapter (590.6).

600.12. Field-Installed Secondary Wiring. The parent language has added skeleton tubing, thereby correlating with the title of Part II, and the three categories in this section point to sections within Part II depending on whether the wiring is over (600.32) or equal to or under 1000 V (600.31) on the secondary side. For LED sign illumination systems operating on Class 2 power supplies recognized in 600.24, the Part II destination is 600.33 using [Chap. 3](#) wiring methods or Class 2

compliant cabling covered in Part II of Art. 725. In general, signs and outline lighting are required to be listed items. Part II of the article covers the portions of a sign installation that must be field installed, including the interconnecting wiring between section signs, and field installations of skeleton tubing signs and outline lighting. This terminology (“secondary”) implies the secondary side of transformers, as are usually involved somewhere in the voltage transformations, either up or down. However, both 600.23 and 600.24 apply the term “secondary” equally to both “transformers and electronic power supplies” for elevated voltage and to “transformers, power supplies, and power sources” in the case of Class 2 sources.

600.21. Ballasts, Transformers, Electronic Power Supplies, and Class 2 Power

Sources. The transformers used to supply luminous gas tubes are, in general, constant-current devices and, up to a certain limit, the voltage delivered by the transformer increases as the impedance of the load increases. The impedance of the tube increases as the length increases and is higher for a tube of small diameter than for one of larger diameter. Hence, a transformer should be selected that is designed to deliver the proper current and voltage for the tube. If the tube is too long or of too small a diameter, the voltage of the transformer may rise to too high a value. The maximum voltage permitted is center-grounded 15 kV (max. voltage to ground on each leg 7500 V) with 300 mA as the maximum current allowed, as covered in 600.23(C&D). The various power sources must be either self-contained or enclosed in a listed sign body or in a listed enclosure.

This section includes numerous rules on location of and access to this equipment. The first consideration is to minimize the length of the secondary conductors, which places the power supply as close as possible to the sign or outline lighting. Locations above suspended ceilings are acceptable as long as the branch-circuit connections use [Chap. 3](#) wiring methods and not flexible cord. Wherever located, the equipment must have work space for servicing, defined as a cubical volume 1 yd (900 mm) on a side, and if located in an attic, there must be access to this space through an access door no thinner than the spacing between standard framing on 24-in. (610-mm) centers, and at least 900 mm (3 ft) high. There must be a permanent walkway to the location at least 300 mm (1 ft) wide and the work space must be lit with the lighting controlled either by a snap switch or a pull chain, as long as the control can be activated at the point of entry. Note that because Class 2 power sources have been added throughout 600.21, this special access provision even applies to a Class 2 transformer, which may seem excessive. When challenged on this highly controversial point, the Code panel defended it as justified based on the line-voltage, primary-side connections.

600.23. Transformers and Electronic Power Supplies. This equipment must be listed, and must incorporate, with limited exceptions, secondary-circuit ground-fault protection. Arcing failures on the secondary side of these transformers involve very small but ignition-capable currents. This major design innovation responds to numerous documented fires from this source. The power supply must be marked accordingly.

600.24. Class 2 Power Sources. Thanks to the evolution of LED light sources, some signs and outline lighting can actually operate under Class 2 power limitations, and those are covered here.

600.31. Neon Secondary-Circuit Wiring, 1000 Volts or Less, Nominal. This section covers small neon applications that operate at not over 1000 V and can use conventional [Chap. 3](#) wiring methods. It is included to completely fill out the wiring requirements for the full range of sign applications covered in 600.12.

600.32. Neon Secondary-Circuit Wiring, over 1000 Volts, Nominal. These are the

wiring rules governing the secondary side of a neon-lighting power supply. Most [Chap. 3](#) raceways are permitted, but ENT is not, based on concerns it may sag over time in a way that would not have been apparent during the original installation or inspection, and drop the contained single-conductor GTO cable too close to a grounded surface. As noted in [Fig. 600-4](#), these surfaces must also meet the distances required of bonding conductors, and for the same reasons. In running nonmetallic raceways, nonmetallic methods must be used to secure the raceways away from grounded building elements to the extent required. This rule does not, however, prevent the use of grounded metal raceways, because the ground plane evenly surrounds the cable. The final choice of wiring method involves consideration of permitted length of cable run (advantage: nonmetallic) versus spacing requirements (advantage: metallic) along with any other design factors. These may include recommendations of the power supply manufacturer, which may include limitations based on the amount of capacitive reactance its power supply can cope with. Note that the maximum distances specified here are not accumulative distances as in 600.7, but only to the first tubing connection. Where the GTO cable emerges from a metallic raceway, the insulated cable must extend not less than 65 mm (2½ in.) beyond the raceway end.

The 2014 **NEC** deleted PVC and RTRC conduits from the acceptable list of wiring methods for neon secondary-circuit wiring. The change was very poorly substantiated based on the 105°C rating of the enclosed GTO cabling exceeding that of the PVC and RTRC conduits. However, just because a wire has a temperature rating it does not follow that it will operate at this temperature; the rating may be directed to the behavior of the expected terminations. This is certainly the case of wiring terminating at an arc discharge point on neon tubing, which is far different from heating produced by current draw over the length of these conductors. In addition, the UL Guide Card information shows RTRC as inherently capable of 110°C operation, and the temperature limits for LFNC, the last nonmetallic wiring method remaining, are generally similar to PVC conduit. This is not really unexpected given that both wiring methods start with the same chemical conduit (polyvinyl chloride) and then plasticizer is added to the flexible product. In addition, LFNC is inherently more flexible than ENT, and ENT was omitted from the list because of its flexibility compared to PVC.

600.33. Class 2 Sign Illumination Systems, Secondary Wiring. This section centralizes the requirements that apply to LED circuits used in signs, incorporating a reference Part III of Art. 725 and the sign manufacturer's instructions together with a general reference allowing any [Chap. 3](#) wiring methods as would apply to the installation conditions to be used on the supply side of the sign, as covered in 600.12. Class 2 wiring must be listed and no smaller than 22 AWG or the amount required by the load served if larger. Note that the **NEC** does have an ampacity table that applies to small conductors such as this (Table 522.22) in the event the installation instructions are not clear. Applications in wet locations must use cable identified for that usage or a moisture-impervious outer sheath is required. For all other locations, any cable permitted in Table 725.154(G) is permitted. The 2017 **NEC** has imported the relevant information from [Chap. 7](#) regarding cable types and allowable substitutions into this section. Nothing really changed except the code book got a little longer so sign installers will not have to pay attention to the rest of the book. This is an unfortunate trend.

Part (B) incorporates the contents of 725.24 (Mechanical Execution of Work), applying them to "support wiring." The 2017 **NEC** added a maximum support interval of 6 ft. Connections are to be made with insulating devices and only where accessible after installation. Connections in a wall must be made in a listed box. The remaining material requires wiring protection in accordance with 300.4 in locations subject to physical damage, and incorporates the grounding and bonding rules in 600.7.

Note that 600.7(B)(1) Exception waives the bonding requirements for “remote” metal parts of a section sign or outline lighting system from any need to be connected to an equipment grounding conductor.

600.34. Photovoltaic (PV) Powered Sign. This section adds little to the requirements of Art. 690, to which this section promptly refers. The components must be listed for PV applications. The wiring must be as short as possible, routed close to the sign body, and protected from damage. If used, flexible cord must be extra hard usage, and suitable for outdoor use. A disconnecting means must be provided as covered in Art. 690. Note that these self-contained signs, if operating at 30 or less, are not required to be grounded by the UL product standard. Part (F) does require that the design be such that a tool must be used to open the battery compartment.

600.41. Neon Tubing. Part (D) requires protection in the form of guards or other approved means if the skeleton tubing is accessible to other than qualified persons. Also note that 600.32(I) forbids the use of this type of installation in (or on) a dwelling occupancy.

600.42. Electrode Connections. These requirements have been toughened over the years, and now require listed components for most of this part of the installation.

ARTICLE 604. MANUFACTURED WIRING SYSTEMS

604.1. Scope. This article covers modular prefab wiring systems for ceiling spaces, raised floors, and increasingly walls as well. Both the system wiring and the associated components must be listed (604.6).

These manufactured wiring systems were logically dictated by a variety of needs in electrical systems for commercial-institutional occupancies. In the interest of giving the public a better way at a better price, a number of manufacturers developed basic wiring systems to provide plug-and-receptacle interconnection of branch-circuit wires to luminaires in suspended-ceiling spaces. Such systems afford ready connection between the hard-wired circuit homerun and cables and/or ducts that form a grid- or tree-like layout of circuiting to supply incandescent, fluorescent, or HID luminaires in the ceiling.

Acknowledged advantages of modular wiring systems are numerous and significant:

- Factory-prewired raceways and cables provide highly flexible and accessible plug-in connection to multicircuit runs of 120- and/or 227-V conductors.
- Drastic reductions can be made in conventional pipe-and-wire hookups of individual circuits, which are costly and inflexible.
- Plug receptacles afford a multiplicity of connection points for luminaires to satisfy needs for specific types and locations of lighting units to serve any initial layout of desks or other workstations while still offering unlimited, easy, and extremely economical changes or additions of luminaires for any future rearrangements of office landscaping or activities.
- Systems may also supply switches and/or convenience receptacles in walls or partitions, with readily altered switching provisions to provide energy conservation through effective ON-OFF control of any revised lighting layout.
- Work on the systems has been covered by agreement between the IBEW and associated trades.
- Such systems have a potential for a tax advantage of accelerated depreciation as office equipment rather than real estate.

604.10. Uses Permitted. Modular systems may be used in air-handling ceilings. Equipment may be used in the specific applications and environments for which it is listed by UL. Note that one end of such a system can be concealed, such as when it is fished down a wall that is open above a suspended ceiling, and used to connect either a switch or an outlet.

604.100. Construction. Prewired plug-in connections may be AC or MC cable or metal flex. The permitted conductors must be copper, and limited to a minimum of 12 AWG and running up to 8 AWG, and including a fully sized copper equipment grounding conductor (insulated or bare) is always required in each cable or flex length—even though flex itself is otherwise permitted to be used by the **NEC** without an equipment grounding conductor in lengths not over 6 ft (1.8 m), provided the wires within it are protected at not over 20 A, and AC cable in other uses is recognized by the Code and by UL for equipment grounding through its armor and enclosed aluminum bonding wire (Fig. 604-1). Type MC cable of the smooth or corrugated variety with a qualified armor and equipment grounding conductor combination is also permitted, provided it is equivalent to the ungrounded conductor sizing. The purpose for the 8 AWG is the reduction of voltage drop and not high ampere loading, and therefore the equivalent sizing is appropriate in these branch circuit sizes to meet 250.122(B).

Fig. 604-1. Modular wiring systems are fully recognized by the Code. (Sec. 604.100.)

The same sizing applies to conductors in flexible metal raceways. Here, however, a whip to a luminaire is permitted at not over 1.8 m (6 ft) using not less than 18 AWG taps. In addition, 12 AWG or larger flexible cord suitable for hard usage, not over 1.8 m (6 ft) long and visible over its entire

length, is permitted as a supply to equipment not fixed in place, such as some display cases. This wiring system is also permitted to contain signaling and communications wiring, within the limits set in Art. 725 and [Chap. 8](#).

Listed manufactured wiring systems may also incorporate unlisted flex of smaller than **NEC** recognized trade sizes, and/or noncircular cross-section, provided the systems are supplied with fittings and conductors when manufactured. Flexible cord suitable for hard usage is also permitted in sizes not smaller than 12 AWG to provide for wiring transitions to utilization equipment that is not permanently installed and secured to the building. It must be visible over its entire length and provided with appropriate strain relief.

These systems may incorporate busways, and also prewired surface metal raceways that meet the requirements of 386.100 as part of their design, and they must be installed in accordance with Arts. 386.12, 386.30, and 386.60. Note that as worded, 386.100 appears as an installation criterion, which is obviously a mistake because an installer has no control over the extent to which a surface metal raceway complies with the manufacturing criteria in that section.

ARTICLE 605. OFFICE FURNISHINGS

605.1. Scope. This Code article covers electrical equipment that is part of manufactured partitions used for subdividing office space, as shown in [Fig. 605-1](#). The 2014 **NEC** has revised the article throughout to replace the terms “relocatable wired partitions” and “partition” and related terminology with “office furnishings” to correlate with the terminology used in the product safety standard for this equipment, and as now formally defined in Sec. 605.2.

Fig. 605-1. This article covers electrical wiring and electrical components within or attached to manufactured partitions, desks, cabinets, and other equipment that constitute “office furnishings.” Photo at top shows interior wiring in base of partitions, to supply luminaires and receptacle outlets—as shown at arrows in bottom photo of a typical electrified office work station.

605.3. General. Only those wiring systems “identified” to supply lighting and appliances may do so. Check the listing data and manufacturer’s installation instructions to ensure proper use and installation. The partitions must not extend from floor to ceiling without the permission of the inspector, and if they do reach the ceiling, they must not go above it in any way.

605.5. Office Furnishing Interconnections. Wired partitions may be interconnected by a cord and plug. If cord is used, the partitions must be “mechanically contiguous” and the cord must be of extra-hard-usage and of 12 AWG minimum, and no longer than required to make the connection and never longer than 600 mm (2 ft). The basic rule calls for interconnection of partitions by a “flexible assembly identified for use with wired partitions.”

605.9. Freestanding-Type Office Furnishings, Cord-and-Plug-Connected. A partition or group of connected partitions [not over 9.0 m (30 ft) long] that is supplied by cord-and-plug connection to the building electrical system must not be wired with multiwire circuits (all wiring must be 2-wire circuits) and not more than thirteen 15-A, 125-V receptacles may be used. The receptacles included in the count include either duplex receptacles (therefore counted as one) or two adjacent single receptacles not more than 0.3 m (1 ft) apart. The supply receptacle(s) must be on its (their) own circuit(s) and not more than 300 mm (12 in.) from the partition supplied. The supply cord must meet the same requirements as for interconnecting cords as covered in 605.5. Note that 605.7 requires fixed partitions to be connected using [Chap. 3](#) wiring methods, and 605.7 & 8 [see also 605.9(D) informational note] do allow multiwire circuits to supply freestanding partitions, but only where [Chap. 3](#) wiring methods bring them (must comply with 210.4) to the partition.

ARTICLE 610. CRANES AND HOISTS

610.11. Wiring Method. In general, the wiring on a crane or a hoist should be raceways, or Type AC with a grounding conductor, Type MC or Type MI. However, for practical considerations, short lengths of flexible conduit or metal-clad cable and even open conductors may be used for connections to motors, brake magnets, or other devices where a rigid connection is impracticable because the devices are subject to some movement with respect to the bases to which they are attached. In outdoor or wet locations, liquidtight flexible metal conduit should be used for flexible connections. Part (E) also recognizes listed festoon cable for flexible uses. This is defined in 610.2 as either single or multiconductor, and it is available with temperature ratings from 60°C up through 105°C and it carries a 600-V insulation rating as well. Do not confuse this wiring method, which has been listed expressly for Art. 610 context, with “festoon lighting” covered in 225.6(B), 225.24, and 520.65. It is also recognized in 610.13(C) for flexible applications, and it can be rolled into a take-up device or reel.

610.14. Rating and Size of Conductors. Crane conductors operate for very limited time intervals, and the NEC includes a special ampacity table for this purpose. Note that there is exactly one place in the NEC where 5 AWG wire has formal recognition and it is here in this table. Part (E)

covers motor calculations such as where multiple motors could operate at one time. As covered here using nameplate data, take the largest motor or group of motors for any particular crane motion, and add 50 percent of the next largest motor or group of motors, in all cases using the column of Table 610.14(A) that applies to the longest time-rated motor.

610.21. Installation of Contact Conductors. Part (F) permits use of the track as one of the circuit conductors. In some cases, particularly where a monorail crane or conveyor is used for handling light loads, for the sake of convenience and simplicity it may be desirable to use the track as one conductor of a 3-phase system. Where this arrangement is used, the power must be supplied through a transformer or bank of transformers so that there will be no electrical connection between the primary power supply and the crane circuit, as in Fig. 610-1. The secondary voltage would usually be 220 V, and the primary of the transformer would usually be connected to the power distribution system of the building or plant. The leg connected to the track must be grounded at the transformer only, except as permitted in 610.21(F)(4).

Fig. 610-1. Isolating transformer is used to power track of crane or conveyor. (Sec. 610.21.)

610.32. Disconnecting Means for Cranes and Monorail Hoists. This disconnect is an emergency device provided for use in case trouble develops in any of the electrical equipment on the crane or monorail hoist, or to permit maintenance work to be done safely. A motor-circuit switch, molded-case switch, or circuit breaker (or other 430.109 compliant method) must be provided in the leads from the runway contact conductors or other power supply on all cranes and monorail hoists. The disconnecting means must be capable of being locked in the open position. As in other places where the **NEC** discusses required disconnecting means, the provision for locking or adding a lock to the disconnecting means must be installed on or at the switch or circuit breaker used as the disconnecting means and must remain in place with or without the lock installed. Portable means for adding a lock to the switch or circuit breaker is not permitted.

Where a monorail hoist or hand-propelled crane bridge installation meets all of the following, the disconnecting means need not be installed:

1. The unit is controlled from the ground or floor level.
2. The unit is within view of the power supply disconnecting means.

3. No fixed work platform has been provided for servicing the unit.

Where the disconnecting means is not readily accessible from the crane or monorail hoist operating station, means must be provided at the operating station to open the power circuit to all motors of the crane or monorail hoist.

610.33. Rating of Disconnecting Means. It is possible that all the motors on a crane might be in operation at one time, but this condition would continue for only a very short while. A switch or CB having a current rating not less than 50 percent of the sum of full-load current rating of all the motors will have ample capacity. The continuous ampere rating of the switch or circuit breaker specified above shall be not less than 50 percent of the combined short-time ampere ratings of the motors nor less than 75 percent of the short-time ampere rating of the motors required for any single motion.

Note that Art. 610 uses the wording “within view” in several places instead of “in sight” consciously in order to avoid the 15 m (50 ft) limitation built into the **NEC** definition of “in sight.” Many large industrial cranes are too big to make the 15 m (50 ft) limit workable.

610.61. Grounding. All exposed non-current-carrying metal parts of cranes and hoists must be bonded together, usually by the usual mechanical connections, to make an effective ground-fault current path. Moving parts may have their equipment grounding continuity established through metal-to-metal contact on bearing surfaces, making it unnecessary to run very long, strain-relieved bonding conductors that would need to accommodate major frame movements of perhaps hundreds of feet at large industrial facilities. However, as of the 2005 **NEC**, the contact between the wheels of a trolley (the part that makes the load go up and down) and its associated bridge girder can no longer be depended upon for grounding continuity, and now a bonding conductor must be installed between these two parts. The wording change only covers the trolley frame, and not the bridge girder as its wheels turn on the runway, even though the contact surfaces seem identical. There was no substantiation to distinguish one from the other, nor was there any loss experience presented to suggest that the prior allowance, unchanged since the 1962 **NEC**, was deficient.

ARTICLE 620. ELEVATORS, DUMBWAITERS, ESCALATORS, MOVING WALKS, PLATFORM LIFTS, AND STAIRWAY CHAIR LIFTS

620.1. Scope. These provisions may also be considered as applying to console lifts, equipment for raising and lowering or rotating portions of theater stages, and all similar equipment.

620.2. Definitions. Informational note Fig. 620.2 presents an overview of the components of a modern elevator control system, and the definitions in 620.2 create a context that correlates provisions of the principal elevator safety document (ASME A17.1, *Safety Code for Elevators and Escalators*) with provisions in Art. 620.

620.11. Insulation of Conductors. The major concern in this section is with the integrity of electrical systems in a hoistway that is a natural chimney in the event of fire. The hoistway door interlock wiring must be suitable for 200°C for this reason, and the traveling cables must be one of the kinds listed in Table 400.4 for this purpose. Other insulation must be flame retardant. Alternatively, an approved conductor assembly can be used if suitable for the same temperature exposure.

620.12. Minimum Size of Conductors. Code Tables 310.15(B)(16) to 310.15(B)(19) do not include the ampacity for 20 AWG copper conductors. However, it is generally considered that 20 AWG conductors up to two conductors in cable or cord may safely carry 3 A (and Table 522.22 allows 5 A). This section amends 310.10(H) and permits those smaller conductors to be paralleled to equal the capacity of a 14 AWG wire in this case. This type of allowance makes for more flexible traveling cable make-ups, which is essential in today's very tall buildings.

Because of wider use of advanced semiconductor computer equipment, use of wire smaller than 20 AWG is permitted for other than lighting circuits by part (B), with 24 AWG as the minimum, and even smaller if listed.

The development of elevator control equipment, which has been taking place for many years, has resulted in the design and use of equipment, including electronic unit contactors, requiring very much smaller currents (milliamperes) for their operation.

620.13. Feeder and Branch Circuit Conductors. This section and the next track the requirements in Art. 430 quite closely, but include a demand factor table that is unique to multicar elevator groups, in Sec. 620.14. There are two examples in Annex D (Examples D9 and D10) that demonstrate multiple elevator loading calculations as covered in these Code sections very well.

620.14. Feeder Demand Factor. When multiple elevators are connected to the same feeder, not all of them will be in use at the same time and this section through its demand table allows for demand factors to be applied to these loads.

620.21. Wiring Methods. The parent language here provides the default wiring method choices for this wiring, including heavy-wall steel and "nonmetallic" conduit (an error, should be changed to PVC or RTRC conduit), EMT, wireways, or MC, MI, or AC cable. Hoistways add flexible methods for door operating controls, etc., as well as instrumentation on cars, and the length in many cases is not limited to 1.8 m (6 ft). For obvious reasons the supply cords of listed cord-and-plug-connected equipment need not run in a raceway.

620.22. Branch Circuits for Car Lighting, Receptacle(s), Ventilation, Heating, and Air Conditioning. This section establishes that each elevator car will be served by two dedicated circuits, one for heating and air conditioning, and one for lighting, the receptacle on the cab top or similar for service work, and other accessory loads. The wiring sequence on this circuit must be such that the service receptacle, which will be a GFCI receptacle per 620.85, must not disconnect the cab light if it trips. The overcurrent protective devices for these circuits must be located in the machine room or other control space for that car. A similar requirement governs lighting and receptacles in machine rooms and similar control spaces, as given in the next section (620.23), and another similar requirement governs hoistway pit lighting and its required receptacle outlet as covered in the section after that (620.24). As of the 2017 **NEC**, the lighting must not share the branch circuit with the receptacles in either the machine room or the pit.

620.32. Metal Wireways and Nonmetallic Wireways. This section allows the wire fill in wireways to more than double, from the 20 percent allowed in 376.22(A) to 50 percent. Note, however, that no mention is made of the derating factors in 310.15(B)(3)(a) that apply to the entire fill as soon as the 30 current-carrying conductors threshold is reached, and to all conductors in a nonmetallic wireway. Because no exception to this [Chap. 3](#) rule is taken in this [Chap. 6](#) article, the derating factors will apply, and they could easily hit 0.35 (example: for 41 wires, 12 AWG THHN, $30 \text{ A} \times 0.35 = 10.5 \text{ A}$) if the wireway were actually stuffed to 50 percent fill.

620.36. Different Systems in One Raceway or Traveling Cable. It would be difficult, if not practically impossible, to keep the wires of each system completely isolated from the wires of every other system in the case of elevator control and signal circuits. Hence, such wires may be run in the same conduits and cables if all wires are insulated for the highest voltage used and if all live parts of apparatus are insulated from ground for the highest voltage, provided that the signal system is an integral part of the elevator wiring system. These are very sophisticated, listed cables, and if multiple cables were required, they could easily tangle in the long lengths that are required in today's high-rise applications.

620.37. Wiring in Hoistways, Machine Rooms, Control Rooms, Machinery Spaces, and Control Spaces. Although hoistways are very tempting chases to run from floor to floor, they are not permitted for this purpose. The only wiring permitted in an elevator hoistway is wiring for the elevator functions. Neither are hoistways permitted to contain, nor the vertical elevator rails permitted to be, down conductors for a lightning protection system. However, if a hoistway happens to run close enough to a down conductor for a lightning protection system such that **NFPA 780** requires that rails in the hoistway be bonded to the down conductor to eliminate the possibility of side flash, then that bonding may proceed.

620.51. Disconnecting Means. A disconnecting means must be provided for every elevator (or any other form of lift covered in the article), and it must open all loads connected with that elevator except three, which are forbidden to be disconnected as a result of this disconnect being in the open position. The three exceptions are the cab lighting and accessories circuit, the cab heating and air conditioning circuit, and the hoistway and machine room lighting and service receptacle circuit(s). These must stay on so cab occupants will stay comfortable and not panic in the event of a malfunction, and so maintenance can proceed on the failed elevator under emergency conditions.

This main disconnecting means can be a switch or a circuit breaker. It can open automatically but must only close manually. It cannot be arranged to open from "any other part of the premises." If there is an elevator control panel, it must have a field marking showing the available fault current along with the date the calculation was made. If there are modifications that affect this number, then it must be revisited, recalculated, and redated. Of course, the most likely impact on this number is utility activity, which will not be known to a facility electrician absent a formal request. Refer to the commentary at 110.24 for additional information on this type of requirement. The adjacent hoistway is not considered an "other part of the premises." Further, if sprinklers are installed in the hoistway, this disconnect must open prior to waterflow. The usual protocol to bring this together involves a smoke detector in the hoistway that will detect smoke considerably prior to when the sprinkler head fuses. Upon detecting smoke, the smoke detector, supervised as part of a fire alarm system, initiates a control sequence that parks the elevator on the recall floor and discharges passengers. Adjacent to the sprinkler head, a heat detector, also supervised by the fire alarm system, activates the shunt trip on the disconnect if the temperature continues to rise, doing so before the sprinkler head fuses to start the flow of water. This prevents waterflow onto an active elevator, which would be an extreme hazard as the brakes could slip and the controls fail. Effective with the 2017 **NEC**, if one or more of the elevators has been designated an emergency system load, surge protection must be provided. A survey of facility managers found that nearly a quarter of them had experienced surge damage to elevators, and this change responds to that finding with a new 620.51(E).

620.53. Car Light, Receptacle(s), and Ventilation Disconnecting Means. There

must be a disconnecting means for this circuit, described in 620.22, located in the machine room or control space for the associated elevator. The disconnecting means must be permanently capable of being locked in the open position. A factory-designed locking hasp for the circuit breaker originating this dedicated circuit would allow the circuit breaker to fulfill both requirements, provided it is in the machine room or control space for the associated car. It must be plainly labeled as to its function and the identity of the elevator for which it provides this function. As in the case of the required branch circuit for heating and air conditioning, the next section (620.54) provides parallel requirements for the heating and air conditioning circuit. An exception permits this disconnecting means to be a manual motor controller, or a general-use snap switch, or an ac snap switch, all as covered in 430.109(C) for this purpose.

620.61. Overcurrent Protection. These requirements directly track other sections in the **NEC**.

620.62. Selective Coordination. This was the first mandatory selective coordination rule in the history of the **NEC**. It was substantiated on the basis that if an elevator feeder opened because of a fault, and if the upstream overcurrent protection opened due to a lack of coordination, people would be trapped in all the elevators stranded by the upstream protection opening, and service personnel might not be able to figure out on a timely basis how to find and reclose the upstream protection. Of course a sign on the elevator disconnect could solve that problem, but the panel insisted on solving a problem in a way that was both unprecedented and poorly substantiated. Depending on the relative size of the two levels of overcurrent protection and the trip curves for each this may be a simple or an intractable problem. Refer to the discussion at 700.32 for more information on a very controversial topic. The 2014 **NEC** has added more expense by making it mandatory to have a selectivity evaluation by a licensed professional engineer.

620.85. Ground-Fault Circuit-Interrupter Protection for Personnel. All 125-V 15- and 20-A receptacle outlets in pits, hoistways, “on the cars of elevators and dumbwaiters associated with wind turbine elevators,” on the platforms or in the runways and machinery spaces of platform lifts and stairway chairlifts, and in escalator and moving-walk wellways must be provided with GFCI protection, and this protection must be at the point of use, that is, through the use of a GFCI receptacle. A GFCI circuit breaker ahead of the receptacle is not permitted. The issue is the difficulty in resetting a tripped GFCI protective device that is nowhere near the worker who may need to reset the device immediately. On the other hand, for the receptacle outlets in the machine room or in the machinery space a worker can more easily reach the originating panelboard and reset the device, so either approach is permitted in those areas.

The material in quotation marks in the preceding paragraph is a verbatim restatement of new 2017 **NEC** text, and it is astonishing. Since most elevators are not associated with wind tower elevators, the comma placements in the literal text effectively remove the requirement from every conventional elevator. The public input that put this change in motion, from an elevator professional, used the following wording: “installed on the cars of elevators and dumbwaiters, in the wellways or the landings of escalators or moving walks, in the travel path or on the cars of wind turbine tower elevators, or in the runways and machinery spaces of platform lifts and stairway chairlifts shall be of the ground-fault circuit-interrupter type.” This is substantively what the sentence is actually supposed to say, based on technical merit. How and when this gets corrected is unknown for now.

ARTICLE 625. ELECTRICAL VEHICLE CHARGING SYSTEMS

625.1. This article regulates the sizing and installation of equipment and conductors used to supply electrical vehicle charging systems and the electrical vehicle. This article does not apply to battery charging systems that are used for fork-lifts, etc., but rather automobile-type electrical vehicles, including plug-in hybrid electric vehicles (PHEVs).

625.10. Electric Vehicle Coupler. This is the interface between the premises wiring system and the vehicle electrical system for propulsion. The couplers must be configured to avoid inadvertent contact by untrained persons with uninsulated live parts. The coupling from connector to vehicle inlet must be positive so as to prevent unintentional disconnection. Unless listed otherwise, it must have a grounding pole that is first make/last break. Presumably the inductive paddles qualify as listed otherwise (see 625.16).

625.15. Markings. In addition to an electric vehicle usage label, there will also be a marking with respect to whether or not ventilation is required. The vehicle owner should know which type of battery he or she has. Some are sealed or of a chemistry that does not emit hydrogen, and others do emit hydrogen. As provided in 625.52(A) if a vehicle requiring ventilation to remove hydrogen gas accumulations plugs into a charger marked ventilation not required, the charging station will listen for a coded signal indicating the appropriate battery is present, and not receiving it, will not charge the battery.

625.16. Means of Coupling. Again, the coupling can be inductive or conductive, or even wireless, and the connecting devices must be listed for the purpose.

625.17. Cords and Cables. This section covers both the power supply *cord* that runs from the premises outlet to the vehicle charging equipment, and the output *cable* that runs from the charging equipment to an electric vehicle connector, defined as the device that either inductively or through conduction transfers power to and exchanges information with an electric vehicle. Part (A) covers the supply cord, and the permitted length depends greatly on the location of the protective system required by 625.22. That section requires protection in the cord cap or within 12 in.; this section, to not be inconsistent, sets the cord length limit at 12 in. if the protection is in the charging equipment and 15 ft if it is in the cord cap. If the shorter length applies, clearly the location of the premises wiring outlet must be exact.

Part (B) covers the output cable. Special cords have been developed for these connections, easily identifiable by the “EV” (electric vehicle) letters in their type designation. They can be either hard usage or extra-hard-usage. They must not exceed 25 ft as the overall total length of the flexible connection on both sides of the charging equipment (unless equipped with a cable management system), and they can use the higher power cable ampacities in Table 400-5(A)(2) (unless they are No. 10 or smaller). The rule also allows for hybrid cables that include signaling circuits (or optical fiber cables). The measurement begins at the charging equipment where it is fastened in place and from the end of the supply attachment cord cap if the charging equipment is free to move. In either case, the measurement ends at the face of the vehicle connector.

625.18. Interlock. The charging system must be designed with an interlock that deenergizes the cable and connector whenever it is not connected to the vehicle. This is not required on the 15- and 20-A 125-V charging systems. This interlocking system will also prevent charging a vehicle that uses batteries that outgas hydrogen unless the installation is arranged with ventilation as provided in

625.52(B). It is also not required on a dc supply of less than 60 V. However, 625.52(D)(4) does require a switching mechanism for both these dc systems and the 15- and 20-A ac systems that will disable or disconnect the charger unless the required ventilation is operating “during the entire electric vehicle charging cycle.” There should be better correlation between the wording here and that in 625.52(D)(4).

625.19. Automatic De-energization of Cable. The electric vehicle supply cord and system must include some method of deenergization in the event of excessive strain on the cable, such as by driving away while plugged in. This is not required on the 15- and 20-A 125-V charging systems, or on portable systems covered in 625.44(A).

625.22. Personnel Protection System. The electric vehicle supply system must incorporate shock protection that may differ somewhat in trip thresholds from conventional GFCI levels, but that has the same effect. The test labs and manufacturers are being given some needed design flexibility here given that the output current may be dc or at different voltages. If the charging equipment is cord-and-plug-connected, then this function must be built into the attachment plug or into the supply cord within a foot of the plug. This system is not required for power supplies operating at less than 60 volts dc.

625.40. Electric Vehicle Branch Circuit. This section (relocated from 210.17) requires the use of individual branch circuits for this equipment. In general, this is relatively high capacity equipment; a typical rating is 32 A. with an intended connection to a 40-A. 240-V circuit. However, there are some portable chargers that are far smaller and capable of being connected very comfortably to a 15- or a 20-A 125-V circuit. This section may require relief in the future for such equipment.

625.41. Overcurrent Protection. As noted in the discussion under Sec. 625.42, these chargers are defined as a continuous load, and therefore the conductor ampacity and the overcurrent device must be increased by an additional 25 percent. As covered in 625.40, these vehicle recharging circuits must be wired as individual branch circuits.

625.42. Rating. This must be high enough for the load to be served and must be considered as continuous. Although some highway quick-charge protocols assume a 10- or 15-minute recharge at very high ampere values, and with component specifications established accordingly, the rule is for a continuous classification on any load. The more usual anticipated charging protocol involves 32-A charging current from a 208-V wye or delta (or even single-phase) connection on a 40-A branch circuit. In addition, there are many vehicle charging stations manufactured for and connected to ordinary 15- or 20-A, 120-V circuits. The rule also accommodates automatic load management systems, and where in use, the loading to be entered in a feeder or service calculation is that presented by the maximum draw of the installed management system.

625.43. Disconnecting Means. High-capacity charging equipment (over 60 A or over 150 V to ground) must have a disconnecting means in a readily accessible location. It must be able to be locked in the open position. This is a disconnecting means for the equipment, and therefore a unit switch in the equipment would not comply, even if it opened all ungrounded conductors. Maintenance personnel must be free to service the entire unit without hazard.

Note that this equipment would meet the definition of an appliance (other than industrial, produced in standard sizes, etc.) and therefore must comply with 422.31(B). That rule also requires a local disconnect, which can only be the branch-circuit protective device if it is within sight or can be

locked open. These provisions can be enforced on any capacity charging system.

625.44. Electric Vehicle Supply Equipment (EVSE) Connection. This section is extremely poorly written and governs all supply connections for vehicle supply equipment made to a premises wiring outlet, which as of the 2014 **NEC** must be in one of three categories. Part **(A)** allows mating 15- and 20-A 125-V plugs and receptacles (via flexible cord described in Sec. 625.17) by right. This category also includes dc supplies not over 60 V maximum, at 15 or 20 amperes.

Part **(B)** covers stationary equipment, defined as “fastened in place in such a way as to permit ready removal for interchange, facilitation of maintenance or repair, or repositioning.” This equipment will be cord-and-plug-connected to one of three system outlets, as follows:

1. Single-phase ac: A nonlocking 2-pole 3-wire grounding receptacle rated from 15 to 50 amperes and either 125 or 250 volts.
2. Three-phase ac: A nonlocking 3-pole 4-wire grounding receptacle rated from 15 to 50 amperes, 250 volts.
3. DC: 2-pole, 3-wire grounding receptacle rated from 15 to 20 amperes, not over 60 volts.

Note that the requirement uses the phrase “fastened in place.” This terminology is specifically defined for use in this article in 625.2 as “specifically designed to permit periodic removal for relocation, interchangeability, maintenance, or repair without the use of a tool.” It presumably would have been better to simply use the defined term, which will still apply anyway.

Part **(C)** covers all other EVSE. This would include equipment rated for higher voltages, or current, or both. The equipment must be fastened in place and hard wired, and it must have no exposed live parts.

625.46. Loss of Primary Source. The charging equipment must be arranged so the energy stored in the car batteries cannot backfeed into the supply wiring if the supply power fails. The vehicle cannot be allowed to serve, even if so desired, as a standby power source unless (as covered in 625.48) listed for this purpose, in which case the provisions in Art. 702 must be met for standby power and Art. 705 for interactive power, as applicable, must be met. An informational note identifies numerous applicable standards that would be involved in these connections.

625.47. Multiple Feeder or Branch Circuits. If identified for such connections, multiple supply circuits are permitted.

625.50. Location. The charging equipment must be located so the charging cable can connect directly to the vehicle. Unless listed and marked differently, the vehicle coupling means must be stored or located at a height of not less than 18 in. above the floor (indoor locations) and 24 in. above grade (outdoor locations). Note that these requirements do not apply to portable equipment covered in 625.44(A). This term is specifically defined in Art. 625 as designed to be transported in the vehicle when not being used because it is intended to be carried from one charging location to another.

625.52. Ventilation. This section covers indoor enclosed spaces. Part **(A)** covers instances where ventilation is not required because of the nature of the battery system in the vehicle, as noted in 625.15(B); mechanical ventilation is not required in such cases. A great deal of effort has gone into the production of batteries for these vehicles that do not out-gas significant quantities of hydrogen, and thereby allow this provision to be utilized. The majority of batteries now being produced do qualify as not requiring enhanced ventilation. The ventilation required otherwise is a substantial burden on the acceptance of this technology.

Mechanical ventilation as covered in part **(B)** must be provided with systems that are suitable for charging electric vehicles that outgas hydrogen and that are identified accordingly in 625.15(C). It must be permanently installed and it must include both supply and exhaust equipment arranged to take air from and exhaust air directly out to the outdoors. This ventilation must be interlocked with the charging system and it must operate during the entire charging cycle. The required volume of air to be exchanged is provided in a table based on the ampere rating and voltage of the branch circuit supplying the charging equipment. For example, a 20-A 120-V supply requires 49 cfm, and a 200-A 480-V 3-phase supply requires 3416 cfm. These numbers apply for each space equipped to charge an electric vehicle. If there are two spaces, then the required ventilation doubles. The 2014 **NEC** has also inserted ventilation information for dc supplies operating not over 50 V.

A large proportion of battery charging involves the release of hydrogen gas. This is a Class I Group B gas, extremely dangerous, and its lower explosive limit is only 4 percent. That means that a hydrogen-air mixture over 4 percent hydrogen by volume can explode. Although hydrogen is much less dense than air and dissipates rapidly, charging operations can generate enormous quantities. Actual testing showed ignitable concentrations of hydrogen near the ceiling even on 15-A branch circuits in residential garages with the door open! The mechanical ventilation requirements in this section need to be taken seriously.

Part IV. Wireless Power Transfer Equipment. Although the energy transfer process may be wireless, the infrastructure to support it is anything but. 625.102 covers the transmitting (primary) pad and how it is to be positioned, together with the mounting requirements for the charger power converter, and protection requirements for the output cable. 625.101 covers the composition of and the grounding requirements for the primary pad base plate, which must be of non-ferrous metal. This part involves unfamiliar technology and will require careful attention to the definitions in 625.2 and the installation directions supplied with this equipment.

ARTICLE 626. ELECTRIFIED TRUCK PARKING SPACES

626.1. Scope. This article, new in the 2008 **NEC**, covers what is defined in 626.2 as a “truck parking space that has been provided with an electrical system that allows truck operators to connect their vehicles while stopped and use off-board power sources in order to operate on-board systems such as air conditioning, heating, and appliances, without any engine idling.”

Environmental concerns about diesel exhaust together with skyrocketing costs for diesel fuel are creating a very strong market for this type of service. This new article creates the necessary standardization of approach because a truck moves from jurisdiction to jurisdiction and needs to be able to connect to this infrastructure in any state in order for this to work.

626.10. Branch Circuits. Each stand must be supplied from a 208Y/120V system or a 480Y/277V system, with an exception for existing 120-V facilities.

626.11. Feeder and Service Load Calculations. Each parking space must be calculated on the basis of not less than 11 kVA each, although part **(B)** applies a demand factor to this load based on expected heating and air-conditioning burden. This is related to the “USDA Plant Hardiness Zone Map” and decreases from a high of 70 percent (Fairbanks, Alaska) to a low of 20 percent (Houston, Texas) with some small increases to 24 percent for the highest zones (Miami, Florida and Honolulu, Hawaii) where an increased air-conditioning load would take over from decreased heating load. The

selection of a plant-hardiness map based on worst-case winter temperature is probably appropriate in terms of predicting worst-case winter loading, but may prove inaccurate in terms of predicting summer air-conditioning load. It would seem to have been questionable in terms of predicting maximum demand, but data submitted with the proposal that tabulated actual measured demand from existing facilities showed close agreement with table predictions. These facilities are typically 100 percent occupied at night and therefore all available spaces go into the calculation prior to applying the demand factor.

Note that the 11 kVA is figured on the basis of the maximum power capability of the receptacles required by 626.24(B), that is, two 20-A receptacles on 120-V circuits, and one 30-A circuit on a 208-V circuit, as follows:

$$2(120 \text{ V} \times 20 \text{ A}) + (208 \text{ V} \times 30 \text{ A}) = 11,000 \text{ VA}$$

Note that some gantry operations with umbilical assemblies drop from overhead and supply recirculated air from the truck cab after heating or cooling it as required. In practice such heating and air-conditioning units in the gantry are not centralized, but remain on a site-by-site basis, because each truck is charged on the basis of specific services provided by the site operator. In these cases the heating and air conditioning is still part of the electrical load for each site, although it will not appear in the truck cab as a receptacle. As long as the feeder to a group of sites includes within its load profile the heating and air conditioning load for each of those sites, this calculation and the demand factors that follow will be correct.

626.22. Wiring Methods and Materials. If the supply is from a pedestal or raised concrete pad, the mounting height must be at least 600 mm (2 ft) above grade or above the prevailing high-water mark in areas subject to flooding. Supplies that drop from a gantry are obviously not subject to this limitation. The supply equipment must be accessible through an entryway not smaller than 600 mm (2 ft) wide and 2 m (6½ ft high). There must be a remote, permanently lock-open capable disconnecting means, readily accessible, that will open the supply to one or more spaces.

626.24. Electrified Truck Parking Space Supply Equipment Connection Means. This section begins with a requirement for extra-hard-usage service cords to each connection, run together as a “single separable power supply cable assembly.” The receptacle requirements are unusual. For example, consider the requirement in (B)(1) for three receptacles (minimum), each two-pole three-wire grounding and two of the three connected to at least two different branch circuits. The intention is for a conventional duplex GFCI receptacle in one case, and a single receptacle on another gang strap because some loads expected to use these devices have plugs too large to connect to adjacent halves of a duplex receptacle. Note that (D) requires that any receptacle outlets installed in accordance with this section have GFCI protection. No single GFCI receptacles are now in production, so this would mandate protection in the form of a faceless GFCI or a GFCI circuit breaker at a considerable distance away, wherever this distribution originates.

There is a widely circulated set of full-color photographs of one of these umbilical-supplied assemblies that drop from an overhead gantry and are designed to mount in the passenger-side window. It is equipped with a conditioned air supply, a touch-screen computer terminal with a USB port and a card stripe reader, Ethernet port, etc. It also has two GFCI duplex receptacles, at least of the kind the manufacturer apparently thought were two receptacles, because actually there are two GFCI duplex receptacles, for a total of four receptacles in violation of (1). But wait. If you look at the

outside photo carefully, there is a double flap wet location cover for both halves of a duplex receptacle, not GFCI, with no provisions for it to be weatherproof while in use. This is where you plug in the block heater, as it turns out. It is apparent that we have quite a way to go before the equipment on the ground meets the **NEC**, and frankly, to where the **NEC** should be in terms of fine tuning this article.

This section also recognizes a single receptacle, “3-pole 4-wire grounding-type, single-phase rated either 208Y/120V or 125/250V.” Because there is no NEMA configuration for a 208Y/120V single-phase receptacle at any amperage, this is confusing at best. There is an informational note following that describes a standard for pin-and-sleeve devices. However, that is not a requirement, and 30 ampere 125/250V plugs and receptacles are used by the million on identical distributions as these. The majority of multifamily housing is supplied through 208Y/120V three-phase services, and almost without exception, the feeder to each apartment consists of two-phase conductors and a neutral. Every conventional dryer receptacle outlet will have one of these devices providing the same sort of connectivity on the identical distribution system. It appears the reference to 208 V may have been an attempt by a proprietary interest to game the process and should be ignored. As of the inception of the 2008 **NEC**, there was very little in the way of an installed user base and so there was no consensus as to what these receptacles should have been. No clarification succeeded in the 2011 cycle; however, in the 2014 cycle in a panel statement on a related action, the panel effectively stated that it now intended the provision of three receptacles exactly as defined in Art. 100, which would mean three single receptacles or a single and a duplex receptacle.

This receptacle is intended to supply heating and air-conditioning equipment in the truck cab. If the conditioned air will be supplied by the truck stop through an umbilical connection instead, then this receptacle need not be provided. This is covered in 626.24(B) Exception, which requires careful study. The exception applies to the entirety of 626.24(B), and therefore waives the 125/250V 30-A receptacle in (B)(2), along with one of the three 20-A, 125-V receptacles in (B)(1), leaving only two in place as the minimum standard. Just as the exception covers all of 626.24(B), note also that the literal text of 626.24(D) reaches not only the 125-V receptacles, but the 125/250V 30-A receptacle as well.

626.25. Separable Power-Supply Cable Assembly. These are the rules, not inconsistent with the receptacle configuration rules in 626.24, that govern the power supply cords run from the site outlets to the truck. 15-A assemblies are permitted to operate an engine block heater on existing vehicles. The overall length of the cord is to be 7.5 m (25 ft) unless, if longer, a listed cable management system is employed.

626.26. Loss of Primary Power. This section and the next directly correspond with 625.46 and 625.48. It is not clear why these sections, which cover battery-powered vehicles for which there could be a use for the energy stored in the battery to power dwelling unit loads either on a stand-alone basis (625.46) or possibly in parallel with the utility (625.48), are being duplicated at a diesel truck stop. However, they do no harm.

626.30. Transport Refrigerated Units. These are the refrigerated trailers that are one of the principal reasons for diesel trucks to sit idle, and they represent a very significant load. This load is not included in the site load calculation of 626.11. There are two conventional voltage options given here, either 30-A on a 480-V 3-phase system or 60-A on a 208-V 3-phase system, so these are significant power loads. The cord connections will be through extra-hard-usage assemblies with a 90°C conductor rating along with an outer jacket evaluated for sunlight resistance and wet locations,

and additional ratings for cold weather, oil and gasoline, ozone, acids, other chemicals, and abrasion. Worthy of note is that effective with the 2017 **NEC**, this section gives full recognition to a 20-ampere, 1000-volt, 3-pole, 4-wire grounding receptacle, configured as a pin and sleeve type.

ARTICLE 630. ELECTRIC WELDERS

630.1. Scope. There are two general types of electric welding: arc welding and resistance welding. In arc welding, an arc is drawn between the metal parts to be joined together and a metal electrode (a wire or rod), and metal from the electrode are deposited on the joint. In resistance welding, the metal parts to be joined are pressed tightly together between the two electrodes, and a heavy current is passed through the electrodes and the plates or other parts to be welded. The electrodes make contact on a small area—thus the current passes through a small cross section of metal having a high resistance—and sufficient heat is generated to raise the parts to be welded to a welding temperature. Either type of welding and cutting power equipment used with the scope of Art. 630 must be listed (630.6).

In arc welding with ac, an individual transformer is used for each operator; in other words, a transformer supplies current for one arc only. When dc is used, there is usually an individual generator for each operator, though there are also multioperator arc-welding generators. Note that the scope also includes plasma cutting operations where the electrical equipment is involved in creating and maintaining the arc that creates the ionized gas that does the cutting.

630.11. Ampacity of Supply Conductors. The term *transformer arc welder* is commonly used in the trade and, hence, is used in the Code, though the equipment might more properly be described as an *arc-welding transformer*. Refer to the informational note following 630.31, where the term *duty cycle* is explained.

It is evident that the load on each transformer is intermittent. Where several transformers are supplied by one feeder, the intermittent loading will cause much less heating of the feeder conductors than would result from a continuous load equal to the sum of the full-load current ratings of all the transformers. The ampacity of the feeder conductors may therefore be reduced if the feeder supplies three or more transformers. Note that if the value “ $I_{1\text{eff}}$ ” is provided on the welder name plate, then this value must be used instead of the value determined from the table. This value can also be calculated using the formula in the informational note under 630.12(B). This is the effective current for the welder; it contrasts with “ $I_{1\text{max}}$ ” which is essentially the rated primary current, as further described in the same note.

630.12. Overcurrent Protection. Arc-welding transformers are so designed that as the secondary current increases, the secondary voltage decreases. This characteristic of the transformer greatly reduces the fluctuation of the load on the transformer as the length of the arc, and consequently the secondary current, is varied by the operator.

The rating or setting of the overcurrent devices specified in this section provides short-circuit protection. It has been stated that with the electrode “frozen” to the work, the primary current will in most cases rise to about 170 percent of the current rating of the transformer. This condition represents the heaviest overload that can occur, and, of course, this condition would never be allowed to continue for more than a very short time. However, rating of the OC protection can be based on 200 percent of the maximum value of supply current or primary current of the welder, at the maximum

rated output (next higher standard size permitted). The OC device may be located at the welder or at the line-end of the supply circuit.

630.31. Ampacity of Supply Conductors. The explanatory information that formerly resided in the parent language about the relationship between sizing for acceptable voltage drop compared with sizing for a potential overload condition has been, quite properly, relocated as an informational note. Subparagraph (A)(1) applies where a resistance welder is intended for a variety of different operations, such as for welding plates of different thicknesses or for welding different metals. In this case, the branch-circuit conductors must have an ampacity sufficient for the heaviest demand that may be made on them. Because the loading is intermittent, the ampacity need not be as high as the rated primary current. A value of 70 percent is specified for any type of welding machine that is fed automatically. For a manually operated welder, the duty cycle will always be lower and a conductor ampacity of 50 percent of the rated primary current is considered sufficient.

example 1 A spot welder supplied by a 60-Hz system makes 400 welds per hour, and in making each weld, current flows during 15 cycles.

The number of cycles per hour is $60 \times 60 \times 60 = 216,000$ cycles.

During 1 h, the time during which the welder is loaded, measured in cycles, is $400 \times 15 = 6000$ cycles.

The duty cycle is therefore $(6000/216,000) \times 100 = 2.8$ percent.

example 2 A seam welder operates 2 cycles “on” and 2 cycles “off,” or in every 4 cycles the welder is loaded during 2 cycles.

The duty cycle is therefore $2/4 \times 100 = 50$ percent.

Transformers for resistance welders are commonly provided with taps by means of which the secondary voltage, and consequently the secondary current, can be adjusted. The rated primary current is the current in the primary when the taps are adjusted for maximum secondary current.

When a resistance welder is set up for a specific operation, the transformer taps are adjusted to provide the exact heat desired for the weld; then in order to apply subparagraph (A)(2), the actual primary current must be measured. A special type of ammeter is required for this measurement because the current impulses are of very short duration, often a small fraction of a second. The duty cycle is controlled by the adjustment of the controller for the welder.

The procedure in determining conductor sizes for an installation consisting of a feeder and two or more branch circuits to supply resistance welders is first to compute the required ampacity for each branch circuit. Then the required feeder ampacity is 100 percent of the highest ampacity required for any one of the branch circuits, plus 60 percent of the sum of the ampacities of all the other branch circuits.

Some resistance welders are rated as high as 1000 kVA and may momentarily draw loads of 2000 kVA or even more. Voltage drop must be held within rather close limits to ensure satisfactory operation.

630.32. Overcurrent Protection. In this case, as in the case of the overcurrent protection of arc-welding transformers (630.12), the conductors are protected against short circuits. The conductors of motor branch circuits are protected against short circuits by the branch-circuit overcurrent devices and depend on the motor-running protective devices for overload protection. Although the resistance welder is not equipped with any device similar to the motor-running protective device, satisfactory operation of the welder is a safeguard against overloading of the conductors. Overheating of the circuit could result only from operating the welder that either the welds would be imperfect or parts of the control equipment would be damaged, or both.

630.42. Installation. This section governs the placement of welding cables in cable tray, which must then be labeled accordingly. This cable is *not* fine-stranded building wire that happens to be easy to bend and install in motor control centers, etc. The UL data on this cable clearly limits its use to the “secondary circuit of electric welders” and is as follows:

This category covers welding cable, which is a single-conductor cable intended for use in the secondary circuit of electric welders in accordance with Art. 630, Part IV of ANSI/NFPA 70, “**National Electrical Code**.” The conductors are flexible-stranded copper, 8 AWG through 250 kcmil, the individual strands of which are 34 through 30 AWG.

Welding cable is rated 60, 75 or 90°C and 100 or 600 V.

The voltage and temperature ratings, if higher than 100 V and 60°C, respectively, are identified by printing on the surface of the insulation.

ARTICLE 640. AUDIO SIGNAL PROCESSING, AMPLIFICATION, AND REPRODUCTION EQUIPMENT

640.1. Scope. Centralized distribution systems consist of one or more disc or tape recorders and/or radio receivers, the audio-frequency output of which is distributed to a number of reproducers or loudspeakers.

A public-address system includes one or more microphones, an amplifier, and any desired number of reproducers or speakers. A common use of such a system is to render the voice of a speaker clearly audible in all parts of a large assembly room. The article does not cover fire and burglar alarm signaling devices.

640.2. Definitions. “Abandoned Audio Distribution Cable” is previously installed cable that is not terminated at equipment and not identified for future use with a tag.

“Audio Signal Processing Equipment” essentially covers the range of equipment covered by this article, and the note that follows gives a full picture of the coverage. Note that a sound signal processor such as a computer creating sound signals from a MIDI (musical instrument digital interface) file is included.

“Technical Power System” covers systems using isolated grounding as covered in 250.146(D). However, the terminology is intriguing because it appears in another location in the **NEC**, namely, 647.6(B) and 647.7(A)(2). The provisions of Art. 647 are predominantly the creation of an audio engineer who was looking for a way to eliminate audio hum in recording studios. He succeeded so well that the grounding system in that article (center-tapped 120 V operating with both circuit wires running 60 V to ground), which started out in Art. 530, is now a stand-alone article with provisions to balance loads across a three-phase distribution. It can certainly be used to power Art. 640 applications, and with far more effective results than simply relying on 250.146(D), whose effectiveness is now widely questioned.

640.3. Locations and Other Articles. In general, the power-supply wiring from the building light or power service to the special equipment named in 640.1, and between any parts of this equipment, should be installed as required for light and power systems of the same voltage. Certain variations from the standard requirements are permitted by the following sections. For radio and television receiving equipment, the requirements of Art. 810 apply except as otherwise permitted here.

640.9 covers wiring to loudspeakers and microphones and signal wires between equipment

components—tape recorder or record player to amplifier, and so on. As shown in Fig. 640-1, amplifier output wiring to loudspeakers handles energy limited by the power (wattage) of the amplifier and must conform to the rules of Art. 725. As shown in 725.41(A), the voltage and current rating of a signal circuit will establish it as either Class 2 or Class 3 signal circuit. Amplifier output circuits rated not over 70 V, with open-circuit voltage not over 100 V, may use Class 3 wiring as set forth in 725.41(A).

Fig. 640-1. Sound-system speaker wiring may be either Class 2 or 3 signal system, but must not intermingle with those systems. (Sec. 640.9.)

Article 725 of the Code covers, among other things, signal circuits. A signal circuit is defined as any electrical circuit that supplies energy to a device—such as a loudspeaker or an amplifier—that gives a recognizable signal.

640.6. Mechanical Execution of Work. Part (A) requires cables that are exposed (including above a hung ceiling) to be supported such that normal building use will not damage them. Above the hung ceiling, the cabling must meet 300.11(A), which means staying off ceiling support wires that are an integral support of the ceiling system, but additional wires are allowed; refer to that discussion in Chap. 3 for more information. Abandoned cables (not identified for future use with a tag) must be removed. Tagged cables left in place must have tags that will hold up in their environment and the tags must give the date of identification, the date of intended use, and information relative to the intended use.

640.7. Grounding. Part (A) has the usual grounding requirements for wireways and auxiliary gutters. Parts (B) and (C) address implementation of Art. 647. See the comments offered here in the definition of “Technical Power System” for more information.

640.8. Grouping of Conductors. In this class of work, the wires of different systems are in many cases closely associated in the apparatus itself; therefore, little could be gained by separating

them elsewhere.

640.9. Wiring Methods. Part (A)(1) requires wiring connected to the premises wiring system to comply with [Chaps. 1](#) through [4](#) except as modified.

Part **(A)(2)** requires separately derived systems to comply with Code rules generally. This subsection also recognizes the procedures in Art. 647, which effectively allows the full 60/120-V system procedures to be used in the context of this article.

Part **(A)(3)** requires all other wiring follow the rules in Art. 725.

Part **(B)** requires auxiliary power supply wiring to equipment with a separate input therefore must follow Art. 725 rules; batteries must be installed in accordance with Art. 480. Auxiliary inputs mean that normal premises wiring supplies are also intended as a supply. An UPS is not an auxiliary input unless it is a direct part of the equipment and providing a dc supply. True auxiliary inputs may include fire alarm or other paging inputs typically involving a 10- to 50-V supply.

Part **(C)** allows amplifier output wiring to follow the normal rules in Art. 725 for the Class of circuit generated, whether Class 1, 2, or 3, (and the amplifier must be listed and marked accordingly) except that common raceways or enclosures must contain only audio circuits of the same class (see [Fig. 640-1](#)). Note that there are subtle differences in the capacities of audio power supplies and output circuits that, while allowing them to use limited energy wiring protocols, make them unsuitable for intermixing in common raceways. Therefore even in cases where you have a Class 2 audio output, that circuit may not be run in the same raceway as a normal Class 2 signaling circuit. This is addressed directly in 725.139(F).

Part **(D)** requires audio transformers and autotransformers to be used so as not to exceed the product limitations. System grounding is not required for circuits on the load side of this equipment, in contrast with the usual requirement for power circuits in 210.9. These transformers are generally used to match impedances between an amplifier and a speaker, and should not be grounded unless so designed by the system manufacturer.

640.10. Audio Systems near Bodies of Water. This section covers audio systems near bodies of water. An exception waives the requirements for watercraft, even if supplied by shore power. Wiring on these vessels would be exempt anyway, because Sec. 90.2(b)(1) provides that such wiring is beyond the scope of the Code. The rules in this section turn on whether the equipment is supplied by “branch-circuit power.” If so, it has to be kept at least 5 ft away from the water; otherwise, if rated as Class 2, then it is limited only by the manufacturer’s instructions.

640.21. Use of Flexible Cords and Cables. Cords used for connection to branch circuits are permitted according to the normal rules. Cords running between amplifiers and speakers, or speaker to speaker, or equipment to equipment, follow applicable Art. 725 requirements, with an allowance for other cabling. In addition, for equipment to equipment applications, other cabling can be used if specified by the manufacturer. Battery and other power sources need to follow the applicable code rules. The note points out that some of these additional sources will end up being the only source, but that they may be supplied in turn by intermittent or continuous power from a branch circuit.

Part **(E)** permits cords to be used to connect permanently installed equipment racks to facilitate equipment access or for “isolating the technical power system of the rack from the premises ground.” This relates to the definition of “Technical Power System” and therefore appears intended to refer to isolation in the sense of connecting to an isolated-ground receptacle, as covered in 250.146(D). That wiring protocol still requires an equipment grounding conductor running with the circuit conductors.

Therefore this would refer to a grounded cord plugged into an isolated ground receptacle. That receptacle might be supplied, however, by a “Technical Power System.” Refer to the discussion at 640.22, below.

640.22. Wiring of Equipment Racks and Enclosures. This covers the wiring of equipment racks, which if made of metal (the usual condition) must be grounded. The racks have to be neat and workmanlike and there needs to be “reasonable access” to equipment power switches and overcurrent protective devices. The supply cords have to terminate within the equipment rack enclosure in an “identified connector assembly.” They have to be able to carry the load and have overcurrent protection, which could be on the branch circuit.

Bonding is not required if the rack is supplied by a “technical power ground” (Fig. 640-2). Sec. 640.2 defines a “Technical Power System” as one in which insulated grounding receptacles are used in accordance with 250.146(D). However, 640.7(B) specifically refers to 647.6, which mandates the use of the term “Technical Equipment Ground” in reference to separately derived 120-V systems operating with a midpoint ground (and therefore 60/120 V). Since the original proposal to add this system to the **NEC** came from the audio engineering community, probably the reference here to a “technical power ground” is indeed to a system covered by Art. 647.

Fig. 640-2. Grounding in racks may correlate with Art. 647 provisions. (Sec. 640.22.)

640.24. Wireways and Auxiliary Gutters. Wireways and auxiliary gutters follow the normal fill requirements; the 75 percent allowance in all versions of this article prior to the 1999 rewrite was not reinstated.

640.25. Loudspeaker Installation in Fire Resistance-Rated Partitions, Walls, and Ceilings. Speakers placed in fire-resistant partitions must be listed for the purpose or else go into enclosures (or a recess in the wall) that will maintain the fire-resistance rating.

640.41. Multipole Branch-Circuit Cable Connectors. Multipole branch-circuit cable connectors must be polarized and must not transmit strain to terminations, and the female half must be

attached to the load end of the power supply cord. Differently rated devices must be uniquely configured so they cannot intermate, and they must not intermate with nonlocking devices used for speaker connections, or with connectors rated 250 V whether locking or not. This suggests 125-V locking configured devices could be acceptable for speaker connections.

Signal cabling not intended for such speaker connections must not be intermateable with multipole branch-circuit cable connectors of “any accepted configuration.” Note that this first part of this section substantially duplicates the language found in 520.67.

640.42. Use of Flexible Cords and Cables. This section covers the use of flexible cord for portable and temporary audio system applications, and parts (A) through (D) are essentially the same as Sec. 640.21 for permanent installations. Part (E) requires that flexible cord run to supply a portable equipment rack must use listed extra-hard-usage cord. For outdoor use, the cord must also be suitable for wet locations and sunlight resistant. If the racks also supply lighting or power equipment, Arts. 520 and 525 apply as appropriate. The use of any cable extensions, adapters, and breakout assemblies must meet the applicable provisions of those articles as well, because of the references in 640.3(F) and (G). Note that the relevant requirements principally appear in 520.68(A)(4) and 520.69.

640.43. Wiring of Equipment Racks. This section covers wiring of portable or temporary equipment racks, and it is similar to Sec. 640.22, which covers the permanent variety. There are significant differences, however. If the rack is nonmetallic and equipped with a cover, removal of that cover must not allow access to Class 1, Class 3, or “primary circuit power” without removal of terminal covers or the use of tools. Wiring that leaves such equipment to other equipment or a power supply must have strain relief or other arrangements so pull on the cord will not increase the risk of damage.

640.44. Environmental Protection of Equipment. This section requires protection of portable or temporary equipment used outdoors from adverse weather conditions. If the equipment is expected to remain operational, arrangements need to be made including ventilating heat-producing equipment.

640.45. Protection of Wiring. If there is public accessibility, cord cannot be laid on the ground or floor without being covered with approved nonconductive mats and there must not be a tripping hazard. This is essentially the same as 525.20(G), and as of the 2011 NEC, there is the same waiver of 300.5 allowing for temporary shallow burial.

640.46. Equipment Access. Equipment likely to be hazardous to the public needs to be protected with barriers or supervised by qualified personnel to prevent public access.

ARTICLE 645. INFORMATION TECHNOLOGY EQUIPMENT

645.1. Scope. This article applies only to an information technology equipment room. Because this article covers all of the designated “equipment,” “wiring,” and “grounding” that is contained in a room, there is no question about the mandatory application of these rules to such “rooms.” But the specific nature of that word *room* in the 645.1 statement of “Scope” leaves some uncertainty about electronic computer/data processing equipment and systems that are *not* installed in a dedicated room. In such cases, one must follow all the rules given in Chaps. 1 through 4 and ignore the rules and permissions given in Art. 645. The point being: If you do not have a computer room, as defined by 645.42, then Art. 645 does *not* cover the installation, because, as given in the first sentence of 645.1,

only equipment and the like installed in “an information technology equipment room” *is* covered.

Furthermore, this article is unusual in that it is, in effect, voluntary. If you do not want to comply with its provisions, simply make sure that one (or more) of the conditions in 645.4 is not met, and the article does not and never will apply. The article offers certain wiring advantages that may be beneficial, but there is no obligation to implement those advantages. To assist in the orderly application of this article, information technology equipment now has a formal definition in 645.2. Note that it carefully excludes the processing of communications circuits. These are the exclusive province of Art. 800, and the power-limited cabling connected to this equipment is generally covered by Art. 725 (and also Art. 770 if applicable) with additional conditions and provisions found here. However, due to provisions in 645.3, any power-limited cabling, as covered in Arts. 725, 760, 770, 800, etc. must adhere to the listing protocols established within those articles.

645.4. Special Requirements for Information Technology Equipment Room. Six conditions are described that must be complied with in order for Art. 645 to be applied to data processing equipment rooms:

1. Disconnects in accordance with 645.10 are provided.
2. A dedicated HVAC system must be used for the room, or strictly limited use involving automatic actuation of fire/smoke dampers may be made of an HVAC system that “serves other occupancies.”
3. Only “listed” (such as by UL) information technology equipment may be installed.
4. The computer room must be “occupied by, and accessible to, only those personnel needed for operating and maintaining the computer/data processing equipment.”
5. The room must have *complete* fire-rated separation from “other occupancies.”
6. Electrical equipment not associated with the information technology room is installed within that room.

It is very clear from the wording that if any of these conditions is *not* met, the entire computer/data processing installation is *not* subject to the rules of Art. 645. But such an installation would be subject to *all* other applicable rules of the **NEC**.

645.5. Supply Circuits and Interconnecting Cables. Part (A) limits every branch circuit supplying data processing units to a maximum load of not over 80 percent of the conductor ampacity (which is an ampacity of 1.25 times the total connected load).

Part (B) covers use of computer or data processing cables and flexible cords, which can be up to 4.5 m (15 ft) long, and must be protected from damage if run across the floor. As shown in [Fig. 645-1](#) (under a raised floor), part (C) permits data processing units to be “interconnected” by flexible connections that are “of a type permitted for information technology equipment.”

Fig. 645-1. Connection of data-processing units to their supply circuits and interconnection between units (power supply, memory storage, etc.) may be made only with cables or cord-sets specifically listed [see (B)(2)] as parts of the data processing system. (Sec. 645.5.)

Part (C) covers interconnecting cables, which are not subject to the 4.5 m (15 ft) limitation. Part (D) requires supply circuits and interconnecting cables to be protected if they are exposed to damage,

such as running across a traveled walkway. Presumably this rule can also be applied to insist floor openings have protection against abrasion of cords and cables passing through them. This used to be explicitly covered in the same sentence that required minimizing debris entry beneath the floor. The latter concept now lives in the parent language in 645.5(E), but the other half of that sentence covering cable abrasion was lost when 645.5(E) was reorganized in the 2017 **NEC**.

Part (E) permits a variety of wiring methods under an accessible and approved raised floor serving a data processing system, provided the openings are configured so they will minimize the entry of debris into the floor. This part now, for editorial clarity, divides the universe of possible wiring types under raised floors into three categories, for which the first covers the wiring methods for branch-circuit supply conductors. All branch-circuit wiring covered here must be secured as covered in 300.11. The permitted list of wiring methods is extensive because it is a list of 17 items, stated as being in addition to the “wiring methods of 300.22(C).” This would correspond to 300.22(C)(1), and after disregarding the six methods that appear in both places, the result is a total of 20 wiring methods (see [Fig. 645-2](#)) that end up as permissible for branch-circuit wiring under a computer floor. Adding the three additional methods looks like this:

Fig. 645-2. Branch circuits from a panel-board to data processing receptacle outlets can be in a wide variety of [Chap. 3](#) wiring methods. (Sec. 645.5.)

- (18) Totally enclosed nonventilated busway, with no plug-in connections
 - (19) Other factory-assembled multiconductor control or power cable specifically listed for air-handling spaces
 - (20) Listed prefabricated manufactured wiring systems without nonmetallic sheath [Art. 604]
- In addition, in accordance with 300.22(C)(b):
- (21) Solid side and bottom metal cable tray systems with solid metal covers, which brings in all the wiring methods in 392.10(A)

The second category of underfloor wiring consists of “electrical supply cords, data cables, interconnecting cables, and grounding conductors.” This includes a five-part list, as follows:

- (1) Listed information technology equipment supply cords, as covered in 645.5(B)
- (2) Interconnecting cables enclosed in a raceway
- (3) Equipment grounding conductors
- (4) Plenum-grade power limited cabling in 725.136(C), plus higher ranked cables in the 725.154(A) substitution hierarchy
- (5) Listed Type DP cable

Note that as presented in 645.5(E)(2), item (4) above contains potential conflicts unless it is carefully applied. Only the plenum grade cable (CMP) can be used directly; the others listed can be used, but only if completely enclosed in metal raceways or solid metal cable tray as covered in 300.22(C).

The third category of underfloor wiring covers plenum grade optical fiber cable. The reference correctly points to 770.113(C), but adds OFNR, OFCR, OFN, and OFC. Although these additional cable can be used, as in the case of 645.5(E)(1)(4), these non-plenum graded cables must run in metal raceways or solid metal cable trays, as specifically addressed in 770.113(C)(5) and (6).

It appears that the technology of cable construction has advanced to the point that high-speed data transfers can occur over cables that easily meet plenum standards. This was not always the case. Years ago, cables that met plenum standards often had unacceptable performance characteristics in computer rooms, and this part of Art. 645 allowed other than plenum graded cabling under the raised floors for that reason. However, the model building codes had rules for acceptable materials in plenum cavities that, when it came to electrical cables, strictly required plenum ratings. Wiring methods could be changed, but this meant that the equipment would not even function properly. This direct conflict between construction disciplines set the stage for an extended stand-off that continued for years. The solution was arrived at in the 1990s through extended discussion between electrical code experts and leaders of the model building code organizations. The building officials decided that they would not need to classify the underfloor space as a plenum cavity if it would not function in that way during a fire condition. The electrical experts said, in effect, done! There was already a drop-out relay under these floors to shut down the air circulation, as required by 645.10. All that was required was to add a smoke detector under the floor and have it drop out the ventilation if products of combustion were detected. The fan would stop, the air movement would cease, and the plenum cavity designation need not apply. This was the case for four code cycles. Unfortunately, with absolutely zero substantiation that took these past discussions into account, the smoke detector rule was deleted in the 2014 **NEC**. Fortunately, the science of cable construction has, for now, made the conflict academic.

Part **(F)** adds important information by stating clearly that any cable, boxes, connectors, receptacles, or other components that are “listed as part of, or for, information technology equipment” are *not* required to be secured in place, *but* any cable or equipment that is *not* “listed as part of” the computer equipment *must* be secured in accordance with all Code rules covering it.

Part **(G)** requires that the accessible portions of abandoned supply circuits and interconnecting cables, defined as unterminated and unidentified for future use, be removed. The next part **(H)** builds on this by requiring that in order to qualify as identified for future use, the cables needed to be tagged in a manner with sufficient durability for the location and stating the date of identification, the expected date of use in the future, and some information as to what that use is expected to be.

645.10. Disconnecting Means. Part (A) of this section covers conventional ITE rooms and its provisions are similar to those that have applied since the article began in the 1968 **NEC**. Over the intervening decades, information processing has become increasingly critical, and a survey of those who are responsible for these facilities revealed that the overwhelming majority of activations of these EPO switches were either accidental, or acts of sabotage. It was further determined that the average outage was about 4 hours, with a resultant loss of revenue in the seven-figure range. Relocating these control switches is a first step in responding to the changing nature of the importance of these rooms. As shown in Fig. 645-3, a master means of disconnect (which could be one or more switches or breakers) must provide disconnect for all computer equipment, ventilation, and air-conditioning (A/C) in the data processing (DP) room.

Fig. 645-3. Data processing room must have arrangements like those shown here. (Sec. 645.10.) The disconnect control is no longer mandated to be at the principal exit door.

The disconnects called for in this rule are required to shut down the DP system and its dedicated HVAC and to close all required fire/smoke dampers under emergency conditions, such as fire in the equipment or in the room. For that reason, the rule further requires that the disconnect for the electronic equipment and “a similar” disconnect for A/C (which could be the same control switch or a separate one) must be grouped and identified and must be “controlled” from locations that are readily accessible to the computer operator(s) or DP manager. The location of these controls is no

longer required to be at a principal exit door; the requirement now is for a location that is “readily accessible to authorized personnel and emergency responders.” Large rooms requiring multiple protection zones are also recognized [in (A)(3)] provided an approved means exists to confine a fire to its zone of origin. Figure 645-4 shows two control switches—one in the control circuit of the A/C system and the other a shunt-trip pushbutton in the CB of the feeder to the DP branch circuits—with a collar guard to prevent unintentional operation.

Fig. 645-4. Adjacent to the door of a DP room, a break-glass station (at top) provides emergency cutoff of the A/C system in the DP room; and a mushroom-head pushbutton—with an extended collar guard that requires definite, intentional pushing action—energizes a shunt-trip coil in the feeder circuit breaker supplying branch circuits for the electronic DP equipment. (Sec. 645.10.)

Although the present wording of this rule readily accepts the use of a single disconnect device (pushbutton) that will actuate one or more magnetic contactors that switch the feeder or feeders supplying the branch circuits for the computer equipment and the circuits to the A/C equipment, the wording also recognizes the use of separate disconnect control switches for electronic equipment and A/C. Control of the branch circuits to electronic equipment may be provided by a contactor in the feeder to the transformer primary of a computer power center, as shown in [Fig. 645-5](#).

Fig. 645-5. Rapidly accelerating application of DP equipment in special DP rooms with wiring under a raised floor of structural tiles places great emphasis on Art. 645. “Computer power centers” (arrow) are complete assemblies for the supply of branch circuits to DP equipment, with control, monitoring, and alarm functions. (Sec. 645.10.)

A single means used to control the disconnecting means for *both* the electronic equipment and the air-conditioning system offers maximum safety. In the event of a fire emergency, having two separate disconnecting means (or their remote operators) at the principal exit doors will require the operator to act twice and thus increase the hazard that only the electronic equipment or the air-conditioning system will be shut down. If only the electronic equipment is disconnected, a smoldering fire will become intensified by the air-conditioning system force-ventilating the origin of combustion. Similarly, if only the air-conditioning system is disconnected, either a fire within the electronic equipment will become intensified (since the electric energy source is still present) or the electronic equipment could become dangerously overheated due to the lack of air conditioning in this area.

Wording of this rule requires means to disconnect the “dedicated” A/C “system serving the room.” If the DP room has A/C from the ceiling for personnel comfort and A/C through the raised floor space for cooling of the DP equipment, both A/C systems would have to be disconnected. There have been rulings that *only* the A/C serving the raised floor space must be shut down to minimize fire spread within the DP equipment and that the general room A/C, which is tied into the whole building A/C system, does not have to be interrupted. In other cases, it has been ruled that the general room A/C must be shut down, while the floor space A/C may be left operating to facilitate the dispersion of fire suppressant and extinguishing materials within the enclosures of DP equipment that is on fire.

Because of the possibility of various specific interpretations of very general rules, this whole matter has become extremely controversial. Review, as well, the history behind the former wording on 645.5(E)(4), which bears on this question.

The exception to this rule waives the need for disconnect means in any “integrated electrical systems” (Art. 685), where orderly shutdown is necessary to ensure safety to personnel and property. In such cases, the entire matter of type of disconnects, their layout, and their operation is left to the designer of the specific installation.

Part **(B)** covers “Critical Operations Data Systems.” As defined in 645.2, it includes three occupancies (public safety, emergency management, and national security) that are completely logical given its name, and one at the end (business continuity) that is loose enough to include virtually every ITE room in existence, or so their IT staff would undoubtedly insist. These rooms do not require an EPO. Five conditions must be met in order to trade off the lack of the EPO control:

1. AHJ—In this case probably a building or fire inspector and not an electrical inspector, has agreed to a protocol under which power is removed and air movement halted within the room, or within a designated zone, defined as a physically identifiable area in terms of distance or actual barriers and having a discrete power and cooling system.
2. Qualified operators are available 24/7 to advise first responders as to disconnecting procedures.
3. Smoke detectors [already required by 645.5(E)(4) for underfloor spaces] are in place or other “sensing system.”
4. There is an automatic fire suppression system in place and the AHJ, again, probably not the electrical inspector, has approved it.
5. The limited energy wiring under a raised floor is listed for plenum applications and the power circuits meet 645.5(E)(2), or for supply cords, 645.5(E)(3). Note that the reference to 725.135(B) is probably an error and should point to 725.135(C) to correlate with the referenced 800.113(C).

These are actually reasonable requirements and presumably well within the construction budget of any enterprise looking at a multimillion dollar loss for an outage of a few hours.

645.11. Uninterruptible Power Supplies (UPSs). This rule requires disconnects for “supply and output circuits” of any UPS rated over 750 VA “within” the computer room. The UPS disconnecting means *must* satisfy 645.10, and it *must* “disconnect the battery from its load.” The wording of this rule leaves questions about a disconnecting means for a UPS installed *outside* the computer room (Fig. 645-6). The UPS output circuit—which presumably feeds the computer room—would have to be disconnected. But it seems as if the supply to the UPS and the battery charge/supply circuit need not be automatically disconnected when the UPS is located outside the room. On the other hand, the wording clearly does require the UPS output circuit to meet 645.10 even if the battery were not required to be disconnected from its load in such cases.

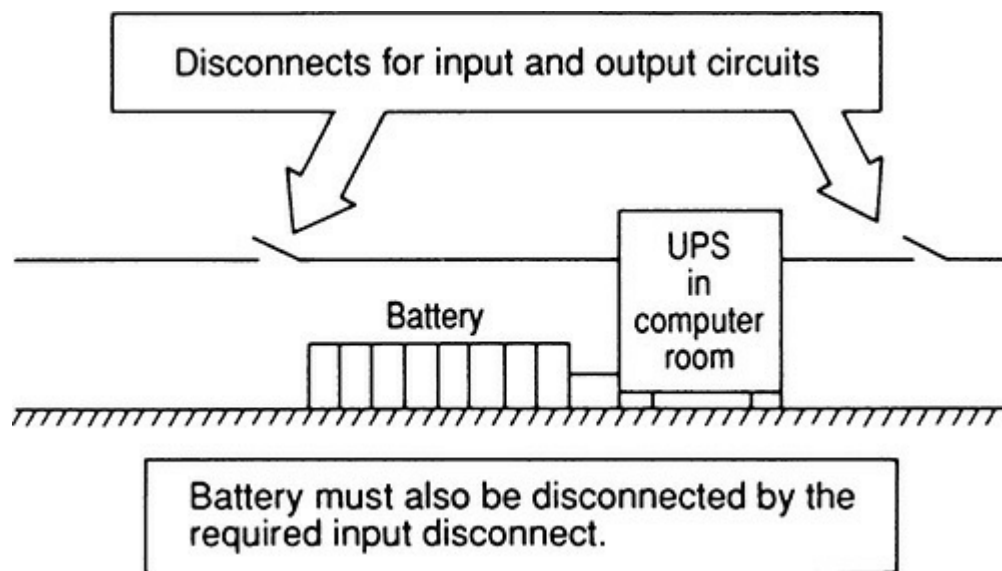

Fig. 645-6. Considerable interpretation latitude is inherent in the rule that requires “grouped and identified” switches or circuit breakers “at principal exit doors” to control an uninterruptible power supply. (Sec. 645.11.)

645.14. System Grounding. The default status of ITE power systems is that they meet the conventional rules in Art. 250. However, immediately following this statement is an allowance that is so important it frequently drives the decision about whether to qualify for Art. 645 coverage or not. Power systems derived within listed IT equipment are not required to comply with 250.30, which sets in motion a chain of events that includes the permission to not bother installing a grounding electrode or making a connection to an existing electrode. The note following explains that listing requirements adequately address the safety issues involved. The principal issue is whether or not the power system includes a system bonding jumper between the neutral and the equipment grounding system between the output terminals of the transformer and the secondary disconnect. If this jumper is properly installed, then any electrical fault will have an effective fault current path to return to the system source. The product standards do ensure that this jumper will be installed.

645.15. Equipment Grounding and Bonding. Data processing equipment must *either* be grounded in full compliance with Art. 250 or be “double insulated.” The last sentence of 680.15 points out the need for bonding of “signal reference structures” where such grids are installed within the information technology room. Presumably this bonding should be provided between the equipment ground bus at the power systems source and the reference grid. As for sizing this bonding jumper, in the absence of a specific rule on this matter, it seems reasonable to size the bonding jumper based on the size of the source’s main or system bonding jumper. Where the room is supplied by a feeder, a bonding jumper not less than the size of the equipment grounding conductor required by 250.122 for the feeder would also seem to satisfy this rule. Such sizing should be viewed as acceptable especially since there is no wording provided to establish a method for the sizing of this required bonding conductor. The 2014 **NEC** added a requirement requiring any supplemental grounding electrodes to comply with 250.54, including the fact that the earth is not to be relied upon as a fault-current return path.

645.17. Power Distribution Units. This section recognizes the use of power distribution units (PDUs) that are equipped with multiple panelboards. That is, PDUs may have more than one panelboard within a single enclosure. The former limitation to 42 circuits per panel was removed

following changes in Art. 408 that removed that limitation generally. Note that because a panelboard is actually the bus structure and not the enclosure, which is an enclosing cabinet, the allowance for multiple panels in a common enclosure was always unnecessary to begin with. Listing for these locations is still required.

645.18. Surge Protection for Critical Operations Data Systems. As of the 2017 NEC, the protection must be provided, which also correlates with 708.20(D).

645.25. Engineering Supervision. This section permits an engineered load calculation to be made in lieu of the usual procedures in Art. 220 with respect to the loads in one of these information technology equipment rooms. A great deal of attention is now being paid to reducing energy budgets in these rooms, both directly in terms of processing power, and indirectly in terms of the removal of heat. As developments proceed, there will be many solutions, all headed in the direction of reduced energy expenditure, and this section will allow those designs to receive the dividends they should in terms of reduced capital expenditures.

645.27. Selective Coordination. This is the latest application of a popular buzz term. Refer to the discussion at 700.32 for in-depth coverage of the merits, and expense, of protecting against a failure mode that has never occurred in an occupied building.

ARTICLE 646. MODULAR DATA CENTERS

646.1. Scope. This article, new in the 2014 NEC, can be thought of as taking the equipment and electrical wiring in Art. 645 and compressing it into prefabricated whole that approximates the size of a shipping container. The informational note attached to the definition in 646.2 is very helpful in rounding out the picture. They can be set up for either indoor or outdoor applications, and they can also be configured with support equipment in a separate enclosure.

646.3. Other Articles. This section, over a full page in length, is harmless but far longer than it needs to be, and clearly is intended as one-stop shopping for designers, installers, and inspectors of this equipment. All the cross-referenced requirements would necessarily apply in accordance with 90.3 with rare exceptions. For example, (L)(1) requires all wiring to be listed and labeled. Although Chap. 3 requirements typically include that for raceways, they often do not for cables. Another provision that will be extremely consequential is (L)(8) that brings in the alternate wiring allowances of Art. 645, but on the same proviso governing that article, namely, that the separation requirements in 645.4 are met. Part (N) requires compliance with 645.10 for the electrical system disconnect and then appears to require “a similar” HVAC disconnect. This will raise the question as to whether the two can be combined if desired. Section 645.10 allows them to be combined, so presumably that permission would carry over.

646.4. Applicable Requirements. The content and format of this section is without precedent in the NEC, and it is therefore very interesting. It establishes the line between MDCs that are submitted for a listing, and those that although a prefabricated whole, are field wired. If the prefab unit (and it will be a prefab unit per 646.2) is wired off-site without the benefit of a listing examination, then the inspector will be looking at field compliance with every provision. If it does go through a listing examination, 646.5 through 646.9 (the remainder of Part I of the article) would have been evaluated by the test lab and the results obvious and available for the AHJ, who will then focus

the inspection on the other sections. It follows that compliance to those other sections should always be scrutinized in the field by all parties whether or not a listing is evident.

646.5. Nameplate Data. This section governs the content of a required nameplate, focusing on how the unit needs to be supplied with power. It must take into account any special loading profiles, including some that might not be obvious for a data processing facility including motor loads complete with 430.26 duty cycling allowances and a reference to 430.26. Note that the reference to duty cycles [and 430.22(E)] is almost certainly incorrect. A duty cycle is unique to a very particular type of motor load and extremely unlikely to be a factor in the load profile of an Art. 646 application. The motor loads in such cases would probably be covered in Art. 440 and enter feeder load evaluations through 430.24. On the other hand, the reference to 430.26 in the informational note is essentially correct, in that 430.26 applies to demand factors and they should absolutely be considered while evaluating these loads. The only quibble would be that as written the reference is in the form of a note and not a [Chap. 6](#) amendment to [Chap. 4](#). If this evaluation is being performed by the inspector under 646.4(2), then such factors can be applied. If the evaluation is performed by a testing lab under 646.4(1), the status of 430.26 as being discretionary on the part of the inspector makes this problematic because a testing lab and an inspector are very different entities. That said, if a testing lab determines through the listing process that a certain rated current is correct it should always be respected.

646.6. Supply Conductors and Overcurrent Protection. This is the expected 125 percent ampacity rule for the supply conductors, presumably based on the likely continuous operating nature of these loads, and the fact that the wires will need to land on a device that will have a correlating requirement for the wires connected to it. The note in part (A) does repeat the erroneous reference to motor duty cycles and could be omitted entirely because the required evaluations would have been part of the nameplate creation process. The provisions of 646.6(B)(2) allow for the orderly implementation of 240.21 in instances where the MDC occurs at the end of a tap.

646.7. Short-Circuit Current Rating. These provisions mirror those for industrial control panels in 409.110 as they would be evaluated for use under 409.22. As in those cases, UL 508A, Supplement SB is essential to making these evaluations.

646.9. Flexible Power Cords and Cables for Connecting Equipment Enclosures of an MDC System. Extra-hard-usage flexible cord, evaluated for outdoor use if necessary, is permitted for one function, and only one function, namely, to interconnect enclosures of an MDC system where the routing is judged to not make it subject to physical damage. As with 520.53(H)(2) single-conductor cord is permitted, but not smaller than 2 AWG.

646.11. Distribution Transformers. This section covers the allowable transformer placements within or even in the vicinity of an MDC. Part (A) is a unique provision in the **NEC** and it forbids a utility-owned transformer within any MDC. The next two parts cover non-utility transformers, the first (part B) being “premises transformers.” This term is also unique, as well as undefined, but the context indicates that this is referring to a transformer on the load side of the service point, and therefore a part of the premises wiring system, that serves the MDC as well as additional loads at the occupancy that are unrelated to the MDC, and that are located near, but not in the MDC. These transformers simply follow Art. 450, but they must be either dry (450.21 or 450.22) or use a nonflammable insulating medium (450.24). Since such transformers are necessarily a type of power transformer also covered in part (C), this interpretation relies on the obvious necessity to

distinguish this provision from part (C). Part (C) allows power transformers that supply power only to the MDC to be located within it, provided they are dry and located within “the MDC equipment enclosure.” Although undefined, there is some useful descriptive text on the topic in the informational note within 646.9(A). Note, however, that such an enclosure need not be separate and could be a component within the overall MDC.

646.12. Receptacles. Every work area within an MDC must include a service receptacle.

646.14. Installation and Use. More one-stop shopping, with an obvious restatement of 110.3(B).

646 Part III. Lighting. This part contains interesting requirements some of which generally belong to building codes, but that are judged necessary because an MDC may arrive as a stand-alone piece of equipment, albeit large enough for employees to work within. The rules meld workspace illumination rules in 110.26(D) with typical building code rules for exit discharge illumination together with typical emergency standby rules for such lighting. Aside from the one-stop shopping considerations, the rules are necessary here because the lighting requirements are coming from the **NEC** and not from a building code, and thereby arguably sidestep the literal application of Art. 700. Clearly 646.17 recapitulates the relevant provisions of that article.

646.19. Entrance to and Egress from Working Space. Due to the incorporation by reference of 110.26 in 646.18, the workspace depth and height dimensions of that section are completely enforceable. The double-end access rule in this section closely parallels all of 110.26(C) (2) but has important differences. First, the rule applies not just to a wide line-up, but to one equally deep as well. In addition, it applies regardless of the amperage rating. Since the amperage parameter is removed from the equation, the panic hardware rule is then applied to all exit doors from an MDC that contains an equipment line-up that trips the 6-ft workspace threshold.

646.20. Working Space for ITE. Workspace for voltage-limited circuits (≤ 30 V RMS; 42 V peak; or 60 V dc) does not need to meet the prescriptive requirements in 646.19; circuits of greater voltage will, however, require that workspace.

646.21. Work Areas and Working Space Around Batteries. In agreement with 480.9(C), workspace around a battery system must comply with 110.26 measured from the edge of the rack.

646.22. Workspace for Routine Service and Maintenance. Work such as air filter cleaning and replacements must have workspace to accomplish those tasks, but there is no prescriptive dimension provided.

ARTICLE 647. SENSITIVE ELECTRONIC EQUIPMENT

647.1. Scope. This article covers a new 60/120-V distribution system designed to eliminate the effects of electronic noise, originally on audio and video production when this material was a Part (G) in Art. 530, and now in a more broadly applicable format. This system, as shown in [Fig. 647-1](#), uses two ungrounded circuit conductors at a potential of 120 V, and the system secondary is midpoint tapped and grounded to hold the system to 60 V to ground.

Fig. 647-1. A panelboard properly wired to distribute power using circuit conductors with 120 V between them and with each wire running 60 V to ground. The system must not be designed to be used for line to neutral load. (Sec. 647.1.)

These systems have proven extremely effective at reducing audio hum and video interference, which is why this system started its days of **NEC** recognition in Art. 530. The noise from the filtering circuits tends to cancel on this type of balanced system and it routinely outperformed the most elaborate grounding arrangements on traditional distributions. All harmonic frequencies cancel. The transformers with the center-tapped 120-V secondaries are increasingly available as well. The location here as a standalone article means that other applications can use its benefits.

647.3. General. These systems can be used to reduce electronic noise in “sensitive electronic equipment locations” provided they are installed only in industrial or commercial occupancies, and under close supervision of qualified personnel.

647.4. Wiring Methods. Part (A) provides that standard panelboards, such as 120/240 single-phase panelboards are permitted, but the voltage system must be clearly marked on the panel face or door. Common-trip two-pole circuit breakers must be used for all circuits (or a two-pole fused switch), and they must be identified for use at the system voltage. In general, circuit breakers work OK as long their voltage rating is not exceeded, and that will not be a problem on this system. As shown in the drawings, all loads supplied by these systems will use two ungrounded circuit conductors.

Part (B) covers junction box covers, which must be clearly marked to indicate the distribution panelboard and the system voltage.

Part (C) covers the identification rules for feeder and branch-circuit conductors, which must be identified as belonging to this kind of system at all splices and terminations by color, tagging, or equally effective means. The means chosen must be marked on all panelboards, and on the building disconnect. This is intended to reduce the possibility of confusion during future alterations.

Part (D) is one of very few instances in the **NEC** of a mandatory voltage drop requirement. The voltage drop on any branch circuit must not exceed 1.5 percent, and the total drop including the feeder contribution must not exceed 2.5 percent. These circuits are operating with only one-half the voltage to ground, which means that in any ground fault, only one-half the fault current would flow across the same fault. The intent of the rule is to maximize the available voltage to ground, which is already starting out at only one-half the normal amount, so overcurrent devices will trip open as quickly as possible in the event of a ground fault. For receptacles the limits are even tougher, with 1 percent on the branch circuit and 2 percent total from source to outlet if there is an intervening feeder.

647.5. Three-Phase Systems. To equalize the load on a three-phase distribution, these systems can be arranged with three transformers connected on their primary side to a premises conventional wye distribution with one primary transformer circuit (see [Fig. 647-1](#)) supplied by each of the three phases ([Fig. 647-2](#)). A maximum of two disconnects per winding are permitted, for a total of six. Note that with two disconnects per winding, the primary side of the transformers would be limited to 125 percent protection per 450.3(B). The more usual case would be three secondary disconnects, one per phase winding. Six-phase transformers operating 60 V to the star point are commercially available to support these wiring systems, with the secondary windings identified as in [Fig. 647-2](#).

Fig. 647-2. Three systems derived from three transformers connected to different phase pairs result in three different technical power systems, each one displaced 120 electrical degrees from the next and capable of supplying two disconnects each. (Sec. 647.5.)

647.6. Grounding. These are separately derived systems, and as shown in the drawing, they must meet the requirements in 250.30. The neutral connection at the center tap of the transformer has no circuit load function; its sole function is to stabilize the voltage to ground and to provide an equipment grounding return path. It supplies, on the downstream side of the main bonding jumper for the system, equipment grounding terminal bars. They must be marked “Technical Equipment Ground.”

If there were a succession of panelboards and the system designer decided to isolate the return path from the enclosing raceways and panelboard enclosures for further noise reduction, this section allows the use of insulated grounding conductors and having the Technical Equipment Grounding busbars isolated from the enclosures. This is the same procedure allowed in 250.146(D) and 408.40. Note, however, that such raceways and enclosures must still be equipment grounding system. This can happen using any of the recognized equipment grounding conductors in 250.118.

Conversely, the last sentence allows for a raceway grounding return path without any additional grounding conductors, provided that the impedance of the grounding return path over the raceway does not exceed the impedance of a separate grounding conductor installed to meet these minimum requirements. This is why the equipment grounding conductors in Fig. 647-1 have the notation “(if required).” Remember, if the circuit conductors have been increased to meet the voltage-drop requirement, then 250.122 requires a corresponding increase in the size of grounding conductors on the same circuit. In this case the raceway impedance must be compared with the lower impedance of the larger equipment grounding conductor that would otherwise have been substituted. The

informational notes that follow reinforce this concept.

647.7. Receptacles. Where receptacles are used to connect equipment, all of the following conditions need to be met. The reason for these requirements is to make as certain as possible that the receptacles are not used for cord-and-plug-connected loads designed for use on systems with only one ungrounded conductor. For example, if a floor lamp were connected, the screw shell would remain alive at 60 V to ground, even with the switch off, assuming a single-pole lampholder:

- (1) All 15- and 20-A receptacles shall be GFCI protected. This item then adds an additional level of safety by requiring GFCI protection at or ahead of all receptacle outlets. Be careful if you are considering using a 2-pole GFCI for this purpose. Its electronic circuitry may not work on a system voltage of only 60 V to ground. The best choice is the so-called “master” GFCI units that are, in effect, feed through GFCI receptacles without the contact slots. They will work because they would see only their design voltage of 120 V. Remember, using an actual GFCI receptacle would violate the configuration rule in (4).
- (2) All outlet strips, adapters, receptacle covers, and faceplates shall be marked: “WARNING—TECHNICAL POWER”; “Do not connect to lighting equipment”; “For electronic equipment use only”; “60/120 V 1Fac”; and “GFCI protected.” These markings are self-explanatory.
- (3) A conventional 125-V 15-A or 20-A receptacle must be located within 6 ft of all permanently-installed 15-A or 20-A 60/120-V technical power system receptacles. This rule relieves the temptation to plug the proverbial floor lamp into the wrong receptacle, because an appropriate receptacle must be nearby.
- (4) All 125-V receptacles used for 60/120-V technical power must be uniquely configured and identified for use with this class of system. These configurations have yet to be developed. When this system first entered the **NEC** (1996 edition), an exception followed, allowing a conventionally configured receptacle in “machine rooms, control rooms, equipment rooms, equipment racks, and similar locations that are restricted to use by qualified personnel.” That exception format has been restored, greatly clarifying how this rule should be applied. In the long term, it is to be hoped that a unique configuration is developed, allowing the main rule to take effect.

647.8. Lighting Equipment. Luminaires and associated equipment operated on these systems must have a disconnect that opens both circuit conductors. They must be permanently installed and listed for operation on these systems. No screw shell for such equipment is permitted to be exposed. Because fluorescent ballasts are a renowned source of electronic noise on wiring systems, placing them on one of these systems and thereby reducing that noise component to zero would benefit the overall system. However, the listing requirement may be excessive and unrealistic in terms of persuading conventional luminaire manufacturers to have their products reexamined.

ARTICLE 650. PIPE ORGANS

650.3. Other Articles. Some pipe organs now utilize sound equipment of the type covered in Art. 640, and those aspects are to be treated in accordance with that article.

650.4. Source of Energy. As now specified here, electronic organs must be supplied from a listed dc power supply with a maximum output of 30 VDC.

650.5. Grounding or Double Insulation of the DC Power Supply. The power supply

must be either double insulated, or its metallic case must be bonded to the supply-side equipment grounding conductor.

650.6. Conductors. In part (A) 28 AWG wiring for electronic signal circuits and 26 AWG for electromagnetic valve supply are recognized minimums. These instruments operate with common return conductors that may see currents from multiple sources at the same time, resulting in a 14 AWG minimum in the return from the electromagnetic supply. In part (C), the wires of the cable are normally all of the same polarity; hence, they need not be heavily insulated from one another. The full voltage of the control system exists between the wires in the cable and the common return wire; therefore, the common wire must be reasonably well-insulated from the cable wires.

650.7. Installation of Conductors. A 30-V system involves very little fire hazard, and the cable may be run in any manner desired; but for protection against injury and convenience in making repairs, the cable should preferably be installed in a metal raceway. Control equipment and bus work involving the common return conductor may be secured directly to the organ structure without additional insulation, and splices need not be made in enclosures. Unterminated and abandoned cables must be identified as such, but need not be removed. The panel determined that in many cases it was not practical to do so in this context.

650.8. Overcurrent Protection. Circuits must be arranged so the 26 and 28 AWG wiring is protected at not over 6 A, with other size wiring protected at its ampacity. The common return wires do not require protection.

650.9. Protection from Accidental Contact. The sounding apparatus, which has exposed wiring, must not be exposed to unqualified contact. However, part of what can prevent unqualified access in such cases is not a sound-obstructing enclosure, but other parts of the organ, such as the pipework or other decorative millwork.

ARTICLE 660. X-RAY EQUIPMENT

660.1. Scope. This covers industrial or other nonmedical applications exclusively; health care provisions are covered in Art. 517, Part V. An x-ray tube of the hot-cathode type, as now commonly used, is a two-element vacuum tube in which a tungsten filament serves as the cathode. Current is supplied to the filament at low voltage. In most cases, unidirectional pulsating voltage is applied between the cathode and the anode. The applied voltage is measured or described in terms of the peak voltage, which may be anywhere within the range of 10,000 to 1 million V, or even more. The current flowing in the high-voltage circuit may be as low as 5 mA or may be as much as 1 A, depending on the desired intensity of radiation. The high voltage is obtained by means of a transformer, usually operating at 230-V primary, and usually is made unidirectional by means of two-element rectifying vacuum tubes, though in some cases an alternating current is applied to the x-ray tube. The x-rays are radiations of an extremely high frequency (or short wavelength), which are the strongest in a plane at right angles to the electron stream passing between the cathode and the anode in the tube.

660.4. Connection to Supply Circuit. Fixed and stationary equipment must be connected through a [Chap. 3](#) wiring method, with an allowance for 30 A and lesser ratings to use hard-service cord and a plug. Portable and relocatable equipment can use cord-and-plug connections up to a 60 A rating.

660.5. Disconnecting Means. The minimum rating is 50 percent of the short-time current rating or 100 percent of the long-time rating, whichever is higher, with an allowance for cord-and-plug connections at 30 A or less and on a 120 V branch circuit. It must be within sight of the control, and readily accessible. An exception waives the requirement entirely with qualified maintenance and supervision, or on a finding of additional hazard or impracticability.

660.6. Rating of Supply Conductors and Overcurrent Protection. Branch-circuit wiring is sized the same as the disconnecting means. Feeders supplying multiple units are sized on the basis of 100 percent of the largest two units (determined by making the comparison required in the branch-circuit analysis), plus 20 percent of all others.

660.20. Fixed and Stationary Equipment. In radiography it is important that the exposure be accurately timed, and for this purpose a switch is used that can be set to open the circuit automatically in any desired time after the circuit has been closed.

660.24. Independent Control. If multiple x-ray units or other equipment are operated from a single circuit operating over 600 V, each such piece of equipment must have its own switch or equivalent. This device shall be arranged and installed such that its live parts will not be contacted by persons using the equipment or others.

660.35. General. A power transformer supplying electrical systems is usually supplied at a high primary voltage; hence, in case of a breakdown of the insulation on the primary winding, a large amount of energy can be delivered to the transformer. X-ray units are supplied at lesser voltages and can do without the protections normally required for transformers in Art. 450.

660.47. General. This section definitely requires that all new x-ray equipment be so constructed that all high-voltage parts, except leads to the x-ray tube, are in grounded metal enclosures. Conductors leading to the x-ray tube are shielded and heavily insulated.

ARTICLE 665. INDUCTION AND DIELECTRIC HEATING EQUIPMENT

665.1. Scope. Induction and dielectric heating are systems, wherein a work-piece is heated by means of a rapidly alternating magnetic or electric field.

665.2. Definitions

Dielectric heating In contrast, dielectric heating is used to heat materials that are nonconductors, such as wood, plastic, textiles, and rubber, for such purposes as drying, gluing, curing, and baking. It uses frequencies from 1 to 200 MHz, especially those from 1 to 50 MHz. Vacuum-tube generators are used exclusively to supply dielectric heating power, with outputs ranging from a few hundred watts to several hundred kilowatts.

Whereas induction heating uses a varying magnetic field, dielectric heating employs a varying electric field. This is done by placing the material to be heated between a pair of metal plates, called *electrodes*, in the output circuit of the generator. When high-frequency voltage is applied to the electrodes, a rapidly alternating electric field is set up between them, passing through the material to be heated. Because of the electrical charges within the molecules of this material, the field causes the molecules to vibrate in proportion to its frequency. This internal molecular action generates the heat used for dielectric heating.

Induction heating Induction heating is used to heat materials that are good electrical

conductors, for such purposes as soldering, brazing, hardening, and annealing. Induction heating, in general, involves frequencies ranging from 3 to about 500 kHz, and power outputs from a few hundred watts to several thousand kilowatts. In general, motor-generator sets are used for frequencies up to about 30 kHz; spark-gap converters, from 20 to 400 kHz; and vacuum-tube generators, from 100 to 500 kHz. Isolated special jobs may use frequencies as high as 60 to 80 MHz. Motor-generator sets normally supply power for heating large masses for melting, forging, deep hardening, and the joining of heavy pieces, whereas spark-gap and vacuum-tube generators find their best applications in the joining of smaller pieces and shallow case hardening, with vacuum-tube generators also being used where special high heat concentrations are required.

To heat a workpiece by induction heating, it is placed in a work coil consisting of one or more turns, which is the output circuit of the generator (Fig. 665-1). The high-frequency current that flows through this coil sets up a rapidly alternating magnetic field within it. By inducing a voltage in the workpiece, this field causes a current flow in the piece to be heated. As the current flows through the resistance of the workpiece, it generates heat (I^2R loss) in the piece itself. It is this heat that is utilized in induction heating.

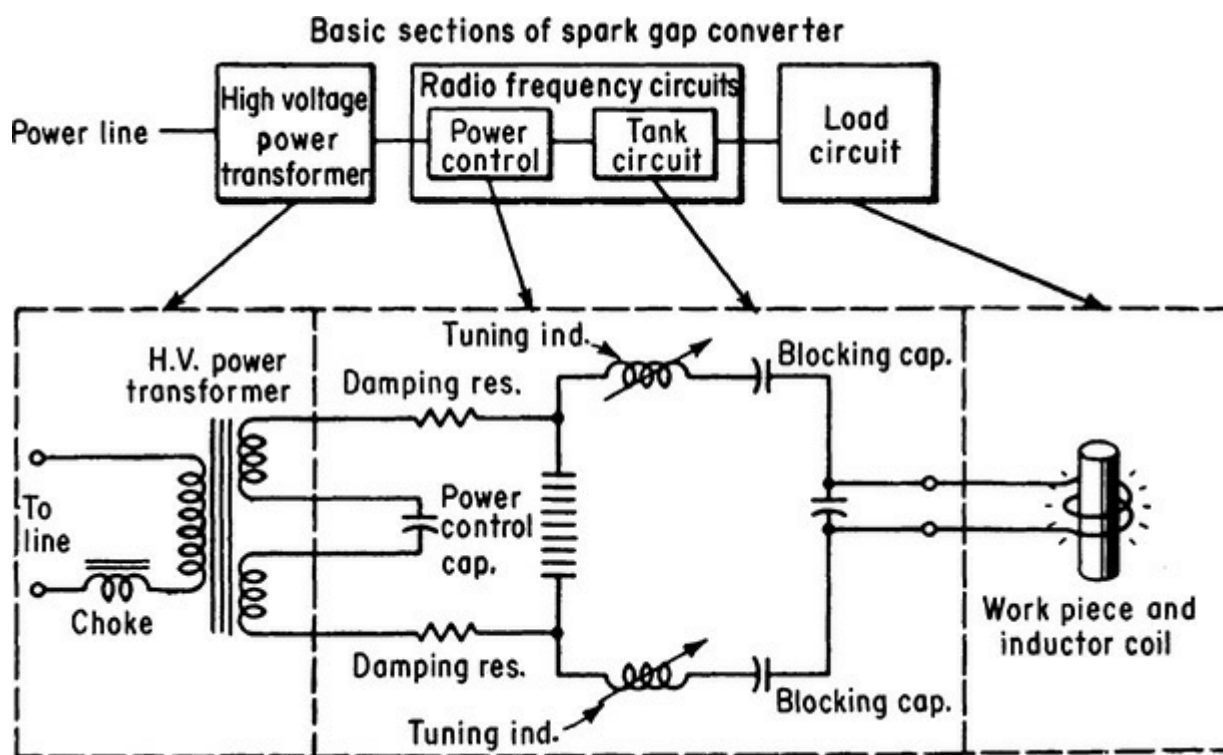

Fig. 665-1. A generator circuit supplies the *work coil* of an induction heater. (Sec. 665.2.)

665.5. Output Circuit. The induction circuit can be isolated from ground, as is often done with induction furnaces that employ water cooling. This mitigates the energy available in a ground fault until the furnace can be shut down. Otherwise, the ground fault could compromise the water jacket. Water hitting molten metal will result in a steam explosion ejecting molten metal from the furnace and endangering anyone nearby. If not isolated, the system must be arranged so there is no shock hazard of over 50 V to ground on any accessible surface, even if the coil and heated object touch.

665.7. Remote Control. In part (A), if interlocking were not provided, there would be a definite danger to an operator at the remote-control station. It might then be possible, if the operator had turned off the power and was doing some work in contact with a work coil, for someone else to apply

power from another point, seriously injuring the operator.

665.10. Ampacity of Supply Conductors. Quite often where several pieces of equipment are operated in a single plant, it is possible to conserve on power-line requirements by taking into account the load or use factor of each piece of equipment. The time cycles of operation on various machines may be staggered to allow a minimum of current to be taken from the line. In such cases the Code requires sufficient capacity to carry all full-load currents from those machines that will operate simultaneously, plus the standby requirements of all other units.

665.12. Disconnecting Means. An in-sight or lock-open disconnect must be provided for each heating equipment, sized to the equipment nameplate.

665.22. Access to Internal Equipment. This section allows the manufacturer the option of using interlocked doors or detachable panels. Where panels are used and are not intended as normal access points, they should be fastened with bolts or screws of sufficient number to discourage removal. They should not be held in place with any type of speed fastener.

665.25. Dielectric Heating Applicator Shielding. This section is intended primarily to apply to dielectric heating installations where it is absolutely essential that the electrodes and associated tuning or matching devices are properly shielded.

RF Lines

When it is necessary to transmit the high-frequency output of a generator any distance to the work applicator, a radio-frequency line is generally used. This usually consists of a conductor totally enclosed in a grounded metal housing. This central conductor is commonly supported by insulators, mounted in the grounded housing, and periodically spaced along its length. Such a line, rectangular in cross section, may even be used to connect two induction generators to the load.

While contact with high-voltage radio frequencies may cause severe burns, contact with high-voltage dc could be fatal. Therefore, it is imperative that generator output (directly, capacitively, or inductively coupled) be effectively grounded with respect to dc so that, should generator failure place high-voltage dc in the tank oscillating circuit, there will still be no danger to the operator. This grounding is generally internal in vacuum-tube generators. In all types of induction generators, one side of the work coil should usually be externally grounded.

In general, all high-voltage connections to the primary of a current transformer should be enclosed. The primary concern is the operator's safety. Examples would be interlocked cages around small dielectric electrodes and interlocking safety doors.

On induction heating jobs, it is not always practical to completely house the work coil and obtain efficient production operation. In these cases, precautions should be taken to minimize the chance of operator contact with the coil.

665.26. Grounding and Bonding

Bonding

At radio frequencies, and especially at dielectric-heating frequencies (1 to 200 MHz), it is very possible for differences in radio-frequency potential to exist between the equipment proper and other surrounding metal objects or other units of the complete installation. These potentials exist because of

stray currents flowing between units of the equipment or to ground. Bonding is therefore essential, and such bonding must take the form of very wide copper or aluminum straps between units and to other surrounding metal objects such as conveyors and presses. The most satisfactory bond is provided by placing all units of the equipment on a flooring or base consisting of copper or aluminum sheet, thoroughly joined where necessary by soldering, welding, or adequate bolting. Such bonding reduces the radio-frequency resistance and reactance between units to a minimum, and any stray circulating currents flowing through this bonding will not cause sufficient voltage drop to become dangerous.

Shielding

Shielding at dielectric-heating frequencies is a necessity to provide operator protection from the high radio-frequency potentials involved, and also to prevent possible interference with radio communication systems. Shielding is accomplished by totally enclosing all work circuit components with copper sheet, copper screening, or aluminum sheet.

ARTICLE 668. ELECTROLYTIC CELLS

668.1. Scope. This article provides effective coverage of basic electrical safety in electrolytic cell rooms.

The presentation of these requirements was accompanied by a commentary from the technical subcommittee that developed them. Significant background information from that commentary is as follows:

In the operation and maintenance of electrolytic cell lines, however, workmen may be involved in situations requiring safeguards not provided by existing articles of the **NEC**. For example, it is sometimes found that in the matter of exposed conductors or surfaces it is the man or his workplace which has to be insulated rather than the conductor. Work practices and rules such as are included in IEEE Trial Use Standard pertinent to such specific situations have been developed which offer the same degree of safety provided by the traditional philosophy of the **NEC**.

As a corollary to this concept, overheating of conductors, overloading of motors, leakage currents and the like may be required in cell lines to maintain process safety and continuity.

Proposed Art. 668 introduces such concepts as these as have been proven in practice for electrolytic cell operation.

668.2. Definitions. The subcommittee noted:

An electrolytic cell line and its dc process power supply circuit, both within a cell line working zone, comprise a single functional unit and as such can be treated in an analogous fashion to any other individual machine supplied from a single source. Although such an installation may cover acres of floor space, may have a load current in excess of 400,000 amperes dc or a circuit voltage in excess of 1000 volts dc, it is operated as a single unit. At this point, the traditional **NEC** concepts of branch circuits, feeders, services, overload, grounding, disconnecting means are meaningless, even as such terms lose their identity on the load side of a large motor terminal fitting or on the load side of the terminals of a commercial refrigerator.

It is important to understand that the cell line process current passes through each cell in a series connection and that the load current in each cell is not capable of being subdivided in the same fashion as is required, for example, in the heating circuit of a resistance-type electric furnace by Sec.

424.72(A).

668.3. Other Articles. Electrical equipment and applications that are not within the space envelope of the “cell line working zone,” as dimensioned in 668.10, must comply with all the other regulations of the **NEC** covering such work.

668.11. Direct-Current Cell Line Process Power Supply. These conductors are not required to be grounded. If that power supply is operating over 50 V between conductors, then the metal enclosures must be grounded either through protective relaying or by using a copper bonding conductor not less than 2/0 AWG in size.

668.12. Cell Line Conductors. These can be of any suitable conductive material, joined by bolting, welding, clamping, or compression, and of such size that under maximum load and ambient temperature their insulating supports will not be unsafely heated.

668.13. Disconnecting Means. As shown in Fig. 668-1, each dc power supply to a single cell line must be capable of being disconnected. And the disconnecting means may be a removable link in the busbars of the cell line.

Fig. 668-1. Removal of busbar sections may provide disconnect of each supply. (Sec. 668.13.)

668.14. Shunting Means. Similar means as for disconnecting can be used to make a shunted current path around one or more cells.

668.15. Grounding. The requirements of Art. 250 apply to any equipment or structure or other apparatus required to be grounded; however, an otherwise qualified water pipe electrode is not required to be included in the grounding electrode system.

668.20. Portable Electrical Equipment. This section and the rules of 668.21, 668.30, 668.31, and 668.32 cover installation and operating requirements for cells with exposed live conductors or surfaces. These rules are necessary for the conditions as noted by the subcommittee:

In some electrolytic cell systems, the terminal voltage of the cell line process power supply can be appreciable. The voltage to ground of exposed live parts from one end of a cell line to the other is variable between the limits of the terminal voltage. Hence, operating and maintenance personnel and their tools are required to be insulated from ground. If the cell-line voltage does not exceed 200 V dc, grounded enclosures are permitted but not required, and such enclosures are permitted to be grounded where guarded. To this end, receptacle circuits that supply this equipment as used within the cell-line working zone must only use ungrounded conductors in their supply created by the use of isolating transformers with ungrounded secondaries. Such tools and equipment must be marked to this effect, and the plugs and receptacles must be so configured that they will not be connectable to conventional receptacles, nor inadvertently interchanged with other equipment designed for conventional

connections.

668.21. Power-Supply Circuits and Receptacles for Portable Electrical

Equipment. Part (A) reiterates the requirement to use isolating power supplies for the ungrounded receptacles in the cell line working zone, and adds the requirement that the transformer primary cannot operate over 600 V with appropriate overcurrent protection. The ungrounded secondary conductors must also have overcurrent protection, and not be operating over 300 V.

668.30. Fixed and Portable Electrical Equipment. AC systems in the cell line working zone, and all exposed conductive surfaces, are not required to be grounded. The wiring to such equipment must be by flexible cord or nonmetallic raceway or cable assemblies. If metal raceways or cables are used, insulating breaks must be installed to avoid a hazardous condition. Fixed electrical equipment operating in the cell line zone is permitted to be bonded to the energized conductive surfaces of the cell line, and required to be so if it is attached to such a surface. Control and instrumentation circuits operating within the cell line working zone do not require overcurrent protection.

668.32. Cranes and Hoists. Conductive surfaces that enter the cell line working zone are not required to be grounded, and any part that contacts an energized cell or equipment attached to such a cell must be insulated from ground. Remote crane or hoist controls must employ (1) isolated circuits; or (2) pendants with nonconductive supports and surfaces, or ungrounded surfaces; or (3) radio controls; or (4) a rope operator. Note that as of the 2014 **NEC**, 610.31 Exception provides a conditional waiver to the normal within view requirement for runway disconnecting means for this equipment.

668.40. Enclosures. General-purpose enclosures are permitted where natural drafts prevent accumulations of gas from the process.

ARTICLE 669. ELECTROPLATING

669.1. Scope. This article covers all electroplating activity including anodizing. These operations often involve very high current at relatively low voltage, to the point that conventional conductors are not practicable.

669.5. Branch-Circuit Conductors. This wiring must be rated for 125 percent of the connected load; busbar ampacity is that of busbars in auxiliary gutters in 366.23.

669.6. Wiring Methods. For systems not over 60 V dc, open wires are permitted without insulated support if they are protected from damage, and bare conductors are permitted where supported on insulators. For systems running at a higher voltage, open insulated conductors can be used where run on insulated supports and protected from damage. Bare conductors are permitted where run on insulated supports and as guarded against accidental contact up to the point of termination using methods in 110.27.

669.7. Warning Signs. Warning signs must be posted indicating the presence of bare conductors.

669.8. Disconnecting Means. A disconnecting means must be provided from each dc power supply, which can consist of removable links or conductors.

669.9. Overcurrent Protection. DC conductors must have overcurrent protection in the form of fuses or circuit breakers, or a current sensing means that operates a disconnecting means, or some

other approved means.

ARTICLE 670. INDUSTRIAL MACHINERY

670.2. Definitions

Industrial machinery (machine) This definition is sufficiently broadly written that it should not be necessary to routinely revisit the definition as technology changes. The provisions do not apply to any machine or tool that is not normally used in a fixed location and can be carried from place to place by hand. The concept in this article is that the rules in this article and Art. 430 apply to the point of connection to the main terminals of the machine. On the load side of those terminals, including control circuit protocols and workspace rules, **NFPA 79**, *Electrical Standard for Electrical Machinery* takes over. This principle applies to machinery prepared as a unit by its manufacturer, but then disassembled for shipment and reassembled on-site. However, normal **NEC** provisions apply when various components are provided from different vendors on-site and then field assembled into a process. For example, motor controllers applied to an extensive conveyor system may or may not come directly under **NEC** provisions depending on whether they were furnished by the OEM as part of its engineered system.

670.3. Machine Nameplate Data. This information has been correlated with 409.110 with respect to the short-circuit current rating requirements. If overcurrent protection is provided as covered in 670.4(B), the machine must be marked accordingly.

670.4. Supply Conductors and Overcurrent Protection. Part (A) requires the supply wiring to have an ampacity not less than 125 percent of resistance loads, plus 125 percent of the largest motor plus 100 percent of all other motors and apparatus, based on their duty cycle and likelihood of simultaneous operation. Part (B) defines the machine as a single entity for the purposes of disconnecting rules, and therefore must be provided with a disconnecting means. Although not stated here, **NFPA 79** is correlated with 404.8(A) and uses the same 2.0 m (6 ft 7 in.) height limit, measured in the same way (the center of the grip in its uppermost position), and arranged to be lockable in the open position. When so locked, the machine cannot be energized by any local or remote action. Part (C) reiterates the rules of 430.62 for motor feeder overcurrent protection limits, because that is, after all, the function that such an overcurrent device on one of these units performs.

670.5. Short-Circuit Current Rating. If the available fault current (see 110.9) exceeds the short-circuit current rating on the equipment nameplate [see 670.3(A)(4)], the equipment is not to be installed and connected. This equipment requires this current to be part of a field marking, which is to be made after an analysis of local overcurrent protection and other factors, and the date of the determination must be included on the label.

670.6. Surge Protection. Safety interlock circuits must be provided with surge protection.

ARTICLE 675. ELECTRICALLY DRIVEN OR CONTROLLED IRRIGATION MACHINES

675.1. Scope. This article covers electrically driven irrigation machines that are not portable by

hand, and used primarily for agricultural purposes. It does not cover water pumps that bring water to the machines.

675.3. Irrigation Cable. This is the cable used to interconnect enclosures on an irrigation machine. It has a number of construction specifications predicated on its expected use in a wet location and where subject to flexing, and requiring metallic armoring in its inner construction. It must be supported at least every 1.2 m (4 ft). The cable is permitted to be a composite with control and grounding conductors included, and must be terminated in fittings designed for the cable.

675.7. Equivalent Current Ratings. For continuous duty the normal rules in Art. 430 apply. Where the duty cycle is inherently intermittent, part (A) determines a continuous current rating by taking 125 percent of the largest motor (using the nameplate rating), adding the sum of all other motor nameplate ratings, and then multiplying the final summation by the maximum percent duty cycle for which they can operate. Part (B) determines an equivalent locked-rotor current by adding the locked-rotor currents of the two largest motors to the full-load current ratings of the remaining motors.

675.8. Disconnecting Means. Part (A) requires the main controller governing the complete machine to at least match the equivalent continuous current rating determined as above, or per 675.22(A) for center pivot machines, and a horsepower rating taken out of the locked-rotor tables at the end of Art. 430 based on the equivalent locked rotor current determined above or by 675.22(B) for center pivot machines. If a listed molded case switch is used for the disconnecting means, it must have the ampere rating as described but it need not have a horsepower rating.

Part (B) requires a main disconnect, which must include overcurrent protection, and can be at the main power connection to the machine or not over 15 m (50 ft) away, provided it is within view and readily accessible with a permanent lock-open feature. Its ratings must not be less than as required for the main controller, although it is recognized that circuit breakers do not carry horsepower ratings.

Part (C) requires individual disconnects for each motor and controller, as covered in Part IX of Art. 430. These disconnects need not be readily accessible.

675.9. Branch-Circuit Conductors. The branch-circuit conductor minimum ampacity follows the continuous current ratings determined by 675.7(A) or 675.22(A).

675.10. Several Motors on One Branch Circuit. This section varies the normal limits in 430.53, and allows several motors, each not over 2 hp and protected not over 30 A at not over 600 V, to operate off of taps made up with copper wire not smaller than 14 AWG and not longer than 7.5 m (25 ft). Each motor so connected must have normal running overload protection and its full-load current must be limited to 6 A. If these conditions apply, individual short-circuit and ground-fault protective devices need not be installed.

675.11. Collector Rings. Collector rings must carry their motor loads, as determined in one of three ways: 1) the result from 675.7(A); or 2) the result from 675.22(A); or 3) 125 percent of the largest controller (NEC says “device”; a motor is not a device but a controller is) plus the full load currents of all other “devices” served. The grounding ring must be fully sized to the same rating. Control and signaling rings must carry their load taken as 125 percent of the largest device plus 100 percent of all other devices. The rings must be in a suitable enclosure so they will withstand the environment they will operate within.

675.12. Grounding. All electrical equipment and enclosures on the machine must be grounded, although a machine that is electrically controlled but not electrically driven is exempt from grounding if the voltage is 30 V or less and the control circuits are power limited in accordance with [Chap. 9](#),

Tables 11(A) and 11(B). This last provision means that the control circuits operate within Class 2 or Class 3 parameters, but need not meet the source requirements for these circuits in 725.121(A) that would actually qualify them for this designation.

675.13. Methods of Grounding. This rule requires on-machine grounding conductors to be fully sized to the ungrounded conductors, and not as permitted in Table 250.122. However, feeder circuits are permitted to use the normal sizing rules.

675.15. Lightning Protection. Irrigation machines with a stationary point must be connected to a grounding electrode system as covered in Part III of Art. 250. Note that this connection alone will not meet the minimum requirements of **NFPA 780**, *Standard for the Installation of Lightning Protection Systems*, but it is the **NEC** minimum.

675.22. Equivalent Current Ratings. This section covers the calculations for center pivot machines that differ from other types of irrigation machinery. Part (A) determines a continuous current rating by taking 125 percent of the largest motor (using the nameplate rating) and adding 60 percent of the sum of all other motor nameplate ratings. Part (B) determines an equivalent locked-rotor current by adding double the locked-rotor currents of the largest motor to 80 percent of the full-load current ratings of the remaining motors.

ARTICLE 680. SWIMMING POOLS, FOUNTAINS, AND SIMILAR INSTALLATIONS

680.1. Scope. Electrification of swimming, wading, therapeutic, and decorative pools, along with fountains, hot tubs, spas, and hydromassage bathtubs, has been the subject of extensive design and Code development over recent years. Details on circuit design and equipment layout are covered in **NEC** Art. 680. Careful reference to this article should be made in connection with any design work on pools, fountains, and so forth. As of the 2017 **NEC**, all equipment and products either in the water or in the structure or decks of pools and other contained bodies of water covered by Art. 680 must be listed (680.4).

Research work conducted by Underwriters Laboratories and others indicated that an electric shock could be received in two different ways. One of these involved the existence in the water of an electrical potential with respect to ground, and the other involved the existence of a potential gradient in the water itself.

A person standing in the pool and touching the energized enclosure of faulty equipment located at poolside would be subject to a severe electrical shock because of the good ground which his or her body would establish through the water and pool to earth. Accordingly, the provisions of this article specify construction and installation that can minimize hazards in and adjacent to pools and fountains.

The potential gradient in the water presents primarily a drowning hazard and not an electrocution hazard. It was determined by actual human volunteers immersed in the water, particularly with any water in their ears, that a gradient of as little as 4 V was enough to cause disorientation to the point that the individual may not be able to leave the water. This is why the bonding requirements for a hydromassage bathtub are less severe than for a spa or hot tub; the bathtub does not present the drowning hazard that a spa or hot tub, or larger pool presents.

Very important: Therapeutic pools in a health care facility are not exempt from this article.

Therapeutic pools in hospitals are subject to all applicable rules in Art. 680, Part VI.

As noted at the end of the first sentence, the rules here also govern the installation of “metallic auxiliary equipment, such as pumps, filters, and similar equipment.” That wording has the effect of requiring that any such “metallic auxiliary equipment” satisfy the requirements of Art. 680. Where a particular installation detail addresses say, a circulating pump, the pump must be installed as described. This is very clearly stated by the first sentence.

One last note applies to the phrase *body of water*. Where a rule refers to a “body of water,” the rule applies to all types of pools, and the like, that are covered by Art. 680. Where individual types of pools, and the like, are identified, then the rule given there applies only to the specified types of pools, and the like.

680.2. Definitions. These definitions are important to correct, effective application of Code rules of Art. 680. Figure 680-1 shows a typical dry-niche swimming pool luminaire, which are now permitted in the pool floor as well as the wall. Figure 680-2 shows a forming shell for a wet-niche luminaire.

Fig. 680-1. Dry-niche luminaire lights underwater area through glass “window.” (Sec. 680.2.)

Fig. 680-2. Forming shell is a support for the lamp assembly of a wet-niche luminaire. (Sec. 680.2.)

The definition of *cord-and-plug-connected lighting assembly* covers a luminaire of all-plastic construction for use in the wall of a spa, hot tub, or storable pool. This type of luminaire operates from a cord-and-plug-connected transformer, and it does not require a metal niche around the luminaire.

A *hydromassage bathtub* is a “whirlpool” or “Jacuzzi” bath for an individual bather, which is smaller than a hydromassage pool (spa or hot tub), but is covered in 680.70 through 680.74. It is designed to discharge its water after use.

The definition of *maximum water level* is, essentially, the deck level, because that is the level where the water can “spill out.” It is not, as generally previously supposed, the maximum fill level of the skimmer trough, because the water does not actually spill out at that point. This definition has serious repercussions on the placement of swimming-pool junction boxes, as covered later.

The *low-voltage contact limit* is the upper limit of voltage that is considered safe for human exposure under wet-contact conditions, and therefore generally applicable to a pool environment. It is taken from the wet-contact limits for power-limited circuits as reflected in Notes 2 and 4 of Tables 11(A) and 11(B) in [Chap. 9](#). These values have a very long pedigree, extending back to the 1975 **NEC**. Under current usage, Tables 11(A) and 11(B) are not for field applications; they remain in the **NEC** only to set policy parameters for qualified testing laboratories to apply in making listing evaluations. These numbers have been brought forward into Art. 680 in order for some installation rules to use as a point of departure for a change in installation protocol, but no installer should attempt actual field measurements to interpret the suitability of a certain product design. Look for a listing, and then review the installation instructions to determine how to proceed.

The definition of *no-niche luminaire* covers a luminaire for installation above or below the water without any niche. This definition correlates to 680.23(D), which provides installation criteria.

Because there are differences in the requirements for “permanently installed” pools and “storable” pools, there has been some confusion in the past as to just what a “storable” pool is. A *storable swimming or wading pool* must not hold a greater depth than 1.0 m (3½) ft of water, or have plastic

or inflatable walls of any dimension, and be “constructed on or above the ground.” The plastic/inflatable wall part of this definition identifies specific types of pool construction that are considered to be storable regardless of water depth. The storable definition has been broadened in the 2014 **NEC** to clarify that it also applies to storable/portable spas and hot tubs.

This definition, as well as two others (*pool* and *permanently installed swimming, wading, immersion, and therapeutic pools*), were changed to add the word “immersion” into the definition (pool), or into the title of the definition. The new title for this definition is “*storable swimming, wading, immersion, and therapeutic pools*.” The changes were made to clarify that a baptistery, whether permanently installed and maintained, or as part of a storable assembly, was covered by the applicable parts of Art. 680.

Figure 680-3 shows a “wet-niche luminaire.”

Fig. 680-3. Wet-niche luminaire consists of forming shell set in pool wall with cord-connected lamp-and-lens assembly that attaches to the forming shell, with cord coiled within the shell housing. (Sec. 680.2.)

680.5. Ground-Fault Circuit Interrupters. This section describes ground-fault circuit interrupters (GFCIs) that are required to be used by other rules of this article. Additional protection may be accomplished, even where not required, by the use of a GFCI. Since the GFCI operates on the principle of line-to-ground leaks or breakdowns, it senses, at low levels of magnitude and duration, any fault currents to ground caused by accidental contact with energized parts of electrical equipment.

Because the ground-fault interrupter operates at a fraction of the current required to trip a 15-A CB, its presence is mandatory under certain Code rules and is generally very desirable. As indicated by the wording here, either receptacle, CB, or “other listed type” of GFCIs may be used to satisfy the rules of Art. 680 where a GFCI is required.

680.7. Grounding and Bonding Terminals. These conductor termination points obviously play a crucial role in how the electrical systems will perform over time in a wet and corrosive environment. UL 467, the grounding and bonding product standard, recognizes copper, brass, bronze, and stainless steel as generally suitable for direct burial exposures, and this rule makes it clear that a listing accordingly is required.

680.8. Cord-and-Plug-Connected Equipment. The 3-ft (900-mm) cord limitation mentioned in this rule would not apply to swimming pool filter pumps used with storable pools under Part III of Art. 680, because these pumps are considered as portable instead of *fixed or stationary*. See the comments following 680.30. The UL Guide Card information [see discussion at 110.3(B) for details] echoes this requirement for motors that will be connected by a cord and plug. Of course, the manufacturer may also omit the attached cord and simply provide a hub or knockout to accommodate a permanent wiring connection, and the decision to add a cord may also be made in the field providing all code rules are followed including the provisions in 110.14 for connections involving fine-stranded conductors. Note that the plugs may be conventionally configured regardless of location now that the locking requirement has been withdrawn from 680.22(A). The equipment grounding conductor in the cord, which as a practical matter usually drives the overall cord size, must not be smaller than 12 AWG, or larger if required by 250.122.

680.9. Overhead Conductor Clearances. The general rule states that service drops and open overhead wiring must not be installed above a swimming pool or surrounding area extending 10 ft (3.0 m) horizontally from the pool edge, or diving structure, observation stands, towers, or platforms. Note that although these rules could limit the placement of a pool, the **NEC** has no jurisdiction over how utility supply lines might be subsequently installed.

Item C in Code Table 680.9 and the diagram clarify the horizontal dimensions around the pool to which the clearances of the table apply for overhead wiring over a pool area ([Fig. 680-4](#), top). The dimension C, measured horizontally around a pool and its diving structure, establishes the area above which such wiring is permitted, provided the clearance dimensions of A or B in the table are observed. The dimensions A and B do *not* extend to the ground as radii, and the dimension C is the sole ruling factor on the “horizontal limit” of the area above which the clearances of A and B apply.

Fig. 680-4. Clearances from Table 680.9 apply as indicated in these diagrams. (Sec. 680.9.)

As the basic rule is worded—and the table and diagram specify—the clearances of A and B must

be observed for utility lines (and overhead service conductors) above the water and above that area at least 10 ft (3.0 m) back from the edge of the pool, all around the pool. But the horizontal distance would have to be greater if any part of the diving structure extended back farther than 10 ft (3.0 m) from the pool's edge. If, say, the diving structure extended back 14.5 ft (4.4 m) from the edge, then the overhead line clearances of A and B would be required above the area that extends 14.5 ft (4.4 m) back from the pool edge, not just 10 ft (3.0 m) back (Fig. 680-4, bottom).

Part (C) of the table says that the horizontal limit of the area over which the required vertical clearances apply extends to the “outer edge of the structures listed in A and B.” That wording clearly includes observation stands in the need to extend the horizontal limit over 10 ft (3.0 m), as shown at the bottom of Fig. 680-4.

The next paragraph in this section (B) provides guidance on use of telephone company overhead lines and community antenna system cables above swimming pools. Although the first sentence of 680.9 generally prohibits “service-drop or other open overhead wiring” above pools, it was never the intent that the rules of this section apply to telephone lines. The general concept of this wording is to specifically permit such lines above pools *provided that* such conductors and their supporting messengers have a clearance of *not less* than 10 ft (3.0 m) above the pool and above diving structures and observation stands, towers, or platforms. However, network-powered broadband communications drops [covered in (C)] can operate at significantly higher voltages and must meet the normal clearances for the 0-750 V column in Table 680.9.

680.10. Electric Pool Water Heaters. A swimming pool heater requires branch-circuit conductor ampacity and rating of the CB or fuses at least equal to 125 percent of the nameplate load current. An electrically powered swimming pool heater is considered to be a continuous load and is therefore made subject to the same requirements given in 422.13 for hot water tanks. In addition, large units must meet the usual load subdivision rules, as for example in 422.11(F)(1).

680.11. Underground Wiring Location. This section is aimed at eliminating the hazard that underground wiring can present under fault conditions that create high potential fields in the earth and in the deck adjacent to a pool. Aside from the electric circuits associated with pool equipment, underground wiring must not be run under the pool. The 5-ft zone around the pool reserved for special coverage in this section was removed in the 2017 NEC cycle in favor of a simple prohibition against running extraneous circuits under the pool. The depth table was also withdrawn in favor of a simple reference to Table 300.5. The complete raceway system rule was also discontinued. Instead, there is a list of permitted underground wiring methods consisting of RMC, IMC, PVC, and RTRC conduits, and Type MC cable suitable for direct burial at that location. There is no horizontal dimension provided to indicate the reach of the rule at this point. One reasonable interpretation would be to apply the permitted raceway list to the horizontal outer limit of pool decks and other comparable structures within the scope of Art. 680.

680.12. Equipment Rooms and Pits. If these areas house electrical equipment, they must not be subject to water accumulations, either from weather, or pool spillage, or filter maintenance, etc. A new (2017) informational note points to the effects of chlorinating chemicals if stored near electrical equipment, and a published standard covering ventilation of such areas and the effectiveness of ventilation in terms of reduction of corrosive vapors.

680.13. Maintenance Disconnecting Means. Here the Code mandates that a disconnect—one or more, as needed—must be provided to disconnect all ungrounded conductors for all pool-associated equipment other than lighting. This disconnecting means can be a unit switch where the

switch disconnects all ungrounded conductors, or it can be a CB in a control panel, or other Code-recognized disconnecting means. If no such disconnect is available, then additional disconnecting means are required to be installed. The required maintenance disconnect must be “within sight” of the utilization equipment, which means not more than 50 ft (15 m) from the equipment, visible, and not guarded by a door that prevents direct access. It must be at least 1.5 m (5 ft) from the pool measured horizontally from the water’s edge, although it can be nearer if behind a permanent barrier that provides a reach path of at least that extent. Because this rule is in Part I of the article, it also applies to spas and hot tubs, as well as fountains and therapeutic tubs.

680.14. Corrosive Environment. As of the 2014 **NEC**, this new section describes the likely corrosive agents in swimming pool/hot tub/fountain/etc. locations, and provides prescriptive information as to appropriate wiring methods. Essentially, the corrosive agents are described in terms of the presence of acids, with or without one or both of two halogens (chlorine and bromine) that are used for water purification and sanitation. There are many acids in the world and no specification is offered in this section. However, generally in this case, the acids are derived from the presence of the halogens, which in free form react with water to form an acidic solution that is very corrosive. The Code focuses on storage areas for pool chemicals, along with circulators, chlorinators (or brominators), filters, and under deck areas abutting the pool as being of particular concern. Part **(B)** cites four raceways as being resistant to the corrosive effects. The two nonmetallic conduits (PVC and RTRC) are obvious; the two steel conduits would probably benefit from supplemental coatings. Zinc, the galvanizing material used with steel conduits, is not particularly resistant to attack from either hydrochloric or hydrobromic acid, and neither is aluminum [hence, 680.25(B)]. However, red brass heavy wall conduit is quite resistive to this sort of chemical attack. Currently no manufacturers are making it in its listed 10-ft electrical put up, but essentially the same heavy-wall product, often sold in 12-ft lengths, is available from some plumbing supply houses.

680.20. General. This rule mandates compliance with the provisions of parts **I** and **II** in this article where installing electrical and pool-associated equipment at a permanently installed swimming pool.

680.21. Motors. Part **(A)** covers wiring methods, and in an obvious error, the paragraph references additional to **(A)(1)** point to the four numbered paragraphs that existed in the 2014 edition, only two of which still exist in the 2017 edition. These general requirements are dramatically different as of the 2017 **NEC**, and now focus entirely on whether or not the wiring under discussion is in a corrosive location as defined in 680.14. Wiring within such areas is generally limited to the four rigid raceways included in 680.14(B), along with permission to use type MC cable “listed for that location.”

This is presumably intended as a reference to typically PVC jacketed MC cables that are suitable for sunlight exposure and wet locations. Although these conditions may not apply indoors, the construction features of such cables make them more stable in even an indoor environment. Although product literature periodically cites the utility of these constructions for swimming pool applications, current UL Guide Card information does not formally describe any category of MC cable as such. This will need to be sorted out with the inspector on a case-by-case basis. Figure 680-5 illustrates some of these rules.

Fig. 680-5. The wiring method requirements at the motor generally follow 680.14(B). As of the 2017 **NEC**, no special requirements apply to any portions of the circuit ahead of the corrosive environmental boundary. (Sec. 680.21.)

As soon as the circuit leaves the corrosive environment, the second paragraph of (A)(1) clearly removes all wiring method limitations at this point beyond normal [Chap. 3](#) provisions. In addition, there are no particular limitations on the size and character of the equipment grounding conductor, or even whether it must be of a wire type at all in the home run.

Flexible connections are permitted, as covered in part (A)(2), only as necessary at or adjacent to the motor, and are limited to liquidtight flexible metal and nonmetallic conduits terminating in listed fittings. Although unmentioned in this paragraph, the copper, insulated, 12 AWG minimum equipment grounding conductor required in (A)(1) is a legacy this paragraph inherits, and must be used with such flexible connections.

The last part, (A)(3), of this section permits use of flexible cord for cord-and-plug-connected pump motors, under the same conditions as described for general cord-and-plug connection in 680.7. The wording of the requirement here for sizing the equipment grounding conductor within the flexible cord had often been interpreted to permit the use of a 14 AWG copper, but that was never the case. The general wording in 680.21(A)(1) requires a 12 AWG minimum equipment ground, and the rules there apply to all motors unless modified in (2) and (3). Because this provision was not expressed as a modification, no such modification was ever allowed and the 12 AWG sizing minimum prevailed. However, in the interest of clarity and consistent application of the rules, the size requirement is now repeated in this paragraph.

The wording of 680.21(B) excludes cord-and-plug-connected double-insulated pumps from the need for bonding. Where such a pump is used, all other components of the pool and its associated equipment must be bonded together, but are required to connect to the pump's equipment grounding conductor. Presumably, this can be done at the receptacle outlet supplying the pump.

Part (C) requires that any pool circulation motor on single-phase 120- through 240-V (includes 208-V) circuits regardless of amperage (as of the 2014 **NEC**) must incorporate GFCI protection for the motor outlet whether the motor is hard-wired or plugged into a receptacle.

680.22. Lighting, Receptacles, and Equipment. Part (A)(1) requires, for all occupancies as of the 2014 **NEC**, at least one 125-V receptacle to be “located” within the 6- to 20-ft (1.8- to 6.0-m) band around the pool for *any* permanent pool wherever constructed. The long-standing limitation on this rule to dwellings only was removed. The word *located* was put in to replace the word *installed*, because there is no need to install such a receptacle if there is already one located within that area around the pool. This rule ensures that a receptacle will be available at the pool location to provide for the use of cord-connected equipment. It was found that the absence of such a requirement resulted in excessive use of long extension cords to make power available for appliances and devices used at pool areas. This required receptacle may not be mounted more than 2.0 m (6½ ft) above the pool and should be located so that it is visible after all the pool-associated equipment is “hidden” by shrubs or other natural or man-made partitions. The basic rules in Part (A) prohibit receptacles within 6 ft (1.8 m) from the pool edge, and part (A)(4) calls for GFCIs to protect all 15- and 20-A 125-V single-phase receptacles located within 20 ft (6.0 m) of the inside walls of indoor and outdoor pools. But part (A)(2) inexplicably required the installation of a receptacle for a swimming pool or fountain recirculating pump, “or other loads directly related to circulation and sanitation,” to be single and locking if less than 10 ft (3.0 m) but not closer than 6 ft (1.83 m) from the inside wall of the pool. This provision was a relic of former provisions that excluded such receptacles from a zone within 3 m (10 ft) at dwellings, and the allowance for a reduced distance of 1.8 m (6 ft) came with additional conditions. Now that such receptacles are allowed generally by right at the shorter distance, these conditions no longer make any sense. The 2014 **NEC** has partially addressed this by withdrawing the locking configuration rule for these receptacles, but leaving the 6-ft spacing rule in place, along with the GFCI and grounding rules, all of which taken together duplicate other requirements. The 2017 **NEC** completed the process by removing the single receptacle rule. Now the circulation and sanitation equipment receptacle rules still have their own numbered paragraph, but the requirements in that paragraph are identical to those that apply to receptacles generally.

Part (A)(3) allows other receptacles, of other configurations, voltages, etc., to be no closer than 1.83 m (6 ft) from the pool.

Part (A)(4) requires that all receptacles within 20 ft (6.0 m) of the inside wall of the pool must be protected by a GFCI. Of course, under current requirements in 210.8, virtually, *all* outdoor receptacles must have GFCI protection—at any distance from the pool.

Part (A)(5) says measurement of the prescribed distances of a receptacle from a pool is made over an unobstructed route from the receptacle to the pool, with hinged or sliding doors, windows and walls, floors, and ceilings considered to be “effective permanent barriers.” If a receptacle is physically only, say, 3 ft (900 mm) from the edge of the pool but a hinged or sliding door is between the pool edge and the receptacle, then the distance from the receptacle to the pool is considered to be infinite, and the receptacle is thus more than 20 ft (6.0 m) from the inside wall of the pool and does

not require GFCI protection ([Fig. 680-6](#), bottom).

1. No accessible receptacles are permitted within 6 ft of the inside walls of the pool

2. For a pool installed at any dwelling unit, at least one 125-V receptacle must be located within the 6- to 20-ft band around the pool and must be protected by a GFCI device.

All pool motor outlets, whether through direct connection or by cord and plug, require GFCI protection for branch circuits rated 15- or 20-A, 120- to 240-V, single-phase.

3. All 120-V receptacles between 6 and 20 ft of the inside walls of the pool must be protected by a GFCI device.

A receptacle for the cord connection of a swimming-pool recirculating pump now follows the same placement and configuration rules as other receptacles of the same rating.

680.22(A)(5) Doors or windows block a receptacle from connection of appliances that might be hazardous at poolside.

Fig. 680-6. Rules cover all receptacles within 20 ft (6.0 m) of the pool's edge. (Sec. 680.22.)

The reference to “existing installations” in 680.22**(B)(3)** must be understood to refer to luminaires that are already in place on a building or structure or pole at the time construction of the pool begins. Where a pool is installed close to, say, a home or country club building, luminaires attached to the already existing structure may fall within the shaded area for a band of space 5 ft (1.5 m) wide, extending from 5 ft (1.5 m) above the water level to 12 ft (3.7 m) above water level all around the perimeter of the pool, as described in part **(B)(1)**. GFCI protection is required for these existing luminaire outlets, as shown in Fig. 680-8. However, new luminaires may not be installed in that space band around the pool.

Under the conditions given in part **(B)(2)** for indoor pools, luminaires may be installed less than 12 ft (3.7 m) above the water of indoor pools. Luminaires that are totally enclosed and supplied by a circuit with GFCI protection may be installed where there is at least 7½ ft (2.3 m) of clearance between the maximum water level and the lowest part of the luminaire. Paddle fans are also permitted in this zone, provided they have been identified as described in this paragraph. They are subjected to a water-spray test and will be marked as acceptable for such applications.

Figure 680-7 applies the foregoing rules to lighting at an enclosed pool, including part **(B)(4)** on GFCI protection for certain outlets in the area adjacent to that immediately above and around the pool itself. Part **(B)(5)** applies the general short cord and 12 AWG minimum size rules in 680.7 to all cord-and-plug-connected luminaires within 16 ft of any point on the water surface, measured in a radius. Part **(B)(6)**, new as of the 2014 **NEC**, correlates with 411.5(B) by providing a specific instance of an acceptable low-voltage lighting system that is acceptable immediately adjacent to a pool.

Fig. 680-7. The luminaires over the pool and for 5 ft (1.5 m) back from the edge must be at least 12 ft (3.7 m) above the maximum water level if their supply circuit is without GFCI protection. If GFCI

protection is provided by a GFCI-type circuit breaker in the supply circuit(s) to these totally enclosed luminaires, their mounting height may be reduced to a minimum of only 7½ ft (2.3 m) clearance above water level for an indoor (but not an outdoor) pool. The luminaires at right side do not require GFCI protection because they are over 5 ft (1.5 m) above the water level and rigidly attached to the structure. Refer to Fig. 680-8. [Sec. 680.22(B)(2) and (B)(4).]

Part (B)(7), new as of the 2017 NEC, covers listed low-voltage gas-fire luminaires, decorative fireplaces, fire pits, and similar equipment using low-voltage ignitors without the need for grounding, and using transformers or power supplies that could qualify for use with underwater luminaires. This equipment can be located inside the usual 5-ft exclusion zone around the pool. Gas piping, if any, requires bonding, both in accordance with 250.104(B) as well as the 680.26(B)(7) rules for the bonding grid.

Part (C) requires that switching devices be at least 5 ft (1.5 m) from the pool's edge or be guarded [Fig. 680-8(c)]. To eliminate possible shock hazard to persons in the water of a pool, all switching devices—toggle switches, CBs, safety switches, time switches, contactors, relays, and so on—must be at least 5 ft (1.5 m) back from the edge of the pool, or they must be behind a wall or barrier that will prevent a person in the pool from contacting them. However, where the switch is specifically listed for installation within the 5-ft (1.5-m) horizontal exclusion area, then the switch may be located closer than 5 ft (1.5 m), where listed for such installation, as indicated by the last sentence.

If at all possible, wiring not associated with pool equipment must be kept out of the ground under a pool and under a 5-ft band around the pool. 680.10

Fig. 680-8. For luminaires and switching devices, installed locations are governed by space bands around pool perimeter. [Sec. 680.22(B).] Drawing (b) applies to an indoor pool.

Part **(D)** requires “other outlets” to observe a 3-m (10 ft) spacing minimum. An informational note describes such “outlets” and such items as fire alarm and communications circuits. Whether this article has jurisdiction in this area is unproven, and the substantiation for requiring a greater spacing for an RJ-11 telephone jack than for a 125-V receptacle outlet is not evident. On the other hand, such circuits do present significant voltage exposures. A typical ring voltage on a conventional telephone circuit can approach 90 V.

680.23. Underwater Luminaires. This section is organized according to a definite and logical plan. The requirements for each part of circuits and equipment for underwater lighting have separately lettered subsection designations. Part **(A)** begins with the actual luminaire and its equipment protection requirements. For example, **(A)(1)** covers the luminaire operation, and **(A)(2)** covers the transformers and power supplies (because the **NEC** now includes LED luminaires in these rules). Parts **(B)**, **(C)**, **(D)**, and **(E)** cover the various types of underwater luminaires that are recognized, with the numbered paragraphs under each lettered subhead covering special wiring requirements that apply to the underwater installation. Part **(F)** covers the branch-circuit wiring requirements for underwater luminaires on the line side of the underwater environment. To complete this overall picture of Part II, Sec. 680.24 covers the swimming pool junction box (and equivalent enclosure) requirements, Sec. 680.25 covers feeder circuits, Sec. 680.26 covers bonding, and Sec. 680.27 covers specialized equipment. In part **(A)** of this section, the wording must be followed carefully to avoid confusion about the intent.

Part **(1)** starts by requiring that any underwater luminaire must be of such design as to ensure freedom from electric shock hazard when it is in use and must provide that protection without a GFCI. Part **(A)(2)** recognizes voltage limitation as a protective scheme and, with the advent of modern technology, also recognizes the low-voltage dc power supplies used to run LED light sources. *But* in part **(A)(3)**, a GFCI *is* required for all line-voltage luminaires (any operating over the low-voltage contact limit, such as a 120-V luminaire) to provide protection against shock hazard during relamping. A GFCI is not required for these typically 12-V low-voltage swimming pool lights.

The UL Guide Card information presents certain essential data on use of GFCI devices, which must be factored into application of such devices, as follows:

A GFCI is a device whose function is to interrupt the electric circuit to the load when a fault current to ground exceeds some predetermined value that is less than that required to operate the overcurrent protective device of the circuit.

A GFCI is intended to be used only in circuits where one of the conductors is solidly grounded.

Class A GFCIs trip when the current to ground has a value in the range of 4 through 6 mA. Class A GFCIs are suitable for use in branch and feeder circuits, including swimming pool circuits. However, swimming pool circuits installed before local adoption of the 1965 **NEC** may include sufficient leakage current to cause a Class A GFCI to trip.

Class B GFCIs trip when the current to ground exceeds 20 mA. These devices are suitable for use with underwater swimming pool luminaires installed before the local adoption of the 1965 **NEC**.

GFCIs of the enclosed type that have not been found suitable for use where they will be exposed to rain are so marked.

It should be noted that *only* a “listed” luminaire should be used—which means only a luminaire listed by UL or other test lab for use at a permanently installed pool, as called for by part **(A)(8)**. In fact, the requirements given in parts **(A)(5)** through **(A)(7)** are very similar to UL data regarding the installation of listed underwater luminaires. UL data on listed luminaires must be carefully observed.

Part **(4)** sets 150 V as the maximum permitted for a pool luminaire, which means that the usual 120-V listed luminaires are acceptable. Note that the actual wording limits “supply circuits,” which allows for a HID luminaire with a higher starting voltage, provided the line connections remained at 120 V.

Part **(5)** repeats the UL limitation on mounting distance of a luminaire below water level. When installed, the top edge of the luminaire must be at least 18 in. (450-mm) below the *normal* level of the pool water ([Fig. 680-9](#)). This 18-in. (450-mm) rule was adopted to keep the luminaire away from a person’s “chest area,” because this is the vital area of the body concerning electric shocks in swimming pools. Keeping the top of the luminaire 18 in. (450 mm) below the normal water level avoids a swimmer’s chest area when he or she is hanging onto the edge of the pool while in the water. *But*, as the last sentence notes, an underwater luminaire may be used at less than 18 in. (450 mm) below the water surface if it is a unit that is identified for use at a depth of not less than 4 in. (100 mm). Part **(6)** requires upward-facing luminaires to have their lens guarded, or be listed for use without a guard.

**Underwater lighting fixtures
operating at more than 15 volts . . .**

**. . . must be approved
fixtures and must be
protected by a GFCI**

NOTE: 12-volt fixtures do not require a GFCI.

4 in. min. above deck and at least 8 in. above water

Fig. 680-9. Mounting of luminaire and circuit components must observe all Code rules and their specific dimensions. (Sec. 680.23.) Note that with the definition of maximum water level now at the point where the water spills out, the water height and the deck height are one and the same in most cases, and therefore the swimming pool junction box will be 200 mm (8 in.) above the deck. Also note that only rigid (or intermediate) metal conduit can support a box directly, without additional support direct to structure, per 314.23(E). Therefore, unless both conduits are metal [two is the minimum for box support in 314.23(E)] additional direct support is required for this swimming pool junction box.

Part (7) presents an interesting requirement on the use of wet-niche luminaires. The rule here requires that some type of cutoff or other inherent means be provided to protect against overheating of

wet-niche luminaires that are not submerged but are types that depend on submersion in water for their safe operation. Note that the UL rules quoted here require some luminaires to be marked “Submerge Before Lighting.” Manufacturers of such luminaires should incorporate this protection—such as in the form of a bimetal switch similar to those used in motor end-bells for motor overload protection.

Part **(B)** details the use of wet-niche luminaires. A wet-niche underwater lighting assembly consists of two parts: a forming shell, which is a metal structure designed to support a wet-niche luminaire in the pool wall, and a luminaire, which usually consists of a lamp within a housing furnished with a waterproof flexible cord and a sealed lens that is removable for relamping.

Part **(B)(2)** requires that the conduit between the forming shell and the junction box or transformer enclosure must be *approved* (1) rigid metal conduit or IMC and made of brass or other approved corrosion-resistant metal, or (2) liquidtight flexible nonmetallic or rigid nonmetallic conduit with a No. 8 *insulated* copper conductor installed in the conduit and connected to the junction box or transformer enclosure and to the forming shell enclosures. The No. 8 insulated copper wire may be stranded or solid. Each enclosure—the forming shell as well as the box—must contain approved grounding terminals.

Note the term “approved” with respect to metal conduit. This is a deliberate [Chap. 6](#) amendment of a [Chap. 3](#) rule, in this case 344.6, that requires all rigid metal conduit to be listed. Listed red brass conduit has not been generally available for decades. However, as heavy wall brass water pipe, it is available from some plumbing supply houses. It threads very well with the usual NPT threading dies, and is an extremely robust product. Without very heavy foot pressure on the bender shoe, an attempt to bend this product by pulling on the bender handle will bend the steel handle and not the pipe. The inside of this pipe is smoother than listed steel heavy wall conduits. The wording in this section at least makes this an option, subject to inspectional approval.

Figure 680-10 shows a typical connection from a forming shell to a transformer enclosure supplying the 12-V lamp in the luminaire. If a 120-V luminaire is used, the conduit from the shell terminates in a junction box, as shown in [Fig. 680-9](#). In the drawing of [Fig. 680-10](#), from the forming shell, a length of metric designator 27 (trade size 1) PVC conduit extends directly to a 120/12-V transformer mounted on the back wall of a planter adjoining the pool [observing the 4-ft (1.2-m) back and 8-in. (200-mm) high provisions of 680.24(B)(2)]. Where the nonmetallic conduit stubs up out of the planter soil, an LB (could be nonmetallic) connects the conduit to the transformer. The required 8 AWG conductor in the PVC conduit is terminated at the grounding bar in the transformer enclosure and on the *inside* terminal of an inside/outside grounding/bonding terminal on the forming shell. The external bonding lug provides for connecting the forming shell to the common bonding grid, as required by 680.26(A) and (B). The 8 AWG in the PVC conduit bonds the forming shell up to the transformer enclosure. Note that this 8 AWG conductor is not needed if metal conduit connects the shell to the transformer enclosure. One of the 12 AWG conductors in the supply circuit is an equipment grounding conductor that runs back to the panelboard grounding block and thereby grounds the 8 AWG and the metal fittings and transformer enclosure.

Fig. 680-10. Grounding and bonding is required in a typical hookup of low-voltage wet-niche luminaire with PVC conduit. (Sec. 680.23.) Note that in order to make the direct connection between the transformer and the luminaire as shown here, the transformer must be listed for such a direct connection. Further, it is to be presumed that such enclosures are not suitable for this task, unless they are specifically marked otherwise.

Part **(B)(2)(b)** requires that the inside forming shell termination of the No. 8 be covered with, or encapsulated in, a UL-listed potting compound. Experience has shown that corrosion occurs when connections are exposed to pool water. Listed epoxies are available to achieve this protection; however, some inspection agencies do accept a waterproof, permanently pliable silicone caulk compound.

Note that the illustrated assembly includes three noncurrent-carrying conductors: (1) an 8 AWG *bonding* conductor connecting the forming shell to the bonding grid; (2) an 8 AWG insulated conductor in PVC conduit between the forming shell and the transformer enclosure; and (3) a *grounding* conductor in the luminaire flexible supply cord. This is why 680.24(D) requires these enclosures to have at least one more grounding terminal than the number of conduit entries; with nonmetallic wiring, the run to the luminaire usually has two grounding conductors; however, for a listed low-voltage lighting system, the equipment grounding conductor in the cord may be omitted.

Part **(B)(4)** requires sealing of the luminaire cord end and terminals within the wet-niche to

prevent water from entering the luminaire. And grounding terminations must also be protected by potting compounds.

Part **(B)(5)** states that an underwater luminaire must be secured and grounded to the forming shell by a positive locking device which will ensure a low-resistance contact and require a tool to remove the luminaire from the forming shell. This provides added assurance that luminaires will remain grounded because, in the case of wet-niche luminaires, the metal forming shell provides a bond between the raceway (or No. 8 conductor in PVC) connected to the forming shell and the noncurrent-carrying metal parts of the luminaire.

Part **(B)(6)** calls for the luminaires to be so located that they can be maintained or relamped without the need to get wet. That is, consideration must be given to ensure that such “servicing” activities can be performed from a “dry location.” Further, the relamping location must be accessible without going into the water. In some instances, including luminaires in the bottom of a pool, these rules may require extensive lengths of cord, perhaps longer than what could be accommodated in the wet niche, and this will require careful design planning and consultation with the owners.

Part **(C)** permits use of an approved dry-niche luminaire that may be installed outside the walls or in the bottom of the pool in closed recesses that are adequately drained and accessible for maintenance. For a dry-niche luminaire, a “deck box,” set in the concrete deck around the pool, may be used and fed by metal (rigid or IMC) or nonmetallic conduit from the service equipment or from a panelboard. Where the circuit conductors to the luminaire are run on or within a building, the rule [680.23(F)(1)] permits the conductors to be enclosed in EMT—but rigid metal or IMC or rigid nonmetallic conduit must be used outdoors when not on a building. And such a deck box does not have to be 4 in. (100 mm) up and 4 ft (1.2 m) back from the pool edge, as required for a junction box for a wet-niche luminaire, because 680.24(A) and (B) only apply to wet-niche and no-niche luminaire wiring. (See [Fig. 680-1](#).)

Some approved dry-niche luminaires are provided with an integral flush deck box used to change lamps. Such luminaires have a drain connection at the bottom of the luminaire to prevent accumulation of water or moisture. The Code also recognizes listed low-voltage luminaires that do not require grounding.

Part **(D)** covers no-niche luminaires. They follow the same rules as wet-niche luminaires, except where a niche is mentioned, the no-niche bracket replaces it. Part **(E)** covers a through-wall lighting assembly, which is designed for above-grade use. Here again the rules in 680.23 apply, except in this case where the connecting point to the wiring system is specified, the conduit hub on the luminaire replaces the niche or the bracket. Review the UL data on this luminaire, quoted in this book at 680.33 below. These luminaires are used for both storable and permanent pools, and frequently wired improperly.

Part **(F)** covers branch-circuit wiring that runs on the supply side of transformer enclosures and junction boxes as shown in [Figs. 680-9](#) and [680-10](#), and on the supply side of dry-niche wiring compartments. The first paragraph covers permitted wiring methods, which include both metallic and nonmetallic heavy wall conduits (RMC, IMC, PVC, RTRC) along with liquidtight flexible nonmetallic conduit, which in the earth must be listed for burial as discussed in Art. 356. An exception follows that permits liquidtight flexible metal conduit to make connections to pool-lighting transformers in lengths up to 1.8 m (6 ft) for any single use and up to 3 m (10 ft) for the total run. Here again, the wiring method limits beyond normal [Chap. 3](#) considerations is, as of the 2017 **NEC**, the limit of the corrosive environment. However the rules for equipment grounding in (2) survive the

transition to a noncorrosive environment and will deservedly constrain the choices of wiring methods. An in-pool light is potentially one of the most dangerous of electrical applications, and the requirements for raceways and unbroken equipment grounding return conductors have been in the **NEC** for about 50 years.

In all instances including the cabled methods an insulated 12 AWG (or larger if so required by 250.122) equipment grounding conductor must be installed, unless the luminaire is a listed low-voltage lighting assembly not requiring grounding. The exception that follows permits an equipment grounding conductor to remain sized in accordance with the branch-circuit protection where run between a transformer enclosure and a swimming pool junction box. Often the wire sizes are increased on transformer secondaries because of the higher currents that follow from the transformation down to 12 V.

The second paragraph adds joint and termination rules for grounding conductors. The basic rule requires the grounding conductor to be installed unbroken at any point. There are two locations, and only two, where this is not so. The first is where the same branch circuit daisy chains through swimming pool junction boxes, transformer enclosures, or dry-niche wiring compartments. In every instance, *the connections must be on “grounding terminals.”* Do not use twist-on wire connectors to make these joints. The second location for joints in the grounding conductor is at the one or more points where the luminaire(s) are controlled by various means including a simple snap switch. Here again, *the connections must be on “grounding terminals.”* This applies even in the case of snap switches, which means field installing a short segment of equipment grounding bus in the device box or some comparable method.

680.24. Junction Boxes and Enclosures for Transformers or Ground-Fault

Circuit Interrupters. Part (A) covers junction boxes that *connect to a conduit that extends directly to a pool-lighting forming shell* or no-niche luminaire mounting bracket, such as shown in [Fig. 680-9](#). The junction box must be of corrosion-resistant material provided with threaded hubs for the connections of conduit, or nonmetallic hubs for nonmetallic wiring methods. Part (A)(3) requires these boxes to ensure continuity between metal conduit entries, even if the box is plastic, through the use of an “integral” means. This would mean a box constructed to meet 314.3 Exception No. 2, (refer to the discussion at that point) and it is unlikely such a box will be encountered. Plan on using metal-based swimming pool junction boxes if you are using metal conduits for wiring.

For line-voltage (120-V) pool luminaires, the so-called deck box (set in the concrete deck around the pool) is no longer permissible (except where approved dry-niche luminaires include flush boxes as part of an approved assembly), because deck boxes, which were installed flush in the concrete adjacent to the pool, were the major source of failure of branch-circuit, grounding, and luminaire conductors due to water accumulation within them. The rule of part (A)(2), covering low-voltage and line-voltage lighting, states that these junction boxes must be located not less than 4 in. (100 mm) above the ground level or above the pool deck, and not less than 8 in. (200 mm) above the maximum pool water level (whichever provides the greatest elevation), and not less than 4 ft (1.2 m) back from the pool perimeter.

Watch out for this placement issue on junction boxes. Now that the “maximum water level” has been defined as where the water can spill out, these two dimensions will use the same starting point (the deck) in most cases, thereby adding 100 mm (4 in.) to the elevation of most deck boxes. Swimming pool junction boxes require a domed cover to lift up and off the enclosed wiring, so a 200 mm (8 in.) spacing to the bottom translates to about 350 mm (14 in.) of minimum clearance from the

deck to the underside of a diving board or other structure the box may be placed under. This will often complicate the location of these boxes, which are a tripping hazard if left in the open. This was the reason for the 100 mm (4-in.) height reduction when it first went into the **NEC**; with the new definition, it no longer has much practical effect.

The wording of part **(A)(2)** does make clear that the elevated junction box could be less than 4 ft (1.2 m) from the pool's edge if a fence or wall were constructed around the pool, with the box on the side of the wall away from the pool, isolating the box from contact by a person in the pool. Or the box could be within 4 ft (1.2 m) of the edge if the box were on the other side of a permanent nonconductive barrier.

Important: The last part of the rule in 680.24(A)(2)(c) still permits flush deck boxes where underwater lighting systems are at the low-voltage contact limit or less if approved potting compound is used in the deck boxes and the deck boxes are located 4 ft (1.2 m) from the edge of the pool. In [Fig. 680-11](#), a deck box for a 12-V luminaire could be used in the deck but the use of the box less than 4 ft (1.2 m) from the pool's edge might be considered a violation, which does not recognize the fence along the pool in the same way as the first part in part **(A)(2)(b)**. That is, the fence is not mentioned in the first part as sufficient isolation of the box from the pool—although the installation certainly does comply with the basic concept in part **(A)(2)(b)**.

Fig. 680-11. The fence here permits the box to be closer than 4 ft (1.2 m) from pool's edge. (Sec. 680.24.)

Part **(B)** covers installation of enclosures for 12-V lighting transformers and for GFCIs that are required for line-voltage luminaires. Such enclosures may be installed indoors or at the pool location.

If a ground-fault interrupter is utilized at a pool, its enclosure must be located not less than 4 ft (1.2 m) from the perimeter of the pool, unless separated by a permanent means, and must be elevated not less than 8 in. (200 mm), measured from the inside bottom of the box down to the pool deck or maximum water level, whichever provides higher mounting. These rules cover installation of transformer or GFCI enclosures that connect to a conduit that “extends directly” to a forming shell.

Part **(B)(1)** specifically and clearly mandates that “other enclosures” be listed *and* labeled for the purpose. Use of any enclosures for GFCIs or transformers permanently installed in swimming pools that are not listed specifically for use at swimming pools is a violation. Enclosures that are so listed will be engineered to meet the following requirements.

Part **(B)(1)(1)** requires any such enclosure connected to a conduit that extends directly to an underwater pool-light forming shell to have threaded hubs or bosses or a nonmetallic hub. An enclosure of cast construction with raised, threaded hubs or with threaded openings in the enclosure wall would satisfy that rule. But because approved swimming pool transformers are usually available *only* in sheet metal enclosures with knockouts, this is usually not practical. Such a transformer connection will not meet other requirements in this section and violate the UL rule that “unless marked otherwise, these transformers are not suitable for connection to a conduit that extends directly to a wet-niche or no-niche luminaire.” In general, plan on running a raceway between the transformer enclosure and a listed swimming pool junction box that will receive the conduit running to the luminaire.

Part **(B)(1)(2)** requires corrosion-resistant construction, using brass, copper, stainless steel, plastic, comparable material. Often a combination of such materials is used.

Part **(B)(1)(3)** also requires that transformer or GFCI enclosures be provided with an approval seal (such as duct seal) at conduit connections to prevent circulation of air between the conduit and the enclosure; that they must have electrical continuity between every connected metal conduit and the grounding terminals by means of copper, brass, or other approved corrosion-resistant metal that is integral with the enclosures; that they must be located not less than 4 ft (1.2 m) from the inside walls of the pool (unless separated by a solid fence, wall, or other permanent barrier); and that they must be located not less than 8 in. (200 mm) from the ground level, pool deck, or maximum pool water level, whichever provides the greatest elevation. This distance is measured from the inside bottom of the enclosure. (See [Fig. 680-10](#).)

Note that part **(B)(1)(4)** intends to ensure a grounding path *from the enclosure and its grounding terminals* to any metal conduit. The section specifically states “metal conduit.” Where PVC conduit is used, the provision is not applicable, and the No. 8 ground wire in the PVC bonds to the forming shell. However, the section requires electrical continuity between an enclosure and “*every* connected metal conduit.” The conduit feeding the transformer primary does not seem to be involved with that rule because the concern is with the grounding path between the transformer or GFCI enclosure and the forming shell and because the No. 12 equipment grounding conductor in the primary supply will carry any current from a fault originating within the transformer enclosure. Local Code authorities should be consulted on the point.

The phrase “integral with the enclosures” is meant to cover a situation where the enclosure is nonmetallic. In this case, electrical continuity between the metal conduits and the grounding terminals must be provided by one of the metals specified, and this “jumper” must be permanently attached to the nonmetallic box so that it is “integral.” Refer to the discussion on the same topic at (A)(3) for swimming pool junction boxes; this is not a practical alternative.

In [Fig. 680-10](#), the transformer enclosure is being used as a junction box to an underwater light, with the equipment grounding conductors terminated at the grounding bar and carried through. The figure is predicated on the unlikely (but conceivable) assumption that the transformer is listed for a direct connection to a forming shell, and therefore meets all the requirements for such enclosures. However, the primary purpose of this enclosure is to house the transformer. Parts **(B)**, **(C)**, **(D)**, **(E)**, and **(F)** of 680.24 still apply. 680.24(A) would apply to boxes connected directly to underwater lights and is intended to cover situations where splices, terminations, or pulling of conductors might be required. Again, plan on providing a listed swimming pool junction box, which will be designed to meet all these rules, at every conduit termination that runs to a forming shell.

Part **(C)** of this section warns against creating a tripping hazard or exposing enclosures to damage where they are elevated as required. It is also important to remember that these junction boxes must be afforded additional protection against damage if located on the walkway around the pool. For protection against impact, they may be installed under a diving board or adjacent to a permanent structure such as a lamppost or service pole. As noted in the discussion at (A)(2), panel action on the maximum water level definition has greatly complicated the placement of these boxes under many diving boards.

Part **(D)** can be satisfied simply by using listed equipment; this is the rule requiring one more terminal than conduit entries, as discussed at 680.23(B)(2)(b). Part **(E)** calls for strain relief to be added to the flexible cord of a wet-niche lighting luminaire at the termination of the cord within a junction box, a transformer enclosure, or a GFCI. This mechanism will be furnished with or as an integral part of any listed swimming pool junction box.

680.25. Feeders. The permitted wiring methods permitted for feeders to panels in cabanas or other locations that supply branch circuits covered by Art. 680 consist of heavy-wall metal and nonmetallic conduits (RMC except aluminum in the pool area, IMC, PVC, RTRC) and liquidtight flexible nonmetallic conduit. Here again, the special wiring method rules only apply to the corrosive environment, and normal [Chap. 3](#) techniques can be used elsewhere. And in the case of feeders, there is no enhanced equipment grounding conductor rule that applies to the home run. Aluminum heavy-wall conduit is not permitted in pool areas where subject to corrosion.

680.26. Equipotential Bonding. The 8 AWG conductor and bonding system required in this section are not part of the effective fault current path that the equipment grounding system establishes, although they are ultimately connected to it. When all the required bonding connections are made at a pool, the entire interconnected hookup will be grounded by the “equipment grounding conductor” that is required to be run to the filter pump and to the lighting junction boxes and is connected to the 8 AWG bonding conductor at the pump and in the boxes. In a pool without underwater lighting, the equipment grounding conductor run with a pump-motor circuit will be the sole grounding connection for the bonded parts—and that is all that is required [see, however, 680.26(B)(6)]. The 8 AWG bonding conductor does not have to be run to a panelboard, service equipment ground block, or grounding electrode.

Its sole function is to reduce voltage gradients in the pool vicinity. A pool that is 750 V to ground because of a voltage transient is only a danger to a swimmer if one side is 752 V and the other side is 748 V, resulting in a 4 V gradient that could result in drowning, as noted in the discussion at the beginning of Art. 680. A bonding conductor extended to a remote panelboard in a basement could definitely save the life of an alien being with indefinitely long and stretchable arms who decided to reach through a cellar bulkhead and touch the panel while swimming in the pool. For the rest of us

such a connection is useless. Likewise, the bonding connections are irrelevant to whether the pool is connected to one or more grounding electrodes. The frequently imposed, and bogus, requirement to drive ground rods around a pool perimeter may assist users in avoiding shocks from the adjacent azalea bushes, but nothing else.

The 8 AWG conductor mandated in this section is a bonding conductor, not an equipment grounding conductor. It must be solid in order to better withstand chemical attack from pool chemicals. Certain controversies regarding this wire in terms of solid versus stranded, insulated or not, color coded or not are resolvable if its status as a bonding conductor is kept in mind.

For example, no rule requires it to be insulated. If it is insulated, inspectors might require green color coding at any permanently exposed termination, if a rigid interpretation is put on 250.119 and if the “bonding” conductor is considered to be an “equipment grounding” conductor. That view is incorrect because 250.102 on “bonding jumpers” does not specify color of insulation or covering any more than there is a color code for a grounding electrode conductor.

Conflict has also arisen in the past over use of this 8 AWG bonding conductor because 310.106(C) requires 8 AWG and larger conductors to be *stranded* where installed in raceways. That rule had the effect of limiting use of *solid* No. 8 conductors, and their manufacture seemed to be curtailed. 310.106(C) has an exception that exempts conductors from being stranded in raceways where other Code rules permit such application. However, while the “8 AWG equipment grounding conductor” covered by 680.23(B)(2)(b) is permitted to be either stranded or solid, the 8 AWG that serves as the common bonding grid is not so exempt and must always be solid.

Part (A) gives a general statement aimed at defining the nature and performance of the bonding connection. This connection is not intended to act as an equipment grounding conductor, which, of course, carries fault current to ensure operation of the circuit OC device in the case of a faulted conductor. The bonding connection required here is only intended to ensure that all noncurrent-carrying parts of the pool and its electrical system are at the same potential with respect to ground at the pool location, thereby reducing voltage gradients in and around the pool (Fig. 680-12). Note that the bonding requirements for components required as part of the bonding grid are not necessarily dependent on any particular proximity to the pool, such as 1.5 m (5 ft). For example, a recirculating pump motor for a pool and the associated piping functionally extends the pool water zone, and requires bonding however far it is from the pool.

Fig. 680-12. All of these metallic, noncurrent-carrying parts of a pool installation must be “bonded together” through the “equipotential bonding grid.” (Sec. 680.26.)

Part (B) reiterates the concept that bonding conductors need not run to remote panels because that would be irrelevant to their intended function. It then spells out in detail the pool components that must be bonded together, using 8 AWG solid copper wire. It also mentions brass conduit as a bonding conductor, which is incomprehensible in terms of functioning as a wire, but apparently intended to address a brass conduit as a collection point for wired bonding connections. Figure 680-13 shows what could be an example. This would be a reasonable application of the wording. There are seven categories of components that must be included in the bonding connections (Fig. 680-14).

Fig. 680-13. 8 AWG insulated bonding conductors from several bonded items connect to the brass conduit, thereby using it as a bonding conductor. 680.26(B)(7) requires bonding of all “metal conduit” within 5 ft (1.5 m) of pool edge. (Sec. 680.26.)

Bonding connections *must* be made with brass, copper, or copper alloy connectors or clamps.

Fig. 680-14. All designated parts must be connected to an equipotential bonding grid. (Sec. 680.26.)

Paragraph (1) covers conductive pool shells. These include pools made of concrete, including concrete block, whether or not it is supported by steel reinforcing. Bonding must be accomplished to the reinforcing steel using bonding connections that are listed for direct burial and for rebar connections; refer to the discussion in this book at 250.52(A)(3) (concrete-encased electrodes) for more information on this point. The reinforcing steel used for this purpose must be the usual, unencapsulated product with crossing points tied by steel tie wires or equivalent methods. If the reinforcing steel is the epoxy coated (typically green) product commonly used for highway bridge construction, then it is ignored and an alternative method is substituted.

The Code does not require each individual reinforcing bar to be bonded. It recognizes that the steel tie wires used to secure the rebars together where they cross each other provide the required bonding of the individual rods. Tests conducted over a period of several years by the **NEC** Technical Subcommittee on Swimming Pools have shown the resistance of the path from one end to the other through the structural steel to remain at less than 0.001Ω . The use of conventional steel reinforcing steel members as a permitted basis of a collective bonding grid has been recognized in the **NEC** since Art. 680 first appeared in the 1962 edition.

If conventional steel reinforcing is not available on a pool defined as having a “conductive pool shell,” then a mandatory alternative method applies. Warning: This method is so expensive that the cost of the required bonding grid alone is likely to be extremely costly, especially after considering required changes to normal trade scheduling in order to accommodate the additional work. Try to make customers aware, as early in the design process as possible, that the lack of conventional reinforcing steel may have this effect. The alternative requires a copper bonding grid to cocoon the pool structure, below as well as on the sides, and arranged to approximate the coverage of normal steel reinforcing. Specifically, 8 AWG bare solid wires must envelop the pool at a distance of no more than 150 mm (6 in.) using a 300 mm by 300 mm (1 ft by 1 ft) pattern (with a tolerance of 100 mm or 4 in.), and with all points of crossing connected in a manner suitable for direct burial. The only practical way to cope with this is through the use of substation grounding mats. These are available in 6-ft wide rolls with a range of bare copper wires and welded grid patterns to choose from, including the 8 AWG 300 mm (1 ft) pattern mandated here.

Paragraph **(2)** covers the pool deck and any other areas that immediately surround the pool perimeter. If there is steel reinforcing in the deck, then it gets the same bonding treatment as for the walls of a pool that use steel reinforcing. The deck reinforcing must be bonded to the method used for the pool walls at no fewer than four points evenly distributed around the edge of the pool. If there is no steel reinforcing in the deck, or if it is epoxy coated, then an alternate method is provided. Unlike the alternate method for the pool walls, the alternate for the deck reinforcing is simple, inexpensive, practical, and well-rooted in historical pool bonding practice. An 8 AWG bare solid copper wire is run around the pool at a distance of 450 to 600 mm (18 in. to 24 in.) from the inside of the pool wall. It must be buried 100 mm to 150 mm (4 in. to 6 in.) “below the subgrade,” which presumably means the distance below the final surface treatment such as coping stones. Any splices must be listed for the application, which means listed and marked “DB” or “direct burial” and comprised of all copper, brass, or bronze components, or of stainless steel. Note that if portions of the perimeter area are separated from the pool by a permanent wall at least 1.5 m (5 ft) high, perimeter bonding is not required for that portion.

Part **(3)** covers metallic components of the pool structure not already covered. This would include the walls of metal-walled pools ([Fig. 680-15](#)). As before, epoxy-coated reinforcing steel is ignored; thereby avoiding a conflict with 680.26(B)(1)(a). The rule does not require individual sections of such pools to be bonded. However, the overlapping ends of each section to be bolted must not be painted. If they are, the paint must be removed completely to restore conductivity. In addition, resistance tests should be made across each bolted section after assembly to ensure low resistance. These sections normally are fastened together by corrosion-resistant bolts at least $\frac{3}{8}$ in. (9.5 mm) in diameter, and such an installation satisfies the bonding objectives. But electrical parts of such a pool must be tied into that common bonding grid by 8 AWG bonding conductors.

Fig. 680-15. Walls of bolted or welded metal pool are metallic parts of the pool structure and require bonding. (Sec. 680.26.)

Part (4) covers the back side of metal forming shells and no-niche luminaire brackets. An exception exempts listed luminaire forming shells that are part of a low-voltage lighting system that does not require bonding.

Part (5) covers all metal fittings in or attached to the pool structure (Fig. 680-16), with the usual exemption (built into the wording of the rule) for small hand grips, etc., that are not over 100 mm (4 in.) in any dimension and that do not extend over 25 mm (1 in.) into the pool wall.

Fig. 680-16. Fittings for pool ladders have bonding strips attached to them for connection of the No. 8 bonding conductor. When the supports are set in the concrete deck, the bonding connections tie them all together. The 8 AWG bonding connections are shown (arrow) and a protective coating is painted on the connectors to protect against corrosion. (Sec. 680.26.)

Part (6) covers electrical equipment associated with the pool, including pump motors and the associated circulation system (Fig. 680-17) and conductive surfaces that are part of pool covers and their motors. Double insulated equipment does not, however, require incorporation into the bonding grid. This includes double-insulated pump motors; however, for those applications a run of 8 AWG bare copper must be extended from the bonding grid to the pump location, and left coiled there long enough so that if the double-insulated motor is replaced with a conventional motor, a bonding connection will be readily accessible.

Fig. 680-17. Water-fill pipe and metal housings associated with the water-circulation system are “bonded” with an 8 AWG solid copper conductor, as required. (Sec. 680.26.)

In addition, in cases where no component in the bonding grid has a connection to the equipment grounding system for the premises, such a connection will be made at this point using this bonding conductor. This could be achieved by connecting it at the outlet passing through a wet-location extension box, or for hard-wired applications entering the raceway and extending to an enclosure through a tee conduit body using a suitable watertight gland connector, or any other workmanlike solution appropriate for the location.

This part also covers pool water heaters that generally require bonding. However, for heaters rated above 50 A and with specialized instructions, only the specifically designated parts are to be bonded, or grounded, or both.

Part (7) includes metal raceways, metal-clad cable assemblies, metal plumbing, metal building components including door bucks, awnings, window frames and all other “fixed metal parts.” This also includes swimming pool junction boxes (Fig. 680-18) and swimming pool transformer enclosures, as well as metal fences, etc., if not separated by a barrier “that prevents contact by a person” or more than 1.5 m (5 ft) away, measured horizontally from the pool walls. In addition, parts more than 3.7 m (12 ft) above the pool or observation stands, diving platforms, etc., are not required to be bonded. Figure 680-19 shows an example of the entire system put together.

Fig. 680-18. Elevated metal junction box within 5 ft (1.52 m) of pool edge must be bonded. (Sec. 680.26.) Note that this is not a swimming pool junction box and therefore violates numerous provisions of 680.24(A)(1). However, the bonding is correct.

Fig. 680-19. An 8 AWG bonding jumper ties each of the indicated parts to the rebar grid, completing the bonding. (Sec. 680.26.)

In that drawing, the steel reinforcing rods, tied together with steel tie wires at intersections, are used as a common equipotential bonding grid to bond together pool equipment. Equipment shown here is required to be bonded. In addition, any metal parts (lighting standards, pipes, etc.) within 5 ft (1.5 m) of the inside walls of the pool and not separated from the pool by a permanent barrier must be bonded. All connections made must be completed with proper connectors, lugs, and so on, as required in 250.8 and as called for by the parent language in part **(B)** of this section.

Part **(C)** of this section is unfortunately worded, because the terminology “bonded water” is an oxymoron, like “married bachelor.” Nevertheless reasonable substantiation was presented that there was a potential problem if there were no electrical connection whatsoever between the conductive pool water and the surrounding bonding grid [which will be required in **(B)(2)** at least, and probably **(B)(6)** and **(B)(7)** as well], because there are significant issues with potential water-to-deck voltages. In past years, this would have been unheard of because something in the pool structure was always tied to the surrounding bonding grid. Today this is no longer an academic concern. Many pools are

now being constructed with all nonmetallic framing, nonmetallic liners, double-insulated pump motors, nonmetallic ladders, no diving board and no in-pool lighting. This rule ensures that in such cases, there will be a functional contact between the water and the surrounding grid.

Nevertheless, there were issues with the requirement, even beyond the terminology about bonding to that which cannot be bonded. The rule was missing any provisions about corrosion resistance of the connecting medium, whether it would likely be disturbed during swimming, etc. There are also practical issues of not wanting an 8 AWG conductor draped over the corner of a pool. The 2014 **NEC** has addressed these issues and provided the tools so inspectors can ensure enforcement.

One way to address this in a very simple, workmanlike way is to put a current collector in the drain line to the pool, as close to the pool drain as possible. If the drain is a metric designator 53 (trade size 2) pipe, a short brass or stainless steel nipple (check with the pool contractor for an assessment/preference as to reactivity with his or her chemicals) placed in the drain line will suffice. There are several patented and listed bonding plates designed for this purpose as well. The area exposed on the inside of this nipple is the circumference multiplied by the length. A nipple just 50 mm (2 in.) long will expose more than enough area to the water.

$$A = \pi Dh = 3.14 \times 2 \text{ in.} \times 2 \text{ in.} = 12.5 \text{ in.}^2$$

Attach an 8 AWG solid bonding wire to this current collector using a pipe clamp listed for this pipe size, and further manufactured using all copper, brass, or bronze, or stainless steel components, enabling a further listing for direct burial and with the appropriate markings. This is critical because replacing this item would involve extensive excavation. Connect the other end of the bonding conductor to the bonding grid, using a direct burial rated splicing device at the other end. Note that this will not only connect the water to the bonding grid, but to the equipment grounding system for the premises as well. This is because, if the installation is fully compliant, the connection mandated in 680.26(B)(6)(a) will have been made as well. Note that a bonded pool ladder frame may also work.

680.27. Specialized Pool Equipment. Part (A) of this section treats connection of loudspeakers for underwater audio output in the same way as a wet-niche pool luminaire. Wording and rules are almost identical to those in 680.23(B)(5). Connection from the speaker forming shell is made to a junction box installed as set forth in 680.21(A) for a luminaire. The wiring methods correlate with 680.23(B)(2).

Part (B) covers pool covers, and the control location must be such that the operator can see the entire pool. The motor(s) must be located to provide at least 1.5 m (5 ft) of space between them and the pool wall unless separated by a “wall, cover, or other permanent barrier,” and they must have GFCI protection. There are now motors that are part of listed systems and that operate within the low-voltage contact limit, and that have power supplies comparable to those for wet-niche luminaires. Exceptions in the 2017 **NEC** permit these motors to be installed within the normal 5-ft exclusion zone around the pool, and to be not subject to GFCI protection requirements.

Part (C) covers deck area heating. These rules cover safe application of unit and radiant heaters. Such units must be securely installed, must be kept at least 5 ft (1.5 m) back from the edge of the pool, and must not be installed over a pool. Permanently wired radiant heaters have the same horizontal clearance, but add a 3.7-m (12-ft) vertical clearance as well. Radiant heating cables are prohibited from use embedded in the concrete deck.

680.28. Gas-Fired Water Heater. If these heaters operate above the low-voltage contact

limit, they must have GFCI protection.

680.31. Pumps. There are portable filter pumps listed by Underwriters Laboratories, and they comply with 680.31. They are both double insulated and equipped with an equipment grounding conductor that picks up the inaccessible dead metal parts, and they must have GFCI protection built in to their power supply cord. Note that the 2014 **NEC** has added storable spas and storable hot tubs throughout Part III so the same rules as for storable pools also apply to this equipment.

680.32. Ground-Fault Circuit Interrupters Required. All 125-V receptacles rated 15 or 20 A within 6 m (20 ft) of the storable pool must have GFCI protection; the distances follow the same rules for measurement as in 680.22(A)(5) and do not pass through a sliding glass doorway, for example.

680.33. Luminaires. Underwater luminaires are available for storable pools in both 12-V versions (“within the low-voltage contact limit”) with a transformer and in 120-V (“over the low-voltage contact limit”) versions with long cords matching those that come with the motor. Usually these will not be subject to the default 450-mm (18-in.) submersion rule in 680.23(A)(5). Review the “through-wall lighting assembly” definition in 680.2 and the wiring rules for permanent pools in 680.23(E), and then factor in the following information from UL on products that are frequently installed improperly:

Underwater Luminaires for Aboveground Storable Swimming Pools—These luminaires are a type of through-wall lighting assembly as described in Art. 680 of the **NEC**. They have been investigated for use with an aboveground storable pool (a pool that is constructed on or above the ground and is capable of holding water to a maximum depth of 1.0 m (42 in.), or a pool with nonmetallic, molded polymeric walls regardless of dimension). They include all three of the following factory-provided parts:

1. Lamp assembly for temporary installation on or through the wall of an aboveground pool
2. Transformer or ground-fault circuit interrupter assembly provided with a 0.9–1.8 m (3–6 ft) power supply cord for connection to a source of supply and for temporary mounting away from the pool (the remote assembly)
3. Jacketed flexible cord of not less than 7.6 m (25 ft) in length connecting the lamp assembly and the remote assembly

These luminaires have been investigated for installation with the top of the lens not less than 200 mm (8 in.) below the top of the pool. A hole through the pool wall may be required for luminaire installation. Unless otherwise indicated in the luminaire’s installation instructions, the luminaire design has been investigated for the lower edge of any hole that a luminaire installer must cut in the pool wall to be no more than 360 mm (14 in.) below the top of the pool wall. The pool wall manufacturer may provide, at a greater depth, a properly sized hole or a reinforced wall section designed for field-cutting a properly sized hole for a luminaire or plumbing fitting. Unless otherwise marked for a maximum installation depth, these luminaires have been investigated for installation in such a hole at a greater depth where the pool installation instructions provide for the hole placement and usage.

Underwater Luminaires for Aboveground Nonstorable Swimming Pools—These luminaires are a type of through-wall lighting assembly as described in Art. 680 of the **NEC**. They have been investigated for permanent installation through or on the wall of an aboveground nonstorable pool. The information provided above for underwater luminaires for aboveground storable swimming pools regarding installation depth and using an existing hole or cutting a new hole for installation also applies to underwater luminaires for aboveground nonstorable swimming pools.

Convertible Underwater Luminaires for Aboveground Swimming Pools—These luminaires are initially configured as an underwater luminaire for aboveground storable swimming pool for use as described above. They include provisions for the one-time field conversion of the luminaire to an underwater luminaire for aboveground nonstorable swimming pool for use as described above. Once converted, these luminaires are not suitable for being modified back to their original configuration.

680.34. Receptacles. Receptacle outlets must be at least 1.8 m (6 ft) from the pool. How this can be enforced with what is in effect an appliance that can be set anywhere the ground is flat and for which no electrical permit will issue is anyone’s guess.

680.41. Emergency Switch for Spas and Hot Tubs. This switch is not a 680.13 maintenance disconnect. It is an emergency stop button for the spa motor, and may or (usually) may

not operate across the line. It must be clearly labeled, adjacent to the unit and within sight, but at least 1.5 m (5 ft) away. The rule does not apply to single-family dwellings.

Its sole function is to allow one or more people using a spa, or even a passerby, usually in a commercial environment, to shut down the motor in the event someone becomes entrapped by suction from the intake of the pump. There have been a number of tragedies from this problem, with documented instances of children being eviscerated after sitting over an intake and the event in New Jersey that directly led to this requirement, where a woman was trapped and drowned as a number of football players tried and failed to pry her away from a broken intake. The real solution to this problem is nonelectrical and has been implemented in the product standards by now, in the form of multiple intakes widely separated so the complete obstruction of one only sends the suction elsewhere, changes to the intake port designs, and other safety improvements.

680.42. Outdoor Installations. Outdoor units must meet the rules in Part II governing permanently installed pools, except as they are varied in this section. There are four such changes. Part (A)(1) allows flexible connections in any length; as of the 2014 **NEC** the former 6-ft limitation has been removed. This procedure is often used to bring a feeder up under a skirt of a spa or hot tub to a panel (makes the wiring a feeder) or to a “control panel” (the wiring lateral may be a branch circuit depending on conditions). Note that this permission only applies to listed units, both the packaged equipment assembly versions and the self-contained spa or hot tub versions that include the tub vessel.

Part (A)(2) allows flexible cord up to 4.6 m (15 ft), thereby extending the usual 900 mm (3 ft) limit in 680.7. GFCI protection is required. Remember that the circuit ratings on this equipment typically run in the 40 to 60 A range. Since this is an outdoor installation, 406.9(B)(2)(a) will ask for an in-use cover for this cord. This may necessitate a mobile-home type receptacle with an angle cord cap on the cord with its grounding pin set opposite to the cord exit.

Part (B) allows the omission of bonding connections to the metal bands or hoops that hold the wooden staves in place at a hot tub. All other requirements in 680.26 regarding equipotential bonding must be met. As of the 2014 **NEC**, the bonding requirements in 680.26(B)(2) no longer apply to listed *self-contained* spas and hot tubs that are evaluated for aboveground use outdoors and that are located on or above grade in accordance with all listing requirements. To qualify for this waiver, mentally extend a plane 30 in. horizontally around the perimeter of the tub or hot tub from the height of the rim. Bonding of adjacent conductive objects can be omitted if all permanently installed surrounding equipment or other surfaces are not less than 28 in. below that plane. Nonmetallic steps are ignored in making the measurements.

Part (C) allows cabled wiring through the interior of a dwelling, whether single-family or part of a two-family or multifamily building, or an accessory building thereto, such as a detached garage. Any [Chap. 3](#) method is allowed and the requirement for a 12 AWG minimum copper equipment grounding conductor as part of the circuit was discontinued in the 2017 **NEC**. This rule is intended to apply to a branch circuit, which is why there is an informational note pointing elsewhere (680.25) for feeders. This allows Type NM cable to run indoors to an outlet on the side of the house or outbuilding, or at that point a transition can also be made to other wiring methods that are recognized in 680.25(A) if the spa or hot tub location is some distance away.

Underwater luminaires, however, must follow the rules for underwater luminaires generally, which would involve a more restrictive list of wiring methods not including Type NM cable. Therefore they would need to be split from the feeder because the last sentence requires compliance

with 680.23. This is why the sentence was placed in this section to begin with; there was never any intent to make a variance for something as potentially hazardous as an underwater luminaire. The interior circuit would require a 680.23(F)(1) wiring method and, perhaps more importantly, a 680.23(F)(2) unbroken equipment grounding conductor return path that extends back to the point where the branch circuit originates. Another option given is a luminaire for a storable pool; this could be brought out on a conventional lighting circuit and the requisite luminaire, or luminaire and transformer, could be plugged in.

680.43. Indoor Installations. Indoor applications require [Chap. 3](#) wiring with an allowance for a cord-and-plug connection for a listed unit rated 20 A or less. The first exception is legitimate because the rule is for a [Chap. 3](#) connection, and the little plug-in models used indoors by definition do not rely on a [Chap. 3](#) connection. The second exception is another matter entirely. It is placed as an exception to the parent language of 680.43, covering indoor installations. The text under exception requires compliance with Parts I and II (which do, of course include 680.26) “*except as modified by this section.*” In fact, 680.43(D), which is incontrovertibly part of Sec. 43, does not require a perimeter bonding grid, only bonding of the specified items on the five-part list. The exception is an exception to nothing, was never required, and should be deleted. The third exception, new in the 2014 **NEC**, extends the principle of 680.42(C) to indoor applications.

Part (A) requires that at least *one* 15- or 20-A, 125-V convenience receptacle must be installed at a spa or hot tub—not closer than 1.83 m (6 ft) from the inside wall of the unit and not more than 10 ft (3.0 m) away from it. This is intended to prevent the hazards of extension cords that might otherwise be used to operate radios, TVs, and so on ([Fig. 680-20](#)).

Fig. 680-20. At least one 15- or 20-A general-purpose receptacle must be installed at a spa or hot tub. (Sec. 680.43.)

As required by part (2) of this section, this receptacle and any others within 10 ft (3.05 m) of the spa or tub must be GFCI protected, including the one supplying the power to the unit. The distance measurements do not pass through doorways, etc., similar to other comparable provisions in the article.

Part (B)(1) classifies luminaires over a spa or hot tub by height, with the limitations becoming more severe as the luminaire descends. First, if the luminaire is at or over 3.7 m (12 ft) above

(measured to maximum water level, which in this case would be the tub rim as per the definition), there is no further limitation. Second, if the lighting outlet is GFCI protected, the luminaire can be mounted as close as 2.3 m (7 ft 6 in.). Finally, if the luminaire is GFCI protected and recessed with either an electrically isolated metal trim or a nonmetallic trim, it can be even closer to the spa or hot tub. The same condition applies to surface-mounted luminaires with a glass or plastic globe and a nonmetallic body or a metallic body isolated from contact. In both of these circumstances the luminaire must be listed for a damp location.

Part **(B)(2)** governs underwater luminaires. Refer to the commentary on 680.42(C) at the end; the last sentence of that rule is the same as this wording and will be applied in the same way.

Part **(C)** requires the same 1.5-m (5-ft) exclusion zone around hot tubs and spas as 680.22(C) does for pools. There is no provision in this location that would recognize a barrier, so the distance cannot be decreased.

Part **(D)** requires bonding of the usual metal parts with 1.5 m (5 ft) of the spa or hot tub, including the pump motors. And there is the usual exception for incidental metal parts such as air and water jets, isolated plumbing fittings, towel bars, etc. Control devices within the 1.5 m (5 ft) zone must be bonded; if further away bonding is optional. A major change for the 2008 **NEC** was that by virtue of what is now an exclusion in (2) a listed self-contained spa or hot tub need not have its pump motors and the associated equipment meet the normal bonding rules.

Part **(E)** allows metal-to-metal contact on a frame or base and threaded piping interconnections for bonding methods, along with the usual 8 AWG solid copper. Part **(F)** requires grounding connections to the spa or hot tub equipment along with other electrical equipment within the 1.5 m (5 ft) zone, which would include such items as a thermostat for electric heat. Part **(G)** requires compliance with all rules in 680.27(A) for underwater audio equipment.

680.44. Protection. The default rule for all spas and hot tubs given here is that they will have GFCI protection in place for the outlet that supplies them. There are two circumstances where this will not be the case. The first concerns listed units, both self-contained units with the tub and equipment assemblies without, that have a system of integral GFCI protection for all components. Such units must be marked accordingly. The second exemption concerns field-assembled units that exceed in rating what is available in GFCI protective devices, specifically, over 250 V, or 3-phase, or over 50 A in heater load.

680.50. General. Part V of the article covers fountains, with a few exclusions. A fountain that is part of a body of water in common with a pool is covered by the requirements for pools generally because they are more severe. Portable fountains are appliances and covered in Art. 422.

680.51. Luminaires, Submersible Pumps, and Other Submersible Equipment. All of this equipment must be GFCI protected unless listed for operation at the low-voltage contact limit or less and fed with a transformer that meets 680.23(A)(2) for equivalent pool equipment. Luminaires are limited in operating voltage to 150 V for the “supply circuits” and for submersible equipment including pumps to 300 V. The “supply circuit” wording allows for an HID luminaire with a higher starting voltage provided its line connection remained at 120 V. Note that the reach of this paragraph, that used to apply to all fountain equipment, now only applies to submersible equipment of the types specified. For example, there are fountains in outdoor northern areas that have 480-V heaters keeping them from freezing. This is not submersible equipment and beyond the reach of this paragraph.

Part **(C)** requires that luminaires must be installed with the lens below the normal water line,

unless listed for use above water. If the luminaire faces up, the lens must be guarded against contact by the public, or it can be specifically listed for use without a guard. 680.23(A)(6) for regular swimming pools has a similar requirement, and UL requires distinctive installation instructions for those luminaires that can be used in the floor. Luminaires that are listed for use in fountains carry the term “submersible” in their description. For example, you might see a “wet-niche submersible luminaire,” or a “special use submersible luminaire.” These are not listed to the same requirements as luminaires listed for swimming pools, and they must not be confused with the other luminaires.

Part (D) states that luminaires and other equipment that must be submerged in order to avoid overheating must have a low-water cutoff or equivalent protection. In the case of luminaires, they will be marked “Submerge Before Lighting” and this will be visible after installation. This rule is similar to 680.23(A)(7) for lights in conventional swimming pools that must be submerged before lighting, which must be “inherently protected against the hazards of overheating.”

Part (E) limits equipment wiring entries such that they must either be threaded hubs or have suitable flexible cord, and any metal parts in contact with the water must be brass or other corrosion-resistant material. Where flexible cord is used, it must not extend more than 3.0 m (10 ft) in the open within the fountain. If the cord extends beyond the fountain, it must run in an “approved wiring enclosure.” This could be a conduit, provided the conduit material was suitable for its location.

Part (F) requires equipment to be removable from the water for normal maintenance or relamping. Luminaires must not be embedded in the walls of the fountain such that the fountain must be drained in order to reach them for maintenance. Part (G) requires equipment in the fountain to be stable so it will not be likely to tip over, or it must be secured.

680.52. Junction Boxes and Other Enclosures. Junction boxes that are not located in the water must meet the same construction requirements as for enclosures connected to conduits leading to forming shells as covered in 680.24.

Part (B) covers underwater enclosures. These junction boxes and other submersible enclosures must:

- Be made with threaded conduit entries, or else be provided with appropriate gland or other sealing connectors for flexible cord.
- Be made of copper, brass, or other suitable corrosion-resistant material such as some types of stainless steel.
- Be potted with an approved compound. Wax is often used for this purpose.
- Be firmly attached to the fountain surface or supports, and bonded as required.

The remainder of the section applies 314.23(E) and (F). Nonmetallic conduit cannot serve as the sole support of a box, and if it is used, the enclosure must have additional supports that are suitably corrosion-resistant so as to survive in the fountain water. If metal conduit is the support, two entries would be required, and it must have the requisite corrosion resistance.

680.53. Bonding. This rule requires piping to be bonded to the branch-circuit equipment grounding conductor. An external bonding conductor would not be required, since the box must be connected to that conductor in its role as an equipment grounding conductor anyway, per 314.4.

The rule for bonding fountains is a very simple one, but it contrasts dramatically with the allowance in 680.26(A)(6) Exception that allows DI motors to be left out of the bonding grid. Metallic piping systems associated with a fountain must be bonded to the equipment grounding conductor of the branch circuit supplying the fountain. Note that this part of the article on fountains

does not specify how the bonding is to be achieved, or any minimum size bonding conductor, etc. It only states that certain piping is to be bonded.

680.54. Grounding. All electrical equipment within 1.5 m (5 ft) of the inside walls of the fountain, and all electric equipment associated with the recirculation system must be grounded. Listed low-voltage luminaires not requiring grounding are exempt from this requirement. In addition, item (3) requires panelboards that supply a fountain to be grounded. Note that 408.40 imposes a grounding rule on all panelboards anyway.

680.55. Methods of Grounding. Essentially the rules that govern an underwater luminaire apply here. Specifically, the following rules for conventional pools, as listed in Part (A) come forward:

- 680.21(A), pool pump motor wiring
- 680.23(B)(3), equipment grounding provisions in cords to underwater luminaires
- 680.23(F)(1), wiring method rules for branch-circuit wiring for underwater luminaires
- 680.23(F)(2), equipment grounding rules in the above branch circuits
- 680.24(F), equipment grounding provisions for supply circuits
- 680.25, feeder wiring methods and grounding

Part (B) has its own rule for grounding equipment supplied by cord and plug. The equipment grounding conductor must be an integral part of the cord, and it must connect the equipment grounding terminal at its supply end with all exposed noncurrent-carrying metal parts of the equipment. This is comparable to rules in 680.7, but it does not include the 900 mm (3 ft) limitation in 680.7(A). By setting the rule up this way, the cord can exceed 900 mm (3 ft) in length. This, in turn, correlates with the allowance for up to 3 m (10 ft) of flexible cord to run within the fountain, as covered in 680.51(E).

680.56. Cord-and-Plug-Connected Equipment. All electrical equipment under this heading, including the power-supply cords, must have GFCI protection ahead of it. Although this only applies to cord-and-plug-connected equipment, 680.51(A) essentially requires GFCI protection on almost everything else.

Part (B) requires that flexible cord that is immersed in or subject to being splashed by the water must be rated for hard-service and also listed with a “W” suffix. This qualifies the cord for continuous submersion.

The ends of the flexible cord jacket, the conductor terminations, and the grounding terminations must all be set in a suitable potting compound so if water somehow gets into the cord, it cannot then get into the equipment. Now that listed potting compound is available for wet-niche grounding terminations [680.23(B)(2)(b)], this might be a good choice for these terminations as well.

Connections made with flexible cord for underwater equipment must be permanent. Although this paragraph allows for attachment plugs and receptacles, this is only for maintenance or storage of equipment that is not in an area of the fountain that contains water. In other words, submersible equipment supplied by a flexible cord cannot have that cord run out of the fixture to a receptacle in some remote, dry location.

680.57. Signs. This section covers signs in fountains, and also signs adjacent to fountains out to a distance of 3 m (10 ft) from the fountain. Part (B) requires GFCI protection on all circuits supplying a sign covered in this section, whether installed on the feeder level or on the branch circuit(s). Part (C) prohibits fixed or stationary signs in fountains from being within 1.5 m (5 ft) from the inside walls of

a fountain. Portable signs must not be placed within a fountain or outside a fountain within 1.5 m (5 ft) of the inside walls of the fountain. Part (D) requires local disconnects for the sign in accordance with both 680.13 and 600.6; both requirements can be met with a single device. Part (E) requires bonding connections in accordance with 600.7. Note that 600.7(B)(8) permits bonding in accordance with 680.53, which in turn enables a bonding connection to local metal piping.

680.58. GFCI Protection for Adjacent Receptacle Outlets. All 15- and 20-A 125-V through 250-V receptacle outlets within 6 m (25 ft) of a fountain must have GFCI protection. Note that this applies not just outdoors, but also within shopping malls and other indoor fountain locations. There is no allowance here for a waiver based on a locking configuration. This may prove problematic when running some maintenance equipment if the receptacle near the fountain is the only one for a great distance.

680.60. General. This is the beginning of Part VI on therapeutic tubs and pools. These are used for therapy in health care facilities, athletic training areas and similar areas. Portable therapeutic appliances need only comply with Art. 422 and do not come under these requirements.

680.61. Permanently Installed Therapeutic Pools. If a therapeutic pool is installed in or on the ground, or within a building, such that it cannot be readily disassembled, then it must comply with all the rules for normal permanently installed pools, as covered in Parts I and II of the article. The only exception is for luminaires; they need not observe either the placement or the GFCI restrictions in 680.22(B)(1 through 4) if they are totally enclosed. The special rules in Part VI of the article discussed here only apply to therapeutic tubs that are essentially stationary. That is, they can be disassembled but are normally left in one place, per 680.62 (below).

680.62. Therapeutic Tanks (Hydrotherapeutic Tanks). These rules roughly correspond to 680.44 for (A), and 680.43 for (B) through (F) on indoor spas and hot tubs.

Part (A) requires that any of the subspecies of therapeutic tanks (See 680.2 for the following definitions: Packaged Therapeutic Tub or Hydrotherapeutic Tank Equipment Assembly; Self-Contained Therapeutic Tubs or Hydrotherapeutic Tanks, and then consider the undefined term used here, Field-Assembled Therapeutic Tub or Hydrotherapeutic Tank) must normally have GFCI protection. Listed self-contained units or listed packaged equipment assemblies that incorporate integral GFCI protection for electrical components need not be wired with additional GFCI protection. Field-assembled units with higher heating loads than 50 A, or that are three-phase or rated over 250 V do not require GFCI protection.

Part (B) covers bonding. Just as swimming pools need a bonded environment for safety, tubs for therapeutic uses do as well. For stationary therapeutic tubs such as those at athletic training rooms and health care facilities (whether indoors or not), the following items need to be bonded together:

Any metallic fittings within or attached to the tub structure.

Metal parts of the circulation system, including the motor. Note that there is no allowance, at least as yet, for an unbonded DI pump motor.

Metal conduit, metal sheathed cables, and metal piping within 1.5 m (5 ft) of the inside walls of the tub, except items isolated by a permanent barrier. Note that this wording is not included in the bonding rules for conventional tubs in 680.43(D)(3). However, because 300.12 requires cable armors to be continuous between enclosures, and because the equipment must be bonded, presumably any metallic cable armor connected to a conventional spa or hot tub will be effectively bonded anyway.

All metal surfaces within 1.5 m (5 ft) and not separated by a permanent barrier from the tub area. A new small parts exception waives the requirement for many small, incidental parts such as metallic rims on water jets and drain fittings (provided they are not connected to metallic piping), towel bars, mirror frames, etc. However, unlike the comparable exception for indoor hot tubs, this exception does not exempt small parts if they are connected to metal framing members, such as metal studs. For this reason, 680.43(D)(4) Exception No. 1 covering conventional spas and hot tubs makes generally the same waiver, although as noted, that exception has no mention of metal framing members.

Electric devices and controls not associated with the tubs must be at least 5 ft away, unless they are bonded to the tub. This means that such items as a thermostat for electric heat must be bonded if they are within the 5 ft radius.

Note on the 1.5 m (5 ft) dimension. The Code is very unclear as to how this should be measured, in a radius or horizontally. The wording of 680.43(B)(1) implies a horizontal measurement by default, because luminaires are excluded from a 1.5-m (5-ft) zone to a height of 2.3 m (7½ ft) above the maximum water level. If we were to measure the 1.5-m (5-ft) distance in a radius, then a luminaire outside the tub would have to be 2.3 m (7½ ft) above the water outside the tub, but could be just over 1.5 m (5 ft) above the water level within the tub enclosure, which makes no sense. Nevertheless, the word “horizontal” is absent from this subsection, as well as subsection (D) on bonding, and the local authority must decide whether it should be inferred from the context. There is not any height limitation expressed either. The 3.7 m (12-ft) GFCI limitation in 680.43(B)(1)(a), and the same bonding limit in 680.26(B)(7) Exception No. 3 suggest that dimension as a reasonable limit. In addition, 680.43(A)(1) uses the phrase “measured horizontally” in the rule on receptacle placements.

Part (C) covers the methods of bonding. The bonding methods are similar for conventional and therapeutic tubs, but not identical. Both types of spas and tubs recognize the continuity of threaded metal piping entering a mated fitting. Both types also allow for metal-to-metal mounting on a common base or frame, just as for outdoor spas and hot tubs. Only therapeutic tubs, however, recognize “suitable metal clamps” for bonding. This may be a distinction without any practical difference, since metal-to-metal connections to a frame are recognized. Both types also require solid 8 AWG copper as the minimum for a separate bonding conductor. The solid conductor has far greater inherent resistance to chemical attack.

Part (D) covers grounding, and requires that all electrical equipment within 1.5 m (5 ft) of the inside walls of the facility, and that all electrical equipment associated with the recirculation system, must be connected to the equipment grounding conductor. Note that [Chap. 6](#) rules cannot supersede rules in [Chap. 5](#). If a therapeutic tub is used for patient care in a health care facility, then the enhanced grounding requirements in 517.13 will apply. An insulated copper equipment grounding conductor must be run to the unit, and the enclosure or armor of the wiring method must independently qualify as an equipment grounding return path. This includes metal-clad, armored, or mineral insulated cables with the outer armor fully qualified as a grounding path, most rigid metallic raceways, and some flexible metallic raceways up to 1.8 m (6 ft) in length.

Portable equipment must comply with 250.114, which requires equipment grounding connections for some equipment, and also the possibility of double-insulated appliances that will not have the grounding connection.

Part (E) requires receptacles within a 1.83 m (6 ft) radius to be GFCI protected. Part (F) requires luminaires to be totally enclosed, but does not impose any GFCI requirements on the lighting.

680.70. General. Unlike other general statements for parts within Art. 680, this one covering hydromassage bathtubs does not bring in other parts of the article. On the contrary, it positions this part as a stand-alone part, and no other part of Art. 680 applies to this equipment.

680.71. Protection. Any hydromassage bathtub and its associated electrical equipment must be supplied by an individual branch circuit and the outlet must be protected by a GFCI that must be readily accessible. All receptacles within 1.5 m (5 ft) of the tub and rated 125 V and not over 30 A must have GFCI protection as well. Note that most such tubs go in bathrooms where all the receptacles will be GFCI protected anyway, but these tubs do show up in other areas, and additional receptacles in the vicinity of the tub will require GFCI protection.

It is quite common to place the GFCI protection for one of these tubs as a GFCI receptacle adjacent to the pump motor, which is accessible (assuming 680.73 is met) but rarely readily accessible. The readily accessible requirement, new in the 2008 **NEC**, will change this practice. In theory, it should be possible in some locations to provide an access panel that is so well made, with obvious handles and unlatching mechanisms, set to open into a completely open area, and so uncluttered behind it, that an untrained person using no tools can quickly remove the panel and immediately find and put hands on the receptacle. That is possible, subject to the inspector's judgment, but not likely. In reality, too many of these receptacle connections require a double-jointed midget with a mirror and a flashlight to find and reset. There are several good solutions to this. One is to use a GFCI circuit breaker, since the panelboard devices must be readily accessible. Another is to use a master-trip GFCI device, the so-called faceless GFCI that takes up one device gang and presents test and reset buttons but no receptacle slots. Remember that a remote GFCI feed through receptacle is not an option because, by virtue of its installation, the circuit it protects is no longer an individual branch circuit as this section requires.

680.72. Other Electric Equipment. Hydromassage bathtubs are not subject to the requirements for spas and hot tubs. Receptacles do not have to be at least 5 ft (1.5 m) from the tub's inside wall, and luminaires do not have to be mounted at least 7½ ft (2.3 m) above the tub's water level.

680.73. Accessibility. This rule reiterates the requirement of 110.26, but does so specifically directed to this equipment. Many hydromassage tub motors have been set behind tiled partitions for which there was no access whatsoever. Effective communication with the general contractor on this as well as many other issues is absolutely essential to the progress of work. In addition, if the hydromassage bathtub is cord-and-plug-connected to a supply receptacle accessible through a service opening, the receptacle must be installed so it is within 300 mm (1 ft) of the opening, and with its face in direct view. The substantiation pointed to the same issues discussed at 680.71 above. An electric appliance that is difficult to disconnect will likely be an appliance worked hot.

680.74. Bonding. Both the metal piping system and the metal parts in contact with the circulation system must be bonded together with an 8 AWG solid copper bonding conductor, connected to the bonding terminal on the motor. Metal wiring methods, exposed metal surfaces, and electrical devices and controls within a 5-ft limit (and not separated by a permanent barrier) whether or not part of the tub assembly join the list. There is a small parts exception, but an adjacent metal faceplate would be included. The 5-ft dimension applies "from the inside walls" and in this case the literal text applies by mentally taking a string that long and include anything it touches, up and out, as it is rotated around the perimeter of the tub. The result, significantly increased in the 2017 **NEC** and clearly based on

680.26(B)(7) for swimming pools, is plainly excessive. For a bathtub a better model might be the self-contained spa provisions in 680.42(B) that approximate a reaching exposure for someone in the tub, or even back to the 2014 edition, which put metal piping systems together with conductive surfaces in contact with the circulating water and called it a day. The principal reason for an equipotential grid is to mitigate a drowning hazard cause by disorientation from voltage gradients. That is a valid concern for a hot tub, but much less so here. Double-insulated motors are exempt from this requirement. However, the bonding conductor must be run to the pump location, long enough to bond a conventional, non-DI motor if one is purchased to replace the original. This is the same principle as that used in 680.26(A)(6)(a) for permanently installed pools. Note that the requirement is to bond piping systems. With today's increasing use of nonmetallic water piping systems there is frequently nothing to bond under the skirt anyway. A metal escutcheon around the faucet with no metal piping behind it is not a metal piping system. It is very possible that even with a motor with a bonding lug, there will be no opportunity to run a bonding conductor. A bond wire must bond at least two things, and increasingly, there is no second item requiring bonding. Neither is it required to run a bonding conductor to the panel or anywhere else. Refer to the bonding discussion at 680.26 for the reasons why this is so.

Part VIII. Electrically Powered Pool Lifts. This part, new with the 2017 NEC, addresses the increasing use of powered lifts, now often required by law for public pools, to allow disabled individuals to enjoy the water. They must be listed for the application in a swimming pool environment unless there are no issues in terms of exceeding the low-voltage contact limit. Lifts run on power circuits must have GFCI protection, and they must be connected to the bonding grid regardless of power source. Switches operating above the low-voltage contact limit must be separated 5 ft, or listed for a closer approach. Battery power lifts must indicate a specific reference and voltage rating, along with the wattage rating.

ARTICLE 682. NATURAL AND ARTIFICIALLY MADE BODIES OF WATER

682.1. Scope. This article, new in the 2005 NEC, provides the first systematic coverage of electrical installations in or adjacent to bodies of water that do not qualify under Art. 680, such as artificial water features as part of landscaping, aeration ponds and storm retention basins, and fish farms in artificial ponds. As defined, the water depths can vary seasonally or be controllable. The article also addresses wiring in natural bodies of water, such as submersible pump in a natural pond for irrigation or other reasons.

682.2. Definitions. Aside from the descriptions of the bodies of water, three definitions are essential to apply this article. The most important is the *electrical datum plane*, which is (oversimplified) basically the horizontal plane that is 600 mm (2 ft) above the highest normal water level, such as the highest high tide. It is not the height of some catastrophic flooding event, such as the level of the 200-year flood as may have been established for other regulatory purposes such as flood insurance boundaries. The actual definition is in four parts and is much more complicated, but this will usually work.

An *equipotential plane*, for the purposes of this article is an area where wire mesh or other conductive elements are on, within, or under a walk surface not more than 75 mm (3 in.) below the top surface, and these conductive elements are bonded to all metal structures and fixed nonelectrical equipment that may become energized, and connected to the electrical grounding system to prevent a

difference in voltage from developing within the plane.

The *shoreline* is the farthest extent of standing water under the applicable conditions that determine the electrical datum plane for the specified body of water.

682.10. Electrical Equipment and Transformers. This is a good example of how the electrical datum plane is used in this article. Here electrical equipment and transformers including their enclosures must be specifically approved for the intended location. Only enclosures that are identified by their manufacturer's published information as being suitable not just for a wet location, but rather for actual operation while submerged, can be used below the electrical datum plane, which is 2 ft above the normal high water mark.

682.11. Location of Service Equipment. This is a good example of where the shoreline definition is used. The service equipment for floating structures and submersible electrical equipment must be on land not closer than 1.5 m (5 ft) horizontally from the shoreline. The live parts must be elevated a minimum of 300 mm (12 in.) above the electrical datum plane, and there must be a shunt trip or equivalent arranged so the service disconnect will open if the water level reaches the height of the datum plane.

682.12. Electrical Connections. All electrical connections not intended for operation while submerged must be located at least 300 mm (12 in.) above the deck of a floating or fixed structure, but also, wherever located, not below the datum plane.

682.13. Wiring Methods and Installation. Liquidtight flexible metal conduit or liquidtight flexible nonmetallic conduit with approved fittings can be used for feeders and where flexible connections are required for services. Extra-hard-usage portable power cable listed for both wet locations and sunlight resistance is also permitted for a feeder or a branch circuit where flexibility is required. Other wiring methods, suitable for the location can be installed where flexibility is not required. Temporary wiring that meets the provisions in 590.4 can also be used.

682.14. Submersible or Floating Equipment Power Connections. Submersible and floating equipment must be cord-and-plug-connected, using extra-hard-usage cord, and with a "W" suffix. Note that this suffix, traditionally denoting water resistance, also guarantees, in accordance with Note 15 to Table 400.4, that the cord is sunlight-resistant. The plug and receptacle combination must be suitable for the location while in use. For the usual outdoor application, this would mean compliance with 406.9(B). In addition, the receptacle outlet must be on the load side of a disconnecting means such that the load can be deenergized without requiring the plug to be removed from the receptacle.

An exception applies to equipment anchored in place and incapable of routine movement by water currents or wind. This equipment can be connected (but does not need to be) through one of the [Chap. 3](#) wiring methods cited in 682.13, such as liquidtight flexible nonmetallic conduit.

As covered in (A), the receptacle disconnecting means (for cord-and-plug connections) and the equipment disconnecting means (for hard-wired equipment) must be a circuit breaker, switch, or both, or a molded case switch, and it must be specifically labeled to show exactly which receptacle or outlet it controls, reiterating 110.22(A).

Part (B) covers the disconnect locations. It must be readily accessible, on land, and within sight of but at least 1.5 m (5 ft) back from the shoreline, and not more than 750 mm (30 in.) from the receptacle it disconnects if applicable. It must be elevated at least 300 mm (12 in.) above the datum plane.

682.15. Ground-Fault Circuit Interrupter (GFCI) Protection. This covers 15-, 20-A 125- to 250-V receptacles that are outdoors, or if located in or on a floating building or a structure used for maintenance, storage, or repair. The rule applies to receptacles falling within the datum plane. GFCI protection must be provided for these outlets, with the protective device located at least 300 mm (1 ft) above the datum plane. As defined in 680.2, the datum plane is 600 mm (24 in.) above water level generally, and in the case of floating structures the plane is 750 mm (30 in.) above the water level and a minimum of 300 mm (12 in.) above the deck. The literal text of this section now imposes a GFCI requirement on all 15- and 20-amp 125- and 250-V receptacles installed outdoors and within the datum plane, which includes floating buildings. Article 553 has no such requirement, and in the absence of any mention, this rule will apply to floating buildings generally.

682.30. Grounding. This section brings over rules from Arts. 553 (floating buildings) and 555 (marinas and boatyards), specifically 555.15. The 555.15 reference includes unremarkable, well known grounding rules, with one major exception, found in 555.15(B). Due to the corrosive effects of a marine environment, metallic raceways are not permitted to be relied on as equipment grounding conductors, and must, where used, be backed up by separate equipment grounding conductors, sized per Table 250.122 and [per 555.15(C)] not smaller than 12 AWG. The rules in Part III of Art. 553 contribute a requirement (from 553.11) that all metal parts in contact with water and any metal piping, as well as the usual metal parts that may become energized, must be connected to the equipment grounding system. No cross connections between neutral conductors and equipment grounding conductors are permitted, courtesy of 553.9.

682.31. Equipment Grounding Conductors. These rules are obvious and are taken from 555.15(C), 555.15(D), 555.15(E), and 553.10(B), as already incorporated by reference in the prior section.

682.32. Bonding of Noncurrent-Carrying Metal Parts. This is taken from 553.11 (see above).

682.33. Equipotential Planes and Bonding of Equipotential Planes. This, start to finish, is critical information that breaks new ground. Much of this, although used in the NESC for utility work, is without precedent in the **NEC**. Review the definition in 682.2 before beginning. The section begins with the basic requirement to install such a plane as set forth in this section to mitigate “step and touch voltages” at electrical equipment. These terms are not defined in the **NEC**, but they are in the IEEE dictionary, as follows:

The *step voltage* is the potential difference between two points on the earth’s surface separated by a distance of one pace (assumed to be one meter) in the direction of maximum potential gradient. This potential difference could be dangerous when current flows through the earth or material upon which a worker is standing, particularly under fault conditions.

The *touch voltage* is the potential difference between a grounded metallic structure and a point on the earth’s surface separated by a distance equal to the normal maximum reach, approximately one meter. This potential difference could be dangerous and could result from induction or fault conditions, or both.

Part (A) requires an equipotential plane to be installed at the service equipment if outdoors, and (assuming access to personnel is provided) at metallic outdoor enclosures for disconnecting means that are likely to become energized and that control equipment in or on the water. The equipotential

plane must begin below the equipment and extend outwards not less than 900 mm (3 ft) in all directions from which one could come in contact with the equipment.

Part (B) covers where the planes are not required, specifically, at the equipment supplied and disconnected by the items specified in Part (A). However, all circuits rated 120 V through 250 V, single phase, equal to or less than 60 A, must have GFCI protection. Note that this is a circuit requirement, so point-of-use GFCI devices, such as GFCI receptacles, will not comply with this requirement.

Part (C) requires the equipotential planes to be bonded to the local grounding system, as also covered in the definition. The bonding conductor(s) must be solid copper, no smaller than 8 AWG, and the connections must be either exothermically welded or made up using copper, brass, or bronze, or stainless steel parts listed for the condition and application. Such connectors will be marked “DB” or “direct burial.”

ARTICLE 685. INTEGRATED ELECTRICAL SYSTEMS

685.1. Scope. This covers a unitized segment of an industrial process and the attendant electrical system that is under highly qualified supervision and maintenance, and for which an orderly shutdown is essential to minimize hazards to personnel and damage to equipment. These issues arise at nuclear facilities and in the chemical process industries. As itemized in **Table 685.3**, many other Code articles have orderly shutdown allowances built into their provisions, and these are incorporated to the extent relevant for any particular application.

685.10. Location of Overcurrent Devices in or on Premises. This rule varies the customary readily accessible requirements and permits overcurrent devices to be out of reach, in elevated locations where they will not be casually operated by unqualified personnel.

The final two sections permit the use of ungrounded circuits, both two-wire dc circuits and 150 V or lesser control circuits from a separately derived system, as required for operational continuity. Note that the rule in 250.21(B) is not varied here, so ground detectors would be required on the ungrounded ac circuits.

ARTICLE 690. SOLAR PHOTOVOLTAIC (PV) SYSTEMS

690.1. Scope. This complete, detailed article covers this developing technology for direct conversion of the sun’s light into electric power. Large-scale PV systems are now (2017 NEC) covered by Art. 691. For that reason most of the medium voltage requirements for PV systems are no longer included in this article.

690.2. Definitions. Solar photovoltaic sources require the collection of solar energy in equipment that can convert it to electricity. A group of *cells*, the base unit of solar production is put together by their manufacturer into *modules*, which are defined as a complete, environmentally protected unit capable of producing power when exposed to sunlight. As a practical matter, modules are usually assembled into *panels*, which are grouped sets of modules that are wired together to make a field installable entity. Multiple panels can be ganged in the field on framing to comprise the *array* that becomes the dc power production source for the occupancy. [Figure 690-1](#) shows four modules in

each of six panels to make up an array that is making power that is being used to offset energy that would otherwise have been purchased from a utility.

PV Array

Service

Metal raceway or Type MC cable Requirements in 690.31:

PV output circuits must be divorced from all other circuits and identified at all connections, including by system if more than one. Flexible wiring in attics to use protective guard strips. Specified high-contrast labels required.

Disconnect, OCPD must have full DC ratings (typ. 600V)

Rapid shutdown: switch: 690.12(C) label: 690.56(C)(3)

TL

Field Label

Max. system voltage [per 690.7(A)]
Short-circuit current [per 690.8(A)]

GFP & functional ground connections here 690.42 & 690.47(A) 3rd¶

DC AFCI protection (per 690.11)

SOLAR

INVERTER

Rapid shutdown label per 690.56(C)(1)(b), not over 3 ft from service

Utility-interactive Interconnection:

Location: opposite end of bus
Rating: Main + PV input \leq 120% of bus
Warning label against repositioning required [assuming 705.12(B)(2)(3)(b) applied]

Ground

PV output meter (if required or desired)

Inverter EGC is PV system ground 690.47(A) 3rd¶

Fig. 690-1. An interactive system involves many **NEC** rules (see text). (Adapted from *Practical Electrical Wiring*, 22nd ed., © Park Publishing, 2014, all rights reserved.)

The wiring between the modules and the common dc connection point attached at the left of the array in [Fig. 690-1](#) is *photovoltaic source circuits*, and the dc wiring from that point to the dc utilization equipment (if any) and to the inverter (if used, true in this case) is the *photovoltaic output circuit*.

A very important definition, describing a new term as of the 2017 **NEC**, is a *functional grounded PV system*. This is a system with an electrical reference to ground, but that is not solidly grounded. The informational note following explains that the functional connection will be through a variety of devices ([Fig. 690-2](#) shows a fused connection) that result in the designated side of the system being at ground potential during normal operation, but likely at some voltage above ground during a fault condition.

Fig. 690-2. The black cylinder at the lower left is a fuseholder containing a small fuse (likely 0.5 or 1.0 amp.) inserted between the negative vertical (black) wire and the system grounding connection wire (green) leaving the fuseholder skirt at a 30 deg. angle upwards to the right. Note that some of the negative array conductors entering from below use white insulation. This wire color was permitted at the time the photo was taken, but now violates 690.31(B)(1). Courtesy, Solar Design Associates, Inc.

This change, rather ingenious in its wording, is easily the most important in the entire article and one of the most important in the 2017 **NEC** cycle. It enables all PV systems to share a common topology. The article no longer refers to grounded and ungrounded systems. Most are all wired the same way. In fact, the overwhelming majority of **NEC** systems have been wired under this protocol for some time. For just one example, any system wired in accordance with the ground fault provisions of the former 690.5 [now moved into 690.41(B)] was, and still is, one of these systems because one of its poles is connected to ground through a small overcurrent device. European standards have been arranged in this manner for some time.

690.4. General Requirements. Part (B) requires the equipment doing the heavy lifting in PV

work, including the modules and panels, the combiner equipment, and inverters, be listed or field labeled for the application. Note that PV has many applications beyond **NEC** work, and some listings may not be relevant to premises wiring work governed by its provisions.

Part **(C)** requires that PV systems be installed by qualified persons. This work is becoming increasingly specialized, and just as in the case of medium-voltage splicing, specialized training beyond generic trade licensure is a necessary part of the work.

Part **(D)** permits the installation of multiple PV systems. If they are remote from each other, the reciprocal signage required by 705.10 must be provided at their disconnecting means. This will augment the labeling already required by 230.2(E), that provides information regarding other inverter locations.

Part **(E)** prohibits PV system equipment and disconnecting means in bathrooms.

690.6. Alternating-Current (ac) Modules. These modules have inverters built in, and their output is classified in Part **(B)** as an inverter output circuit. The former provision for ac ground-fault detection has been removed as of the 2014 **NEC** because no products are available to meet the requirement and conventional GFCI devices were being misapplied for this purpose.

690.7. Maximum Voltage. This section begins by defining the maximum voltage of PV systems in much the same way as in Art. 100 for conventional ac systems, but without the need for rms allowances. It is the highest potential difference (expressed as voltage) between two circuit conductors, or between any one conductor and ground. The section also limits the PV output circuit voltage in one- and two-family dwellings to 600 V dc. Other occupancies are limited to 1000 V dc. The parent language then concludes with an interesting sentence that does not actually address maximum voltage but does make a [Chap. 6](#) amendment of [Chap. 4](#) provisions, by excluding the rules in Art. 490 addressing the majority of medium voltage equipment, switchgear, industrial control assemblies, and substations (all of Parts II and III) from applicability to the listed dc equipment operating at 1500 V or less. This is perfectly appropriate given both the listing requirement and the comparatively limited range of voltage excluded.

Part **(A)** addresses the rating of PV source and output circuits. Modules are rated under standardized laboratory conditions at moderate temperatures. The photochemistry of the crystalline forms of silicon is such that under conditions of constant irradiance, the voltage increases as the temperature drops. For **NEC** application purposes, at a temperature of about -40°C or $^{\circ}\text{F}$ (the temperature scales cross at this point) is generally considered the worst case, and at this temperature the open circuit voltage put out by a photocell is about 125 percent of its rated voltage. For areas with other design temperature minimums, the table factors can be used accordingly. However, the 125 percent factor is the one usually applied. If the module comes with directions to use different adjustments, then those directions trump the numbers in Table 690.7. Looking at [Fig. 690-1](#), the open-circuit rated voltage on a module is given as 64 V. The panel with four modules wired in series will generate 256 V under test conditions. However, applying the 125 percent factor gives a final result of 320 V, and that becomes the voltage rating of the PV output circuit derived from this system. An informational note points to an ASHRAE publication that is useful in determining the extreme cold weather temperature that would be applicable in any locality. Large scale PV systems (≥ 100 kW) qualify for an evaluation of voltage by a licensed PE, presumably using the standard covered in the informational note. The maximum voltage is what will be carried forward to determine the minimum voltage ratings of system components. The process as described in published literature anticipates the

use of computer modeling and significantly increased accuracy.

Part **(B)** covers dc-to-dc converters, capable of changing voltages and thus doing for dc what transformers have done for ac since the days of Tesla. For a single converter the maximum voltage is simply its maximum rated output. However, two of these devices can be series connected in concert with any directions to this end that have been made part of the listing process, and those directions will establish the total maximum voltage. In the event such documentation is unavailable, then the maximum voltage is the arithmetic sum of the two maximum voltages at hand.

Part **(C)** covers bipolar source and output circuits. The maximum voltage is taken as the voltage between the two wires that run from each monopole subarray and not the combined voltage that results from the connections made in the inverter. See 690.31(I) for more information.

690.8. Circuit Sizing and Current. Just as voltage is determined under standard conditions that do not always reflect field conditions, the same is true for current ratings on modules. In this case maximum conditions of solar irradiance for the period running about 2 hours on either side of solar noon can exceed rated current output by, and the recurrence of this number yet again is an extraordinary coincidence, 125 percent. Therefore, this factor must always be applied to rated current outputs on modules. Referring to [Fig. 690-1](#), the short-circuit current rating on the modules is given as 5.4 A. The panels are wired in series, so no change in current there. However the array has six panels wired in parallel [see Part **(A)(2)**], for a total of 32.4 A under test conditions. However, by this rule, this number must be increased by a 125 percent factor, with a resulting current for **NEC** purposes of 41A. Similar to the maximum voltage calculations in 690.7(A)(3), large scale PV systems (≥ 100 kW) qualify for an evaluation of current by a licensed PE, presumably using the standard covered in the informational note. The maximum current is what will be carried forward to determine the amperage ratings of system components. Note, however, that the engineered result must not be taken as less than 70 percent of the traditional calculation.

Part **(A)(3)** requires that the inverter continuous output current rating be taken as the maximum rated output of the inverter, or as in [Fig. 690-3](#) inverters, regardless of whether the array size is capable of delivering that much energy to the inverter. In this case a 5 kW inverter operating on a 240 V circuit will be calculated as $5000 \div 240 = 21$ A in output current. Part **(A)(5)** makes a similar requirement for dc-to-dc converters, and Part **(A)(6)** sums those results when they are connected in parallel. Part **(A)(4)** reflects the fact that stand-alone units are constant power devices that increase current when battery voltage declines.

Fig. 690-3. Six string inverters with their ac outputs combined at junction boxes into two feeders, sized in accordance with the sum of the continuous output current ratings comprising their supply, and increased by 25 percent for continuous duty as required by 690.9(B)(1) and 215.2(A)(1)(a). Courtesy, Solar Design Associates, Inc.

Part **(B)** reflects the fact that under worst (best?) case conditions sunlight is a continuous phenomenon, and that therefore the circuit rating calculated in (A)(1) must be viewed as a continuous load. For conventional overcurrent devices, the result is another 125 percent multiplier, and for the array in [Fig. 690-1](#), that is $41 \text{ A} \times 1.25 = 51 \text{ A}$. The other two paragraphs remind users of the special sizing rules regarding the next higher standard sizing and small conductors, along with UL guide card information about operating circuit breakers in high- temperature ambients. The second numbered topic in (B) also governs conductor ampacity. Once again start with a 125 percent factor for temperature, increase it again for continuous loading because that extra size will be needed as a heat sink when it arrives at a device, but compare that with the size developed from the conditions of use. Some design temperature allowances for array wiring anticipate a 70°C ambient, and after that is factored in, the wire may be larger than it is for continuous loading. And at the end of the process, make sure the overcurrent device protects the wire after all has been said and done.

Part **(3)** recognizes adjustable electronic trip circuit breakers with settings that can match the steps in 240.6, and that are rated for direct current. They do not require the 125 percent factor to be added, and therefore it need not be factored in to a conductor ampacity calculation where these devices are in use.

690.9. Overcurrent Protection. PV circuits are normally required to have overcurrent

protection per Art. 240, with an allowance for conditions where the conductor could not be overloaded even if short-circuited due to the inherent lack of capacity in the system. These devices must now be listed for use in PV systems. Therefore the former separate rule requiring dc ratings has been discontinued because it is inherent to the PV listing. They need to be accessible but not readily accessible. These rules accommodate placements at the array in the form of fuses or circuit breakers, and this location will be required by the terms of the final sentence of 690.9(A) in the majority of cases. They are available in a wide variety of sizes for these applications. In Fig. 690-1, the current determined by 8(A)(1)— $5.4 \text{ A} \times 1.25 = 6.75 \text{ A}$ is then increased by 125 percent per (9)(B): $6.75 \text{ A} \times 1.25 = 8.4 \text{ A}$. The likely next higher available size is a 9-A device, so that is what would be used. Note that (9)(B)(3) correlates with (8)(B)(3) to recognize the adjustable electronic trip devices that, if used, could moderate this calculation.

Note that this fuse will require an acceptable fault clearing rating on a dc circuit. In the case of Fig. 690-1, the fault current is minimal because there are no batteries in the system. However, if there were standby batteries with thousands of amperes available to a fault, a calculation would need to be done as to the available current after the length of the circuit between battery and fuse is considered. Current-limiting fuses can also be installed on the battery connections that have a let-through low enough to coordinate with the fuses at the array. DC ratings on overcurrent devices significantly differ from their ac ratings because a dc circuit with no natural current zero is more difficult to interrupt, and this equipment must be listed for the dc duty that will be required.

Part (C) takes this one step further and requires a specific listing for PV use with respect to overcurrent devices provided for PV source and output circuits. A single device is an option to protect multiple module conductors. However this protection is configured, either all positive conductors, or all negative conductors of a PV system must be protected. Either side can be protected, and the protected side must always be the same polarity throughout the entire system. Disconnecting means, however, must open both sides (690.15). These devices are typically placed near the array, and as such they are subject to wide variations in current draw, ambient temperature, high open-circuit voltages, etc. Product standards are now in place to enable such listings. This provision, rewritten in the 2014 **NEC**, no longer permits the use of supplemental overcurrent devices in 1-A increments for this purpose. Choose from among the large numbers of fully PV-rated overcurrent devices now available to provide this protection.

690.11. Arc-Fault Circuit Protection (Direct Current). PV systems with dc source circuits or output circuits or a combination of both operating (maximum voltage) at or above 80 V must have listed dc arc-fault protection or equivalent. As of the 2014 **NEC** this requirement applies generally and not just to wiring on or penetrating a building. The protective device(s) must respond to any continuity failure and interrupt arcing faults. If it operates, that fact must display at an annunciator. Both the annunciator and the system device must not reset automatically. The product standard is now published and products are available for this function. The fact that this article now uses a common functional grounding topology will continue to assist the development of this technology, which generally relies on a device placed between one of the circuit conductors and ground. The listed combiner box shown in Fig. 690-5 includes this functionality. This is a good example of equipment that can be installed in multiple, thereby mitigating the amount of power reduction in the event of a failure.

An exception, new as of the 2017 **NEC**, does waive the requirement in instances where there would be little practical advantage in applying it. Specifically, PV systems not located on buildings,

and that in addition have no system components that enter buildings, are exempt. In addition there are restrictive wiring method limitations. The exception only applies to output circuits run in metal raceways, or enclosed metal cable trays, or “directly buried.” This raises the important question as to whether the exception is voided if the wiring is in PVC conduit run underground. On the one hand, such wiring is not, strictly speaking, “directly buried.” On the other hand, the PVC conduit in this instance would be directly buried, and little seems to be gained by disallowing it. This will need to be resolved in the next code cycle. The exception also clarifies that wiring entering a utility building with no function other than to house PV equipment does not void the exception.

690.12. Rapid Shutdown of PV Systems on Buildings. This is the “rapid shutdown” section. In effect, PV system circuits on or within buildings must be capable of quickly and dramatically limiting their voltage, regardless of how bright the sun is shining, upon the command of a first-responder seeking access to the vicinity of an array for fire-fighting activities. This is proving to be one of the most technically demanding tasks of electrical standards writing. Everyone agrees on the objective, but the fact that the continuing source of power (sun) is beyond the reach of human intervention complicates the task. Note that the location aspect of the rule applies to “system circuits” and not just to the arrays. This means that a ground-mounted array that extends circuits to a building [see also (A) and the exception] will be usually be subject to the requirements.

Remember that the sun is still shining on the installed array, constantly generating voltage at all times during the day. To completely shutdown every element of a PV array is extremely challenging. To make the project manageable based on the current state of technology, Part (B) divides the implementation of rapid shutdown requirements into two separate zones based on a new concept the NEC refers to as the “array boundary.” Wiring is inside this boundary if it is closer than one foot from the array in any direction, including downwards into, or even through the roof into the space below depending on construction and array separation distances. The definition clearly includes the supports, so the array boundary will almost always penetrate the roof to some degree. Conductors outside the array boundary, and more than 3 ft from an entry point into a building must respond to a rapid shutdown command sequence by falling to 30 V or less (line-to-line or line-to ground) within 30 seconds of the control activation. In fact the 3-ft limitation is to prevent someone from hugging the roof sheathing on the attic side and claiming to have not left the 1-ft halo. This technology is available and no implementation delay will be needed.

The actual PV arrays and associated wiring harnesses, etc. fall on the inside of the array boundary, and controlling what happens here, with the sun out, requires significant additional engineering and product standards work. For this reason a two-year delay, until Jan. 1, 2019 applies to this portion of the rapid shutdown provisions. There are three options, all of which have the two-year window before becoming mandatory. The first is to use a PV array that is either listed or field evaluated and labeled as a “rapid shutdown PV array.” These would consist of arrays equipped with control features that allow them to respond, at the array, to a shutdown control command. An elaborate informational note at this point provides useful information regarding the anticipated design features that may be involved as the technology evolves. The second option is to install control equipment that can be placed at the array location and that will result in the voltage decreasing to 80 volts within 30 seconds of a shutdown being initiated. The third option involves the creation of what might be described as double-insulated PV arrays, that is arrays that are nonmetallic with no exposed wiring methods or other conductive parts, and positioned over 8 ft from any exposed conductive parts, or the earth. Any arrays meeting these requirements would be exempt from the entire rapid shutdown

requirements, because they would not present any issues to first responders.

Part (C) covers the initiation device(s) for the procedure, which must be indicating. An “OFF” indication denotes a command procedure is in effect. The initiating device must consist of at least one of three options (more than one is permitted), beginning with the service disconnect. Also included is the PV system disconnecting means (690.13), and also a readily accessible switch intended for this function and so marked. An informational note correctly explains that this would be appropriate if an Article 702 standby system was in place that would keep premises loads energized regardless of the status of utility power. Whatever option is used, the switch(es) that actually invoke a rapid shutdown must comply with the marking requirements in 690.56(C). If there are multiple PV systems, then the shutdown devices must not number more than six, be grouped, and if auxiliary devices come into play, they must also control all PV systems involved with that service and having rapid shutdown provisions.

Part (D) requires equipment that performs the shutdown function, other than the simple initiation sequence, be listed for that purpose. An informational note advises that inverters not designed for this function often keep the energized input conductors energized for up to 5 minutes, far longer than the shutdown provisions in this section permit.

690.13. Figure 690-4 shows the system disconnect for a system equipped with module-level microinverters. This system, far more expensive than a conventional system, is capable of discontinuing power at the module when the switch is OPEN. Remember a conventional inverter will shut down when it loses access to utility power, and these do the same. This means that this particular installation effectively meets the performance objectives of 690.12(B)(2) already. It offers improved function in terms of shadow tolerance; the effect of a shadow of a branch will have far less impact on the array output as a whole than would occur on a conventional string. It also offers benefits in terms of avoiding problems of module mismatch and unbalanced numbers of module connections in a given area.

Fig. 690-4. The switch (shown in the open position) is the PV system disconnecting means. The utility (in this jurisdiction) required an open blade, outside mounted switch, connected ahead of the service equipment [permitted by 230.82(6)]. The switch is also wired as the rapid shutdown initiation device. Although installed under the 2014 **NEC**, the labeling largely meets the intent of 690.56(C) (3), although it misses the $\frac{3}{8}$ -in. height rule. The labeling does comply with the 2017 **NEC** with respect to its system disconnecting function [690.13(B)]. Courtesy, Solar Design Associates, Inc.

Photovoltaic System Disconnecting Means. The PV system, at a readily accessible location (A), must be fully disconnectable from all other premises wiring components, including energy storage systems, standby power sources, utility power, etc. This switch is intended to provide for safe servicing procedures on the PV system. It is not intended to limit the exposure of the building to energized conductors, and therefore there is no longer any proximity provision relative to the entry point of the conductors attached to this requirement. As explained in the informational note, if there is an emergency, there is now a rapid shutdown procedure to address it. Part (B) adds an advisory marking label to the switch (Fig. 690-4) that voltage may be present on all terminals when the switch is in the open position. If the switch is placed on the line side of the service, as permitted in 230.82(6), Part (C) requires that it must be suitable for use as service equipment. *BE CAREFUL:*

This rule addresses certain construction features of the switch, and does not make it service equipment. The reference to 230.82 necessarily places it on the line side of the service equipment, and 230.40 Exception No. 5 recognizes these connections as well. It does not need to be grouped with the premises service equipment. The requirements in 705.31 govern the distance and protection requirements for this wiring where it is connected in this way.

As covered in Part **(D)**, each PV system requires a disconnect, which can consist of up to six switches, etc. Do not confuse this with a limitation on how many PV set-ups can be installed, which is unlimited. The informational note makes clear that multiple inverter outputs can be combined into a single PV system disconnecting means and input to the electrical system. Any such disconnect **(E)** must have a rating that corresponds to its application, and for dc applications **(F)** it must have operating poles both conductors, marked for PV use, or suitable for backfeed.

690.15. Disconnection of Photovoltaic Equipment. Isolating devices must be provided for disconnecting inverters, charge controllers, etc., from all conductors that are not solidly grounded, and for a functionally grounded PV system, neither conductor is solidly grounded. For dc combiner outputs, or for charge controller or inverter inputs, a disconnect is mandatory if the current will exceed 30 amp. If energy comes from more than one source, then those disconnects must be grouped and identified. In [Fig. 690-1](#), this applies to the inverter, which is why the dc disconnects to the left of the inverter and the circuit breaker to the right must be adjacent to the inverter, or additional disconnect(s) would need to be provided.

Part **(A)** locates equipment disconnects either within the equipment or in sight and not over 10 ft away, with an allowance for a locally mounted remote trip provision for a more distant disconnect. Figure 690-5 shows a dc combiner box with an integrated ac-to-dc power supply at the upper left. The door handle mechanism includes on-off-test switch function and interfaces with the contact block at the center right. The AFCI detection contactor, connected to the main positive busbar of the combiner, opens if the switch is open or if an arc fault is detected. Each source circuit is wired through a current sensor, monitored by the AFCI detection system.

Fig. 690-5. PV equipment disconnection as a part of a dc AFCI combiner box wired under the 2014 NEC. This integral disconnection function meets 690.15(A) on the positive side, but not on the negative side. Because the negative input conductors are not to be considered solidly grounded, this equipment may require redesign for the 2017 edition, and may be a candidate for acceptance by early adopting jurisdictions under 90.4 (3rd ¶). Courtesy, Solar Design Associates, Inc.

Part (B) assures the appropriate interrupting rating, however, a device that will not be used to actually open the circuit under load does not require that rating.

Part (C) covers the various isolating devices for system components. If not designed to open under load, it must be marked accordingly.

Part (D) includes the essential equipment characteristics for this equipment, including simultaneous operation of poles, indication, externally operable, and lockable. Other than connectors (690.33), if both sides are energized in the OPEN position, the warning in 690.13(B) must be provided.

690.31. Methods Permitted. In general, [Chap. 3](#) wiring methods are permitted. In addition, wiring that is nonstandard but part of a listed system is permitted. In the event that PV source or output circuits in readily accessible locations are operating above 30 V, they must be guarded or installed in Type MC cable or a raceway. This would include, on the literal text, MC cable run in accordance with 690.31(G), which probably results from an unintentional failure to correlate this wording and the express permission in the other section. In the general context of Part (A), there are some general wiring issues to explore in this context, one being substantially elevated ambient temperatures, which is a major concern. All wiring terminating on or running with a PV array should be assumed to be operating in a 70°C ambient temperature or higher due to solar heating. This means that the wiring (and any nonmetallic raceway if used) must have a minimum temperature rating of 90°C as a practical matter, and that the effects of temperature on final conductor ampacity will be pronounced. For example, 12 AWG THWN-2, a 90°C conductor with a Table 310.15(B)(16) ampacity of 30 A would end up with (using a 0.58 derating factor) a final ampacity of 17.4 A or even 12.3 A if a higher temperature were assumed. Looking at [Fig. 690-1](#), the wiring between the PV source and the inverter is a feeder for a separately derived system and follows normal rules for sizing, although, depending on how it is routed, temperature may have an important impact. These applications often involve high temperature ambients, for which ampacities require often substantial correction from basic table values. The table provided matches the one in 310.15(B)(2)(a) except a 105°C column is added.

As we have seen, each of the six strings generates 6.75 A, resulting in a total array load of 41 A. Since these wires will be connected to an overcurrent device and switch terminals, and transmit continuous loads, we need to add 25 percent of this number to determine conductor sizes. The minimum ampacity of the feeder conductors would be 125 percent of 41 or 51 A. This corresponds to 6 AWG copper conductors, evaluated under the 75°C column of Table 310.15(B)(16). If these feeder conductors were routed along the array the evaluation would change, because ambient temperature would become a major factor. In such a case (assuming 70°C conditions) the derating factor to be applied to THWN-2 conductors is 0.58. The actual value of maximum continuous current is used here, or 41 A. $41 \text{ A} \div 0.58 = 71 \text{ A}$. Since this is less than the ampacity (in the 90°C column) of these conductors, the 6 AWG conductors can still be used, but the result is far closer to the table limits. Refer to [Chap. 9](#), Annex D, Example D3(a) for a comprehensive explanation of these considerations.

Part (B) requires that photovoltaic source and output circuits, including inverter output circuits, must be divorced from other systems, unless partitioned off, or unless connected together, such as at a common piece of equipment. It also requires PV system conductors to be identified and grouped in several ways. First, PV system circuits must be identified at connections and splices. Because functionally grounded conductors are not solidly grounded, this section [in (B)(1)] now explicitly prohibits them from using white insulation or otherwise using an identification method reserved for truly grounded circuit conductors, as covered in 200.6 Next, if there are multiple PV systems on the premises, and the conductors that are part of more than one such system enter a common enclosure or raceway, the wiring must be identifiable by system at all connections and splices unless the identification is self-evident because of unique entry and exit points, arrangement within the enclosure, or other factors. These identification requirements can be met through tags, marking tape, or other approved means.

Finally, if multiple PV systems occupy a common wireway or box or other wiring method with a removable cover, the wiring must be discernible by both systems and, if both current types are

present, by type of current (ac or dc). This grouping must be by wire ties or equal and take place at least once and then at intervals not to exceed 1.8 m (6 ft), unless the entry is from a unique cable or raceway that makes this grouping obvious. Note that any wireway of a length long enough to invoke the 1.8-m (6-ft) marking requirement is probably one for which a unique entry point would be lost in the middle and therefore no longer obvious.

Part (C) addresses single-conductor cable. Effective as of the 2008 **NEC**, unless conventional multiconductor wiring methods are used, module and panel interconnections must use either single-conductor Type USE-2 cable or the new Type PV (photovoltaic) single conductor wire in exposed outdoor locations for PV source circuits and interconnections; the previous allowance for Types UF, SE, and USE was discontinued. Do not use welding cable. (See commentary at the end of Art. 630 for the UL information on this point.) Note that USE-2 wire must not be used inside a building unless it is dual rated as building wire, as shown by an additional marking of XHHW-2 or RHW-2 or comparable. Note also that the new Type PV conductors have a thicker than usual insulation, and as such require special raceway fill calculations if pulled into a raceway.

Type PV or USE-2 single conductors routed on structures (see [Fig. 690-6](#)) must comply, as of the 2017 **NEC**, with the support distances for NM cable (334.30), certainly met in this case. However, this rule now also references 338.10(B)(4)(b), which includes 334.30 anyway, and which would automatically apply to USE-2 in any event. This does additionally bring in all of Art. 225 Part I, including the requirement of 225.10 to use one of the specified [Chap. 3](#) wiring methods. There is no comparable wiring method on the list; open wiring on insulators is the closest match but it is limited to industrial and agricultural occupancies. Even there, it is a poor match for conventional practice on solar arrays because, historically, it is an antiquated wiring method designed for timber frame buildings. This rule will require careful discussion with the inspector. A sound approach would be to argue that the wording “permitted in exposed outdoor locations ... within the array” constitutes a [Chap. 6](#) amendment of Art. 225.

Fig. 690-6. Single conductors run on structures must comply with Type NM cable support distances

[690.31(C)]. The installation pictured is only accessible to qualified persons. Courtesy, Solar Design Associates, Inc.

These wires have 90°C temperature ratings and tolerate sunlight and wet-location exposure, and they can be connected to the positive and negative leads coming from the modules. However, if the array is readily accessible to passersby, the conductors must usually run within a raceway, as covered in **(A)**. Single-conductor entries into a pull box must have strain relief provided, such as through listed gland-type connectors that maintain the wet-location integrity of the box. Leave enough slack in the module leads so the module can be removed for servicing or replacement. PV source and output circuits are also permitted in outdoor locations to run in cable tray whether or not they carry the CT mark for that purpose. They must be secured not less than every 4½ ft and for ladder tray, the rung spacing must not exceed 12 in. This provision will probably find significant application in industrial occupancies with large solar arrays.

Part **(D)** allows any jacketed multiconductor cable assembly “listed and identified” for the location to be used outdoors to carry PV inverter output circuits from utility-interactive inverters located where they are not readily accessible. It must be secured every 6 ft and include an equipment grounding conductor.

Part **(E)** covers flexible cord for the moving parts of tracking PV equipment, provided the cord meets the ampacity limitations for the high ambient temperatures usually applicable to these applications. A special temperature correction table is available for this purpose, with a 105°C column for cords so rated.

Part (G) is a very extensively used provision that provides a method of routing PV output circuits indoors from a rooftop without providing an additional disconnecting means. The entry point can be remote from its disconnect, thereby allowing the inverter disconnect to serve both functions, provided the wiring between the point of entry and the disconnect is in a metal raceway, such as EMT, or Type MC cable, as of the 2011 **NEC**. This is now less important than in the past, because the shift to functional grounding and the implementation of rapid shutdown provisions have led to the result that the rule requiring protection near the point of conductor entry into the building envelope was no longer valid, and has been removed. See 690.13(A) and the clarifying informational note. However, that note to the contrary notwithstanding, 690.31(A) still asks for raceway or MC cable, which is consistent with this requirement.

Part **(1)** covers PV source or output circuits actually running within a built-up roof surface. Their location, if not “covered by PV modules and associated equipment,” must be evident to a firefighter attempting to ventilate an attic during a fire. This presents a real challenge as far as durability in the presence of UV radiation and precipitation; since there is no current listing category the only possible acceptance criterion at this time is approval by the AHJ.

Additional requirements in paragraph **(2)** apply to Type MC cable and greenfield, and perhaps liquidtight flexible metal conduit although that is not mentioned. If the greenfield is not over metric designator 16 (trade size ½) and if the MC cable is smaller than 25 mm (1 in.) in diameter, then it must be protected by guard strips not less than the cable size where it crosses joists. Note that the size limits in the **NEC** text are not to be equalled dimensions, as opposed to the more usual not be exceeded specifications. Other than that they must follow framing or building surfaces; there is no permission for drilling the centers of framing, other than the alternative for an approved protection scheme, so that could be an area for discussion with the inspector as well.

The PV wiring method, if exposed, must be labeled as such, every 3 m (10 ft) for continuous runs and at least once in shorter runs between vertical or horizontal partitions. In addition, box and other enclosure covers, and even the covers of conduit bodies with an unused hub get the same marking. Parts **(3)** and **(4)** are new for the 2014 **NEC** that is extremely prescriptive labeling information for the required labels. They must be reflective, in all capital letters at least $\frac{3}{8}$ in. high, and done with white printing on a red background. The label must read “WARNING: PHOTOVOLTAIC POWER SOURCE.” It will be interesting to see just how long such labels will stick to MC cable with an interlocking armor.

Part **(H)**, new as of the 2008 **NEC**, addresses fine-stranding. Since the topic has been generically addressed in 110.14, this paragraph now simply refers to that location. Refer to the commentary at 110.14 in [Chap. 1](#) for more information on this point.

Part **(I)** covers bipolar PV systems. If the total open-circuit voltage of the monopole subarrays ([Fig. 690-7](#)) exceeds system parameters (typically 600 V), then the two monopole outputs must be physically separated into separate raceways that go all the way to the inverter, with separate disconnects at the inverter. If the inverter is listed for the total open-circuit voltage and has an internal barrier, then the two raceways may land at the inverter. If the positive and negative conductors from the two subarrays come into contact, the full open-circuit voltage will appear across circuit components that cannot handle that exposure. Actual fires have resulted from these occurrences.

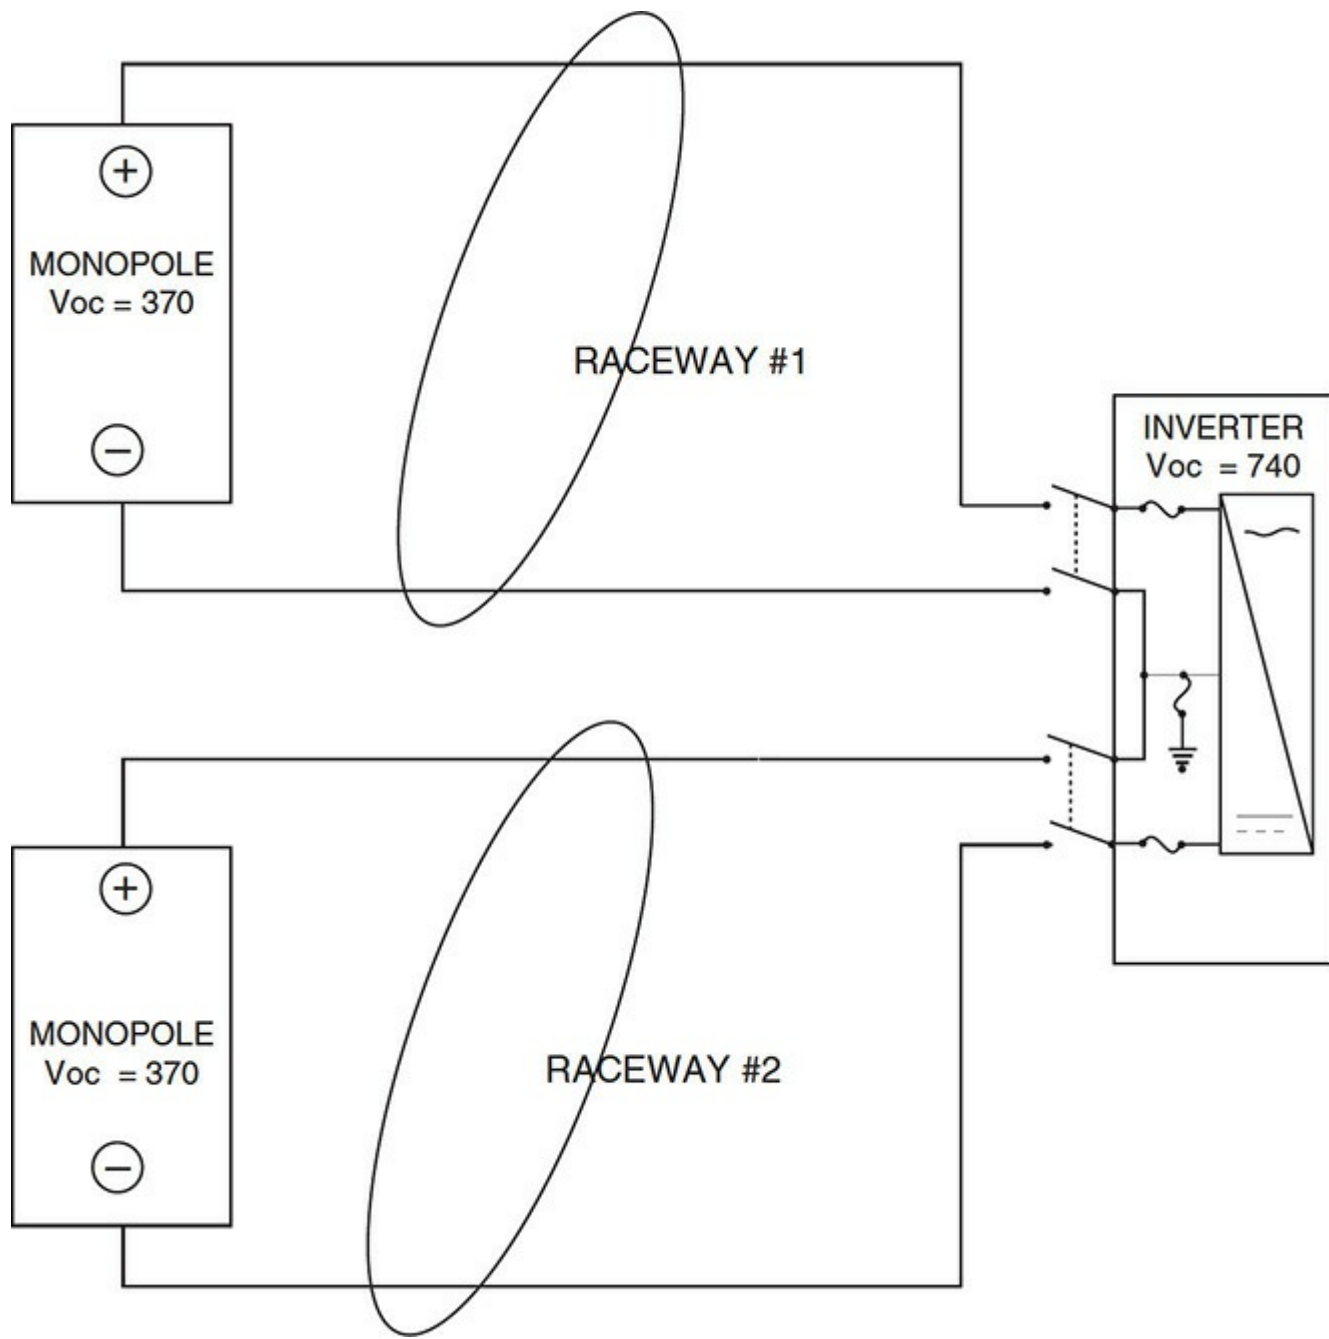

Fig. 690-7. Bipolar system wired with 600-V system components. The wiring to the two subarrays must be completely segregated raceways to the point of interconnection. The inverter connection detail shows that this system is functionally but not solidly grounded.

A warning label must be applied advising as to the consequences of disconnecting the grounded conductor. For the 2017 edition, this warning only applies to solidly grounded systems. Some legacy systems with an actual grounded conductor will need to take this advice seriously. Going forward, the “solidly grounded” parameter will not affect modern systems that are functionally grounded.

An exception follows that allows listed equipment to be used that is rated for the maximum open circuit voltage. This equipment creates a functional grounded center point and it can be positioned near the array. With one of the two wires from each monopole terminated within it, the home run conductors running to the inverter are reduced in number by half. Note, however, that the home run will now be operating well over 600 V, although never over 1000 V to ground. In the case of [Fig. 690-2](#), that voltage would be 740 volts. Type PV wire is rated 600, 1000, or 2000 volts (refer to the UL Guide Card information, code ZKLA) and would be the logical choice, 1000V in this case. Note

also that the exception refers to “switchgear.” This equipment does not meet the terms of that definition; better wording would probably be “control equipment.” However, the intent is clear and this equipment, if appropriately listed, should be interpreted as being in compliance with these terms.

690.33. Connectors. These are different from the ones covered in 690.32 that are concealable, and are used to interconnect panels, etc. They must be polarized and not interchangeable with other receptacles used in different electrical systems. They must be latching or locking, and if used on systems operating over 30 V must require the use of a tool to open if in locations that are readily accessible. They must be rated for interrupting current, or, they must be labeled to not open under load and require a tool to open. If opened improperly these devices will expose anyone fooling with them to full PV circuit voltages.

690.34. Access to Boxes. This is the box access rule in the realm of PV arrays. If not accessible directly, a box is accessible if the module or panel over it is secured using removable fasteners and wired using flexible wiring methods.

690.41. System Grounding. This section now consists of its 2014 **NEC** predecessor melded with the GFP rule formerly in 690.5 (2014 **NEC** in both cases), and then heavily influenced by the new definition of functional grounding. Part **(A)** lists the system allowable grounding configurations, which are roughly arranged by predicted frequency of implementation going forward.

Option (1) is the 2-wire system with one conductor functionally grounded. This is by far the predominant system and is likely to retain that distinction.

Option (2) is a bipolar array with a functional grounding reference at the center tap.

Option (3) is a non-isolated system that uses the ground on the inverter output circuit as the reference. This system has isolation between the ac and dc sides, and no inserted resistance in the ground connection on the dc side for operation. The inverter internal circuitry looks for unequal dc flowing on each polarity; those currents become unequal in the event of a fault. The result is reliable detection of ground faults.

Option (4) is for truly ungrounded systems, and primarily used on very large systems (see Art. 691). These systems typically operate in the context of an ungrounded ac system more common in IEC (European) distributions and may interface with an ac isolation (1:1) transformer. Similar to Option (3) systems, the floating array operates with one or more continuously operating residual current monitor(s) that will disconnect the system in the event of substantial current leakage from either the positive or negative poles.

Option (5) correlates with 690.41(B) Exception and allows for up to two source circuits that are solidly grounded in an application that is only permitted outdoors and unattached to any buildings. This system was formerly 690.5 Exception, and it is used for such applications as PV powered school crossing signals.

Option (6) is a final catch-all for other methods meeting 250.4(A) with listed equipment, and is unchanged from 2014.

The remainder, Part **(B)** is the GFP mandate from former 690.5(B) applied in a world of functional grounding. Every PV system must have GFP in some form, detect ground faults in both ungrounded and functionally grounded conductors and components, and be listed accordingly. This is done by either disconnecting the current carrying conductors of the faulted circuit, or having the inverter (or charge controller) open output circuits. For a functionally grounded dc system, it will isolate the system from the ground reference. [Fig. 690-8](#) shows equipment that senses such faults and

isolates the system by opening the functional grounding connection. Note that the system grounding conductor makes a second turn through the current transformer to increase the sensitivity.

Fig. 690-8. A GFDI (ground-fault detector interrupter) breaker. The far left hand pole opens at (in this case) 0.5 amps. and is mechanically interlocked with the power poles so they will open simultaneously. The negative circuit conductor looping through the multiple poles of the breaker accommodates what is necessary for the breaker to achieve a 600 V dc rating. Since dc circuits have no zero crossing points, elevated voltages may (as in this case) require the interrupting action to be distributed over multiple contact sets. The wording of the warning label and the use of white wire reflects 2014 **NEC** requirements locally applicable to this installation. The 2017 **NEC** [at 690.31(B)(1)] changes the permitted color for this wire, and discontinues this specific warning in favor of the similar warning label required at the PV system disconnecting means at 690.13(B). Courtesy, Solar Design Associates, Inc.

690.42. Point of System Grounding Connection. Systems with GFP will have the connection made where the protective device calls for it because the protective device will be responsible for the insertion of the resistance and/or overcurrent device etc. and for how it functions, all as covered in its listing. In the case of systems with an inverter, this will normally be inside the inverter in accordance with the installation directions. For solidly grounded dc systems, the dc

“circuit grounding connection” must occur at only one point, and the location of where that point is, is a design choice. The terminology “circuit grounding connection” refers to the connection of the dc grounding electrode conductor. The language here correlates this mandated connection with the operation of the GFP in 690.41(B), as discussed extensively in this book at that point. Left unsaid is the connection between the grounding electrode conductor, the grounded dc conductor, and the equipment grounding system. However, this is a dc system, and where Art. 690 leaves a vacuum, Art. 250 rushes in. This connection is covered in 250.168, where an unspliced bonding jumper must be installed at this point, sized in the same way as the grounding electrode conductor, which per 250.166(B) will be the size of the PV conductors with the usual allowances for mechanical permanence and electrode quality. That said, these systems are now quite unusual, as functional grounding predominates.

690.43. Equipment Grounding. Equipment grounding conductors in PV systems follow well understood installation requirements, even being required to stay with the system conductors as they leave the roof although part of a dc system. The frames of electrical equipment and arrays are connected as one would expect, with refinements for listed bonding procedures that may be idiosyncratic to the actual metal framework encountered. Take care in terminating these conductors at an array. Listed modules will provide for grounding connections and they must be used, unless otherwise provided as part of a racking system listed for bonding. Other modules, typically aluminum bodied, will require field terminations. Look for a copper-bodied lug that has a tin coating and is listed for direct burial. These lugs are compatible with an aluminum surface and their stainless steel hardware will survive outdoor conditions. To attach these to the module, drill a small pilot hole, then seat the lug with a 10–32 thread-forming sheet metal screw treated with an antioxidant compound rated for aluminum connections. This is not a “tek” screw with sheet-metal threads; it is an actual machine screw, and the compound will ensure that no oxygen reaches the raw aluminum surface during the thread-making process. This prevents the formation of aluminum oxide and ensures a low-impedance, long-lasting connection. Fig. 690-9 shows an example of this principle as applied to specialized hardware.

Fig. 690-9. Specialized listed bonding hardware can be used in lieu of wired bonding jumpers for components of an array [690.43(A)]. Note that the spacing between the upper frame and the rail

means that the nut has not yet been torqued. This hardware is usually stainless steel. When driven down its teeth embed themselves into the structural aluminum with an airtight bond, preventing aluminum oxide from forming, which would make the connection resistive. Depending on specific equipment hardware design and applicable listing limitations, this equipment is frequently not reusable, or only reusable a very limited number of times. The lack of torque in this photo is not an oversight; the photo was taken before the final position had been determined. Courtesy, Solar Design Associates, Inc.

690.45. Size of Equipment Grounding Conductors. Equipment grounding conductors must follow Table 250.122, based on the PV maximum circuit current if there is no overcurrent protective device, which is 125 percent of the short circuit or other applicable value as determined per 690.8(A). In the case of [Fig. 690-1](#) the maximum circuit current is 41 A. A 10 AWG conductor would be the correct size.

690.46. Array Equipment Grounding Conductors. Equipment grounding conductors run to PV modules must comply with 250.120(C). This rule was originally designed to address equipment grounding conductors run to create 250.130(C) grounding connections, which is why it discusses hollow spaces within walls, etc. It is true that dc grounding conductors need not run with their circuit conductors, as covered in 250.134(B) Exception No. 2. However, this will, as a practical matter, generally mandate raceway protection for smaller equipment grounding conductors, certainly out at the array where there are no hollow wall cavities. Further, 690.43 requires equipment grounding conductors to run with the circuit conductors after leaving the array, which strengthens the argument that all this is about is providing mechanical protection at the array. Note that 690.46 covers the array-to-array routing of the grounding conductors with a reference to 250.120(C). This allows for dc conductors smaller than 6 AWG to run apart from the associated circuit conductors but only where protected from damage or if run within raceways, etc. to provide this protection. Some rooftop designs specify 6 AWG grounding conductors to avoid the issue entirely.

690.47. Grounding Electrode System. After numerous code making cycles that attempted to mandate additional grounding electrodes as lightning mitigation measures for PV arrays on buildings, a subject entirely outside the scope of the **NEC** (it belongs to NFPA 780: Standard for the Installation of Lightning Protection Systems), sanity has largely returned and this section, at least in so far as its mandatory requirements, is completely defensible. First, a building or structure supporting an array must have a grounding electrode system that meets Part III of Art. 250. Well, since the PV system is generally supporting an **NEC** recognized electrical system, there will be a grounding electrode system. Second, the equipment grounding conductors must be bonded to the building grounding electrode system as covered in Part VII of Art. 250. The relevant reference in this case is 250.130(A), calling ultimately for a connection to the grounded service conductor and the grounding electrode conductor. This means that the equipment grounding conductors, which have already been aggregated and connected at the functional grounding connection point in accordance with 690.42, would then seem to be required to be extended into the service equipment, but read on. The next paragraph allows the inverter output equipment grounding conductor, which inevitably moves upstream to the service equipment, to provide the required connection. The informational note takes due note of the historical context and very well explains all of this.

Note that for ground-mounted arrays, which will constitute structures under the Article 100 definition, the array mounting structure will generally require, at some convenient point, a local

grounding electrode. [Fig 690-10](#) shows an example of such a connection.

Fig. 690-10. This wire is properly connected to at least 20 ft of reinforcing steel within the pour and that therefore qualifies as a concrete-encased electrode as covered in 250.52(A)(3). This becomes the grounding electrode system for the outdoor structure supporting the array [690.47(A)]. Courtesy, Solar Design Associates, Inc.

Part **(B)** then allows what has always been allowed but only sometimes not required, namely, for auxiliary grounding electrode connections directly from an array frame to a grounding electrode. Sec. 250.54 has permitted additional “auxiliary grounding electrodes” right along, without limit. Work as hard as you want, put as many as you want in place, and connect them to the array frames which are part of the equipment grounding system. These are entirely optional connections. However, no one should believe that this work is going to remotely substitute for a qualified NFPA 780 Lightning Protection System. In fact, some studies have demonstrated that auxiliary electrodes may exacerbate property risks to connected equipment by providing an unbalanced entry point for voltage wave fronts from nearby lightning strikes. NFPA 780 rules will protect PV arrays, but only if fully implemented. NEC 690.47(B) is a fool’s paradise, but at least this work is no longer mandatory.

690.50. Equipment Bonding Jumpers. If used, they must follow 250.120(C). See comment on 690.46.

690.53. Direct Current Photovoltaic Power Source. This is a field marking requirement, illustrated in [Fig. 690-1](#). If there were battery storage in the illustrated installation, then item (3) would also go on the label specifying the rated output current of the charge controller. If there are multiple outputs, then the label is applied to each.

690.54. Interactive System Point of Interconnection. The point of interconnection must

be labeled as a power source at the disconnecting means, with the rated ac output current and nominal voltage. In the case of Fig. 690-1, that label would go at the location of the 30-A circuit breaker in the panel, perhaps incorporated in the circuit directory.

690.55. Photovoltaic Systems Connected to Energy Storage Systems. Such systems must have a marking showing the polarity of the grounded circuit conductor the maximum operating voltage, and the equalizing voltage if any.

690.56. Identification of Power Sources. For stand-alone systems there must be a plaque declaring that fact and giving the location of the system disconnecting means. The location is to be outside the building at a readily accessible location suitable to the AHJ. For buildings with both a service and a PV system there must be a plaque giving the location of the PV and service disconnects if they are not in the same location. This last item is already required, in better form because its requirement is reciprocal, in 230.2(E). It is also covered, as cited, in 705.10.

Part (C) covers the field labeling requirements for the rapid shutdown systems required by 690.12. There are two labels required at minimum. One alerts the fire service that the building supports a PV system, and that a rapid shutdown system is in place. This label will be located either on or not more than 3 ft from the building service. There are two versions of this sign, with a graphic provided on the Code pages. For both of the signs, the largest lettering at the top reads the same, "SOLAR PV SYSTEM EQUIPPED WITH RAPID SHUTDOWN." The first version covers shutdown systems covered in 690.12(B)(2)(1), where the array itself shuts down as well as the wiring outside the array boundary. This version has that lettering using black lettering on a yellow background, and the sign on the roof also in yellow. This color scheme is recognized as appropriate for a "caution" level of risk in the standards referenced in 110.21(B). The second version covers shutdown systems covered in 690.12(B)(2)(2), where the array does not shut down and the wiring inside the array boundary can remain at as much as 80 volts. This version has the same basic lettering and graphics, but uses white printing on a red background. In addition, the interior graphic that shows a panel on the roof shows color scheme with a red dashed line around the panel as if to express the idea of voltage, and there is also a red exclamation point on a triangle on a red square. This color scheme is recognized as appropriate for a "danger" level of risk.

The second label serves to identify the switch that is supposed to be activated in order to initiate the shutdown sequence. It must be applied to the switch, or be posted within 3 ft, and carry the legend: "RAPID SHUTDOWN SWITCH FOR SOLAR SYSTEM." This label must be reflective and use white lettering on a red background, and with the same font size as the principal lettering in the larger labels. In the event the building has multiple systems with more than one style of shutdown system, or some with and some without shutdown, then a more complicated label must be created that shows a plan view of the roof delineating the extent of each system, and using the dashed line to encircle the system(s) that will remain energized during the day.

690.59. Connection to Other Sources. The requirements for utility-interactive inverters and other aspects of such interconnections are now completely within the scope of Article 705.

690.72. Self-Regulated PV Charge Control. Energy storage system requirements are generally the province of Art. 706. The general requirement in 706.23(A) is that provisions must be made to control the charging process of the energy storage system. This section provides a path whereby the PV system may be able, in effect, to claim inherent compliance with the control requirements. If successful, this would be a major design plus for the PV system. Specifically, the charge control would be deemed to appropriately "control the charging process" if the PV source

circuit is matched in terms of required voltage and charging current to the battery line, and the maximum charging current times 1 hour is less than 3 percent of the total rated capacity of the battery line. If the battery manufacturer has a different parameter, then that would be substituted.

ARTICLE 691. LARGE-SCALE PHOTOVOLTAIC (PV) ELECTRIC POWER PRODUCTION FACILITY

691.1. Scope. This article covers extremely large-scale PV farms, at least 5 MW in capacity, and not under the exclusive control of an electric utility. The article covers a power production operation organized entirely to supply electrical energy that an electrical utility will transfer and resell through its distribution system. The “sole purpose” wording in the first informational note makes this very clear. The need to bring operations of this nature within a regulatory framework is genuine, and the size of the problem based on their ever increasing numbers, especially in rural states with favorable geography and weather is equally clear. It is also very clear that the sophisticated engineering required to make one of these solar farms function on a scale that involves medium voltage at the least and some recent installations have involved 69 kV interconnections, which is a transmission voltage, the scale of these facilities is difficult to even imagine. Renewable energy mandates from government policymaking have the attention of the utilities, and the market economies of scale are driving the creation of these systems in ever increasing sizes. The article submitters are quite correct when they argue that the **NEC** was never and never will be in a position to write prescriptive rules for something like this. The technical merit that underlies the structure of the entirety of this article, open ended provisions that essentially say, “go get competent engineering, qualified personnel, and make sure you are transparent to the local authorities in terms of your design process and documentation” is frankly compelling.

The larger question is whether this article, which effectively regulates a utility generation component, will fit under the usual regulatory structures governing the implementation of **NEC** provisions. It might fit better as regulatory framework for a department of public utilities. This is a question with at least 50 different answers in the United States alone. As this article was moving through the process, it very clearly involved projects outside the scope of the **NEC**. It was only at the very last **NEC** Committee stage, after final panel balloting, that the Correlating Committee stepped in and wisely inserted the words “and not under exclusive utility control” into the scope. This theoretically mitigated the conflict with 90.2(B)(5), which is also flagged in the second informational note. However, this may turn out to be a distinction without a difference because the local utility is necessarily operating as a natural monopsony; no other entity will ever be able to buy its product, and therefore it exercises virtual exclusive control. In fact, one of the substantiating arguments presented in favor of the article stated, “They are under the direct control of a utility via transfer trip relays controlled by the utility.” Further, the purchase agreements involved will necessarily be the subject of review and approval of the regulatory authority governing utility operations.

The analysis that follows of the specific requirements in the article largely quotes from the arguments made by the panel. These arguments largely support the above analysis, but perhaps not its conclusion. One substantially underlies most of the others: “The **NEC** includes a number of specific requirements intended to demonstrate a conservative approach to safety in environments where unqualified persons are present. These provisions can severely constrain the design of large-scale PV

generating stations; therefore, if a less conservative approach is allowed, unqualified individuals must be excluded from accessing the station.”

691.4. Special Requirements for Large-Scale PV Electric Supply Stations. These facilities are expressly prohibited from having any public access. The panel argument for this accurately sets the context for this article: “Unlike smaller scale PV systems, large scale PV electric supply stations are designed and operated similarly to traditional utility power generating assets. Unqualified individuals must not access the system for their own safety and for protection of the system which is crucial to grid stability.” The realities of the power levels involved dictate a utility interconnection at medium or higher voltages and using switching facilities capable of performing the task safely. Article 690 does not address these issues, and neither does Art. 490, which supports the safe use of electricity for premises wiring. Any electrical loads connected at an Art. 691 location are entirely purposed for converting power received from the sun to electricity and making it available to the grid. These systems must never be installed on buildings. The panel decided that such locations could never be adequately secured against unauthorized access.

691.5. Equipment Approval. The usual process of seeking listed products, either off the shelf or as a result of a field evaluation will continue, but the third option of engineering review to ascertain conformance to recognized standards will be the more frequent approach.

691.6; 691.7. Engineered Design; Conformance of Construction to Engineered Design. These systems are relatively uncommon. These sections are controversial in that they allow the enforcing jurisdiction to impose the costs of an external engineering review of both the design and the conformity assessment on the permit holder. This is understandable given the financial realities underlying the usual processes involved in field enforcement of **NEC** provisions, and in these cases such costs could be substantial, especially because multiple engineering disciplines are involved in these large-scale systems. In addition, these systems often create local environmental impacts that dwarf the electrical complexities. There are a number of even small-scale projects (smaller than 5 MV) currently embroiled in disputes such as the mandated height of the fencing vs. local zoning ordinances prescribing a lesser height. The ultimate engineering design and conformity will need to account for all of these variables to the extent the electrical design is impacted.

691.8. Direct Current Operating Voltage. Here again, the panel decided against a reference to Art. 490, and left it to the engineering process. This is appropriate in this case, because we are not discussing a premises wiring issue.

691.9. Disconnection of Photovoltaic Equipment. This is an excellent demonstration of the extent to which this article varies from Art. 690. Typical installations of this sort involve inverter shacks spread out over a large geographic area, buildings constructed to protect the inverters from the weather but never for continuous occupancy, and rapid shutdown provisions are not possible or appropriate. The numbers alone result in separations from disconnecting equipment. On the ac side, the ac disconnect is usually at the substation switchgear, whose distance from the inverters might be measured in miles. On the dc side, some designs have dc disconnects located at large combiner boxes. These might number in the dozens in order to supply an inverter that might be rated in the MW range. Again quoting the panel: “Utilization of one-line diagrams by qualified electricians is the most effective method to ensuring proper isolation of equipment in shelters.”

691.10. Arc-Fault Mitigation. The site review process typically includes fire breaks and vegetation management agreements that are subject to review by fire departments. Attempting

conventional arc-fault control on this scale is impossible. And, the fact that these systems are ground and not building mounted reduces the potential for a conflagration, the effects of which would be felt most keenly by the system owner and not the public.

691.11. Fence Grounding. This is a complicated issue, because there might be more than 10 miles of fencing at one of these facilities. Given the realities of utility transmission systems, the presence of overhead high voltage lines often results in NESC mandates not just for general bonding but also invoking specific NESC requirements relative to step and touch potentials. Here again, this must be part of the engineering design; no prescriptive requirements can be written to adequately address it.

ARTICLE 692. FUEL CELL SYSTEMS

692.1 Scope. This article covers fuel cell systems, which have much in common with solar photovoltaic systems, and as a result many of the article provisions directly correlate. Fuel cells, like PV sources, are inherently dc sources with a finite current output. They also are used in conjunction with energy storage systems and with utility interaction.

692.4. Installation. Part (B) reiterates 230.2(E), but not as well, since it lacks a requirement for reciprocity. The systems are required to be installed by qualified persons only.

692.6. Listing. Fuel cell systems must be listed or field labeled for the intended application prior to installation. Apparently no field listings are acceptable in this category.

692.8. Circuit Sizing and Current. The rated current of a fuel cell is that which is marked on it, with no adjustments for temperature or other complications. The required ampacity of conductors supplied by fuel cells is the greater of (1) the marked rating(s) or (2) the rating of the fuel cell system(s) overcurrent protective device ahead of the conductor. Part (C) of this section matches Sec. 705.95(A); refer to the commentary at that location for details.

692.9. Overcurrent Protection. If conductors are protected by the fuel cell overcurrent device, no further protection is necessary. Overcurrent devices must be readily accessible. If more than one source is contributing power, overcurrent protection must be provided.

692.10. Stand-Alone System. These rules used to be the same as in 690.10; however, most of those moved to the new Art. 710, and that is where this book now addresses the topic. This section needs to be revisited for this reason in the next cycle.

692.13. All Conductors. This rule provides for complete disconnection of all current-carrying conductors of a fuel cell system from all other conductors on-site.

692.17. Switch or Circuit Breaker. This is the same basic requirement as in 690.17; refer to the coverage at that location for more information. The issues here are less complex than with PV systems.

692.31. All [Chap. 3](#) wiring methods are permitted. The function of the last sentence is anyone's guess. It appears to line up with 334.30(C), but what that might have to do with a fuel cell system is unknown. A review of the original proposal submittal shows no explanation or substantiation to support this wording, however; the recognition of all [Chap. 3](#) wiring methods is clear.

692.41. System Grounding. These rules simply apply separately derived system rules to a fuel cell system, which is a separately derived system. Part (C) is a much simpler version of 690.47(C).

Refer to the commentary at that location for more information.

692.47. Grounding Electrode System. Some manufacturers are still enthralled at what they think a ground rod here or there will do for them. This section correctly describes such foolishness as an “auxiliary” grounding electrode, which is covered in 250.54, and correctly directs that it be connected in a manner that will do no harm, that is, to the equipment grounding conductor.

692.53. Fuel Cell Power Source. This requires a plaque to be posted at the fuel cell power source (or other accessible location “on the site”) with the fuel cell system and its principal electrical characteristics such as voltage and power rating.

692.54. Fuel Shut-Off. This plaque is to be posted at the “primary disconnecting means” of the building or circuits supplied, giving the location of the manual fuel shut-off valve.

692.56. Stored Energy. If the fuel cell system stores electric energy, then a plaque as specified in the NEC must be posted warning of “energy storage devices” at the service disconnect for the premises. The fact that this says service and the previous sign said primary strongly suggests that the difference is intended. The proposal for the article used “primary” in both locations; the panel reworded this one to say “service” but failed to document why it made the change. The overall concept is that a fuel cell system will continue to produce energy for a period of time after its fuel supply is shut off, and the original submittal did not want someone to be surprised by the continued generation of power. On the other hand, no one should assume that a circuit is dead, especially when its disconnect is still closed, without testing.

692.59. Transfer Switch. If the fuel cell is used in a noninteractive system that also has a service connection as a backup supply, the fuel cell system is to be connected to the premises system through one side of a transfer switch that keeps the two supply sources separated. This simply requires what 702.5 already requires anyway. Where service conductors are connected to one side of a transfer switch (and the fuel cell on the other side), the switch must meet Part V of Art. 230, and that in effect means that the switch must be listed as “suitable for use as service equipment.”

692.60. Identified Interactive Equipment. Only fuel cells listed and marked as interactive are permitted to be used in an interactive system.

692.62. Loss of Interactive System Power. This rule is the same as 690.61 with some editorial changes in the first paragraph. Refer to the discussion at that location for more information.

692.80. General. This is the medium-voltage part of the article and it contains no useful information, only the requirement to do what the Code requires should be done at these voltages anyway.

ARTICLE 694. WIND ELECTRIC SYSTEMS

694.1. Scope. This article addresses wind generation together with the associated generators (dc), alternators (ac), inverters, and controllers. These systems can be interconnected with a utility supply or function as an island on a stand-alone basis, and for that reason may have provisions for energy storage, such as through the use of batteries.

To formulate the original proposal, Art. 690 was largely cut, duplicated, and pasted as this article. There are important distinctions between those two systems (PV vs. wind) that make this more of a difficult project than seems immediately obvious.

694.2. Definitions. The definition of “Charge Controller” has been relocated to Art. 100. The definitions of a **Diversion Charge Controller**, and an **Inverter Output Circuit** are essentially the same as in Art. 690. Four definitions apply to the windmill structure: A **Diversion Load Controller** is the same as a diversion charge controller, except that the load is not limited to energy storage equipment such as batteries and this equipment is the means of regulating the output of a wind generator. The **Tower** (where needed) supports the **Nacelle**, which houses the **Wind Turbine** that does the work of converting the mechanical energy of wind into usable electrical energy, and the tower may be reinforced by **Guy** wires as required for the height and prevailing conditions. The **Wind Turbine Output Circuit** carries the electrical output running between the internal components of the turbine and other equipment. Three definitions provide the basis for important ratings that are used elsewhere in the article. The **Maximum Voltage** is the maximum voltage the turbine will produce in operation, whether open circuited or not. The **Maximum Output Power** is the highest one-minute average power a wind turbine will produce in operation while functioning in normal steady-state conditions, and the **Rated Power** is the output at its rated wind speed. When all components are put together as required, the result is a wind turbine system, which was defined in the 2011 **NEC** and has been deleted in the 2014 **NEC** because it is not used in the article and therefore need not be defined. However, in lower case wording, that is what is created when everything goes together. It could also be a “wind electric system,” which is used in the article at 694.7(B), although not formally defined.

694.7. Installation. Part (B), which used to require that just the inverters be listed, now as of the 2014 **NEC** requires the entire wind electric system to be listed and labeled. Part (C) covers diversion load controllers used as the principal method of regulating the speed of a wind turbine rotor. Unlike solar panels that can be open circuited without damage, wind turbines will frequently overspeed in such cases, causing excessive noise and very possibly self-destructing. This rule requires that wind systems provide some “additional independent reliable means” to prevent excessive rotor speed, and an interconnected utility power grid is not to be assumed to be adequate as the alternate diversion load for such purposes. There is precedent for this sort of power dump in 620.91 governing regenerative power from a descending elevator. Some form of electrical resistance load is usually configured into the system, and to maximize the energy benefit, electrical hot-water heating is often factored into the mix.

Part (D) breaks new ground, in that it mandates surge protection ahead of all loads served by the premises wiring system that are supplied by the wind turbine system, and as such it is one of very few surge protective devices (Art. 285) mandated in the **NEC**. Part (E) permits the installation of a receptacle, presumably a 125-V 15- or 20-A single-phase style although that is not specified, to the output circuit for data or maintenance applications. This receptacle must be GFCI protected. Part (F) allows a supporting pole for a wind turbine to be treated as a raceway, generally to be addressed as part of the now required listing on the turbine. Part (G) allows a reduction in work space clearances for activity within the equipment by qualified personnel.

694.10. Maximum Voltage. For one- and two-family applications, the maximum voltage on a wind-turbine output circuit is limited to 600 V, and live parts (this is presumably an incorrect application of the term and probably the phrase “uninsulated live parts” is intended) operating above 150 V to ground must not be accessible to other than qualified persons while energized. The default upper voltage limit for other occupancies is 1000 V. DC utilization circuits, used in some off-grid

applications, are limited as described in 210.6.

694.12. Circuit Sizing and Current. Part (B) classifies system currents as continuous and generally requires conductors and overcurrent devices to be sized on the basis of 125 percent of the maximum current, with the next-higher-standard-size device allowable up to 800 A.

694.15. Overcurrent Protection. Part (A) requires overcurrent protection for all circuit components, with particular attention to the possibility of backfeed. An informational note calls attention to some inverters that may operate in reverse for turbine startup or speed control. Similarly, Part (B) requires that transformers must be evaluated in both directions in terms of whether their overcurrent protection meets 450.3. Part (C) requires that overcurrent devices applied to the dc portion of the wiring must have the appropriate ratings. Just as in the case of PV circuit conductors that cannot be damaged by the available current [see 690.9(A) Exception], conductors that cannot be exposed to overcurrent due to the available system capacity need not have overcurrent protection.

694.20. All Conductors. Wiring from a wind turbine must be disconnectable from other premises wiring, and no pole is permitted in a grounded circuit conductor if such a conductor would become or remain energized with the disconnect open. For cases where connected loads on the turbine output circuit are used for speed regulation, a disconnect need not be placed in the output circuit.

694.22. Additional Provisions. The disconnect must be suitable for use as service equipment and readily accessible. It must be externally operable without exposing the operator to live parts (here again, probably “uninsulated live parts” is the intent). It must plainly indicate its open or closed status and it must be appropriately load-break rated. It must be plainly marked with a warning that both line and load terminals may be energized when it is open. Part (B) permits rectifiers, controllers, output circuit isolating and shorting switches, and overcurrent devices (that list pointedly not being exclusive) on the line side of the disconnecting means and part (D) allows rectifiers, controllers, and inverters to be up in the nacelle or otherwise not readily accessible.

Part (C) places the system disconnecting means at a readily accessible location either on or adjacent to the tower, or on the outside of the supplied building or structure, or inside nearest the point of conductor entry. If the installation uses dc turbine output circuits in a building, they must be run in a metal raceway or other metal enclosure (including Type MC cable) to the first readily accessible disconnecting means in accordance with 694.30(C), and that disconnecting means need not be close to the entry point for the wiring. In general, a disconnect is not required at the tower, and it is not permitted in a bathroom.

694.23. Turbine Shutdown. Wind turbines must have a manual means to shut them down. It must also require the shutdown procedure be documented and posted both at the disconnect or turbine controller and at the stop control if it is in a different place. The result must be either the turbine stops, or it retains limited movement combined with a means to deenergize the rotor circuit. An exception waives the requirement for smaller turbines with a swept area of less than 50 m² (538 sq ft) —Note that this metric conversion is a classic example of an illegal soft conversion as described in 90.9.

694.24. Disconnection of Small Wind Turbine Electric System Equipment.

Components of the wind system must be disconnectable, including items such as inverters, batteries, and charge controllers, from all sources of power and if multiple sources potentially feed such equipment, multiple disconnects are required and they must be grouped and identified. For

components that are part of a system that uses the turbine output circuit to govern rotor speed, a shorting switch or plug is permitted to substitute for a disconnecting means. Equipment in a nacelle does not require a disconnecting means.

694.26. Fuses. If a fuse is energized from both directions and accessible to unqualified persons, switches or other disconnects rated for the application must be installed on both sides.

694.28. Installation and Service of a Wind Turbine. Open circuiting, short circuiting, or mechanical brakes (at least one of those three possibilities) must be in place to allow a turbine to be disabled for both the original installation and also for subsequent maintenance.

694.30. Permitted Methods. Chapter 3 wiring methods are generally permitted, with the restriction that turbine output circuits operating at voltages higher than 30 V in readily accessible locations must be installed in a raceway. Flexible cord is permitted for the logical uses, including the connection of moving parts and to provide ready removal of components for repair, all in accordance with Art. 400. The rule specifies hard service cord suitable for extra-hard-usage or portable power cable, listed for outdoor use, water- and sunlight-resistant. This would include the Type S series and Type G cords, with a “W” in the type designation. In accordance with Footnote 9 to Table 400.4, the wet location designation now necessarily includes a sunlight-resistance evaluation. Part (C) on dc output circuits is covered at 694.22(C)(1) in this analysis.

694.40. Equipment Grounding. This is the point of departure where a cut-and-paste approach from Art. 690 into Art. 694 breaks down, and serious issues remain unresolved in terms of conflicts with established nomenclature and requirements in Art. 250. PV arrays are typically large in area and not thought of in the sense of a point source such as a generator, although everyone will agree that they are separately derived systems. In addition, there is usually some form of overcurrent protection at the arrays. Therefore, Art. 690 is generally organized around the terminology of an equipment grounding conductor. A wind turbine is a point source, and so this portion of the article addresses system bonding jumpers and not equipment grounding conductors. In short, it is a permanently installed generator. Where a generator is outside a building and the first disconnect is at the building, Art. 250 has highly evolved terminology for the grounding connections between the two locations, and “equipment grounding conductors” are not used, because they are on the line side of any overcurrent protection. Instead, the appropriate terminology is a “supply-side bonding jumper” and the sizing should follow 250.30(A)(2) and the overall installation should follow 250.30(C). Refer to the commentary in Chap. 2 of this book for more information. The 2017 **NEC** made incremental progress by describing the required connection in terms of bonding “to the premises grounding and bonding system.” For systems with dc turbine output circuits, the applicable language is in Part VIII of Art. 250. The reference to 250.168 in this case would be particularly robust, since it would bring in parts of 250.28 that in turn would bring in 250.8. There has been some progress, but we still have quite a ways to go. The references in 694.40(A) omit Part II of Art. 250 referencing system grounding. On the other hand, the same references now include for the first time Part V, which includes supply-side bonding jumper sizing. Section 694.40(B)(2), which references both the incorrect term and the correct one in the same sentence, is a perfect example of this ongoing work.

Part (B) covers tower grounding and bonding. The requirement for a grounding electrode at the tower is technically justified, but needs to reference the electrode options comprehensively and the connecting conductor needs to be described correctly so it will be sized and installed correctly. The guy wire provision is much improved because it is no longer presumed to be a grounding electrode.

694.56. Instructions for Disabling Turbine. Instructions must be posted at the “turbine location” (one hopes this will be interpreted in the field as the base of a tower and not up at the nacelle) that explain how to disable the turbine.

694.62. Installation. Small wind systems must meet the cogeneration requirements in Art. 705 when other sources are connected.

694.66. Operating Voltage Range. Where small wind systems connect to the end of a dedicated feeder or branch circuit, this section grants permission for the nominal voltage limits for such circuits established in other parts of the **NEC** to be exceeded at the point of connection, provided the voltage at the panel where those circuits interconnect with other circuits in the occupancy remains within normal limits. An informational note explains that wind turbines may use the utility grid to dump energy from a short-term wind gust. Longer-term exposures would presumably require a more comprehensive solution. Review the discussion at 694.7(C) for more information.

ARTICLE 695. FIRE PUMPS

695.1. Scope. This article covers a part of the electrical system that is almost unique in that it is designed to self-sacrifice and run to complete failure. The requirements in this article are organized around the principle that when a fire pump is called into service, it must run until told not to, or die trying. On the other hand, the fire pump and its circuits cannot become a source of ignition that might call the fire pump into service. For this reason, for example, fire pump circuits have no running overload protections but they do have short-circuit protection.

The 2014 **NEC** has made some clarifications in part (B) as to what is not covered in the article. The installation of pressure-maintenance (jockey) pumps (as distinguished from how their existence may need to be factored into the fire-pump electrical installation should they be present) is not covered in Art. 695. A new informational note directs the reader to Art. 430 for the installation of such motors. Another change establishes that transfer equipment installed upstream from any fire-pump transfer switch(es) is not covered within the scope of Art. 695.

695.2. Definitions. A *fault-tolerant external control circuit* is one that however open or shorted after leaving the controller, the fire pump will still be able to start from other means, including the possibility that it may start anyway.

An *on-site power production facility* is a nonutility on-site source such as a power plant that is the normal source of electric supply for the facility.

An *on-site standby generator* only runs when it is called to run for a specific reason, and as a backup supply of electric power. It does not constantly produce power.

695.3. Power Source(s) for Electric Motor-Driven Fire Pumps. The power source(s) must be reliable. The definition of the term “reliable” is not within the province of the **NEC**, because the performance requirements for fire pumps belong to the **NFPA 20** Committee. In the current edition of **NFPA 20-2010, Standard for the Installation of Stationary Pumps for Fire Protection**, there is extensive information on this concept in the annex material on its [Chap. 9](#), specifically A.9.3.2. What follows is an extremely abbreviated summary of material that should be read in its entirety. The qualities of a reliable source include four general characteristics.

First, the source of power should not have shown any outages longer than 4 continuous hours in the

year prior to plan submittal. This is the time threshold in **NFPA 25** for which fire watches and other special undertakings become necessary. Second, no outages were experienced in the area in the utility grid, unless such outages were due to a natural disaster. The annex goes on to say that the normal source is not required to be infallible. The east coast blackout of 1965, for example, would not condemn a utility distribution to forever be deemed unreliable. On the other hand, if the power grid is known to have general reliability issues caused by faulty switching procedures or animals shorting transformer bushings, and those issues were not resolved promptly, then the utility supply could reasonably be described as unreliable.

The third characteristic describes a utility supply fed through overhead drops to the protected premises as inherently unreliable due to fire department operations that result in these supplies being deenergized routinely in order to clear the fireground for ladders and other aerial apparatus. The fourth characteristic concerns local switching arrangements that result in a likelihood that a fire pump will be inadvertently disconnected on-site through erroneous opening of a disconnect. Great care has been taken to coordinate the electrical disconnection rules between the **NEC** and **NFPA 20**, so it would be fair to say that if the local distribution system complies fully with the current **NEC**, then the facility must be presumed to be compliant with the fourth characteristic, and only the first three need to be further evaluated in a reliability determination.

It should be further noted, that a backup generator does not, in and of itself, make an unreliable supply reliable. Backup generators have a long record, and that record is replete with issues around failure to start and other reliability problems. However, under the circumstances defined in this section, it can add enough to the mix to make the overall picture one of reliability.

Part **(A)(1)** is the first preference, and it is for an individual, reliable source. For example, a separate utility service connection from a reliable utility grid through an underground supply would presumably pass muster as “reliable” and be acceptable. Note that such a connection must be ahead of the service and if tapped from the utility lateral, the tap cannot be in the same cabinet, enclosure or vertical switchboard section as the service disconnecting means. The actual service disconnect for the fire pump must comply with 230.72(B), which makes it remote from the normal service, and usually right at the fire pump so someone opening service disconnects will not inadvertently disconnect it. Part **(A)(2)** allows for a reliable on-site power plant with a comparable record of reliability, especially in terms of the first characteristic of reliability covered above. In such cases, and with a comparable disconnect location [230.72(B) does not apply because this is not a service supply, but 695.4(A) does], and a direct connection from such a source would be viewed as reliable.

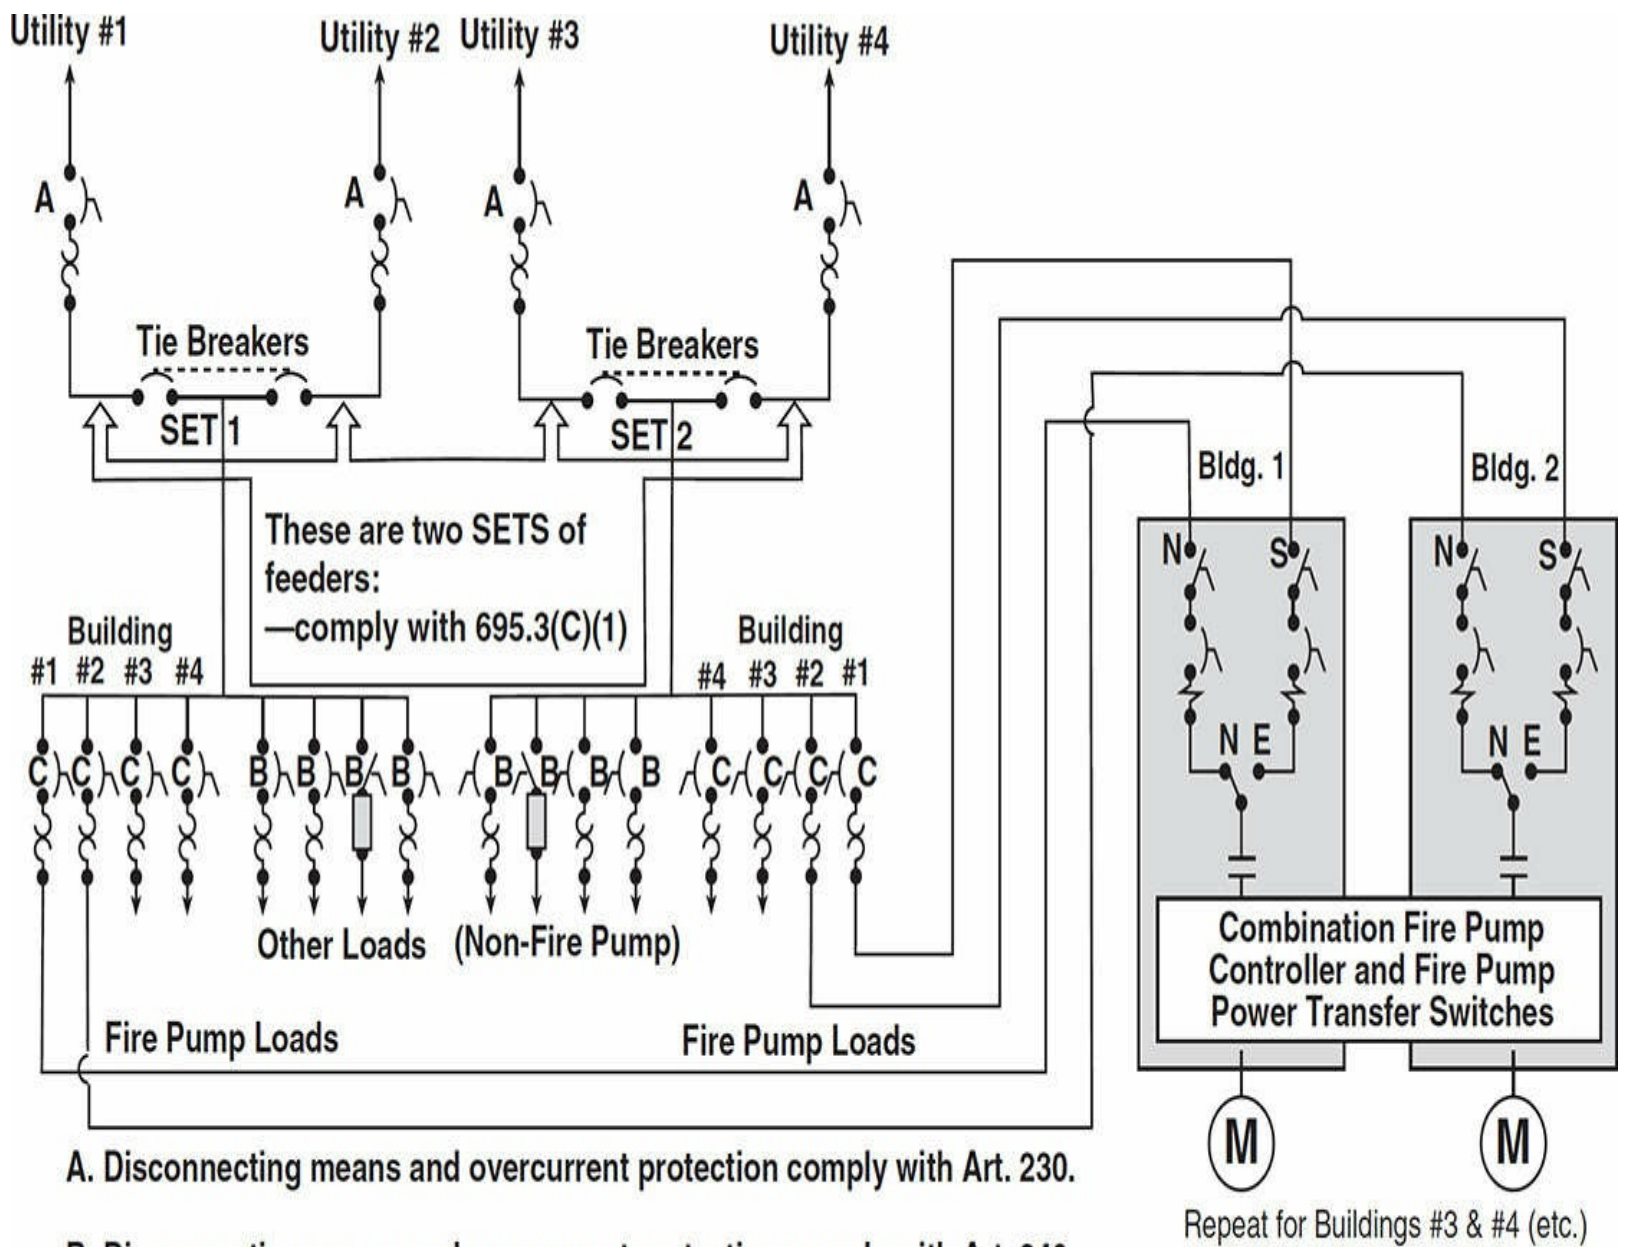

Part **(A)(3)** covers a dedicated feeder originating at a service connection. Such a feeder must meet the wiring requirements in 695.4(B)(1), which are covered in detail at that location below. Part **(B)** covers the case where the sources in (A) are available, but judged unreliable. The first option is two of the sources in (A) wired as alternate sources of supply and landing at a listed fire pump transfer switch. The second option is an approved combination of one (or more) part **(A)** source(s) and an on-site standby generator that qualified under 695.3(D) (see below). Another option, covered extensively in **NFPA 20**, is where a backup fire pump is in place driven by a nonelectric prime mover, either engine-driven or steam turbine-driven.

Part **(C)** is where the process gets more complicated. This is where the requirements begin to accommodate large industrial or institutional campus distributions, where a service connection is out of the question. Consider, for example, the matter of a fire pump in a college academic building thousands of meters (feet, does not matter) from the service for the campus. This service is 13.8 kV

because the college owns its distribution. A literal service connection is inconceivable, but a connection to gear fed from the medium-voltage loop is quite feasible. Similar conditions apply at countless industrial plants throughout the country.

There are two options, and in both cases it must be demonstrated that the overcurrent devices in the chain of supply to the fire pump selectively coordinate. This is a performance requirement from **NFPA 20** and because this material is extracted from that document, the **NEC** can not change it. Refer to the extensive presentation at 700.32 in this book for an extensive discussion of this concept and the practical difficulties in implementing it. This application is particularly bizarre, because it only applies to the fire pump circuit. Essentially, it says this: In the event of a short-circuit in the fire pump branch circuit, the branch-circuit protection will clear without opening the feeder protection above it and causing a wider outage. And the same process applies for the chain of protective devices above that. In effect, this rule protects the rest of the facility from the fire pump, instead of protecting the fire pump from the rest of the facility, which would have at least a faint basis in logic. Possibly what is intended is a requirement for all overcurrent protective devices on the supply side of the fire pump to be selectively coordinated with all overcurrent protective devices supplied by them that serve non-fire-pump loads. However, that is most certainly not what this rule now says. And if it were so worded, the consequences of effectively imposing a selective coordination requirement on an entire industrial distribution just to provide a fire pump supply would be so severe as to discourage the installation of such protection.

The first option is to arrive at the fire pump controller and transfer switch with two feeders that are derived from separate utility services ([Fig. 695-1](#)). The chain of supply to each feeder must meet the requirements in 695.4(B). The second option is a single feeder arriving at the fire pump transfer switch with the alternate source being a standby generator ([Fig. 695-2](#)) or other alternate, completely independent source of power.

A. Disconnecting means and overcurrent protection comply with Art. 230.

B. Disconnecting means and overcurrent protection comply with Art. 240.

C. Disconnecting means and overcurrent protection comply with 695.4(B).*

*NOTE: Only these devices are "unique to the fire pump"

Fig. 695-1. Two or more feeders comprise a reliable source if fed from different utility services. The NEC no longer requires multiple sets of feeders, so the double-ended service arrangements shown here are not required, but still permitted. The minimum requirement is one service for each feeder.

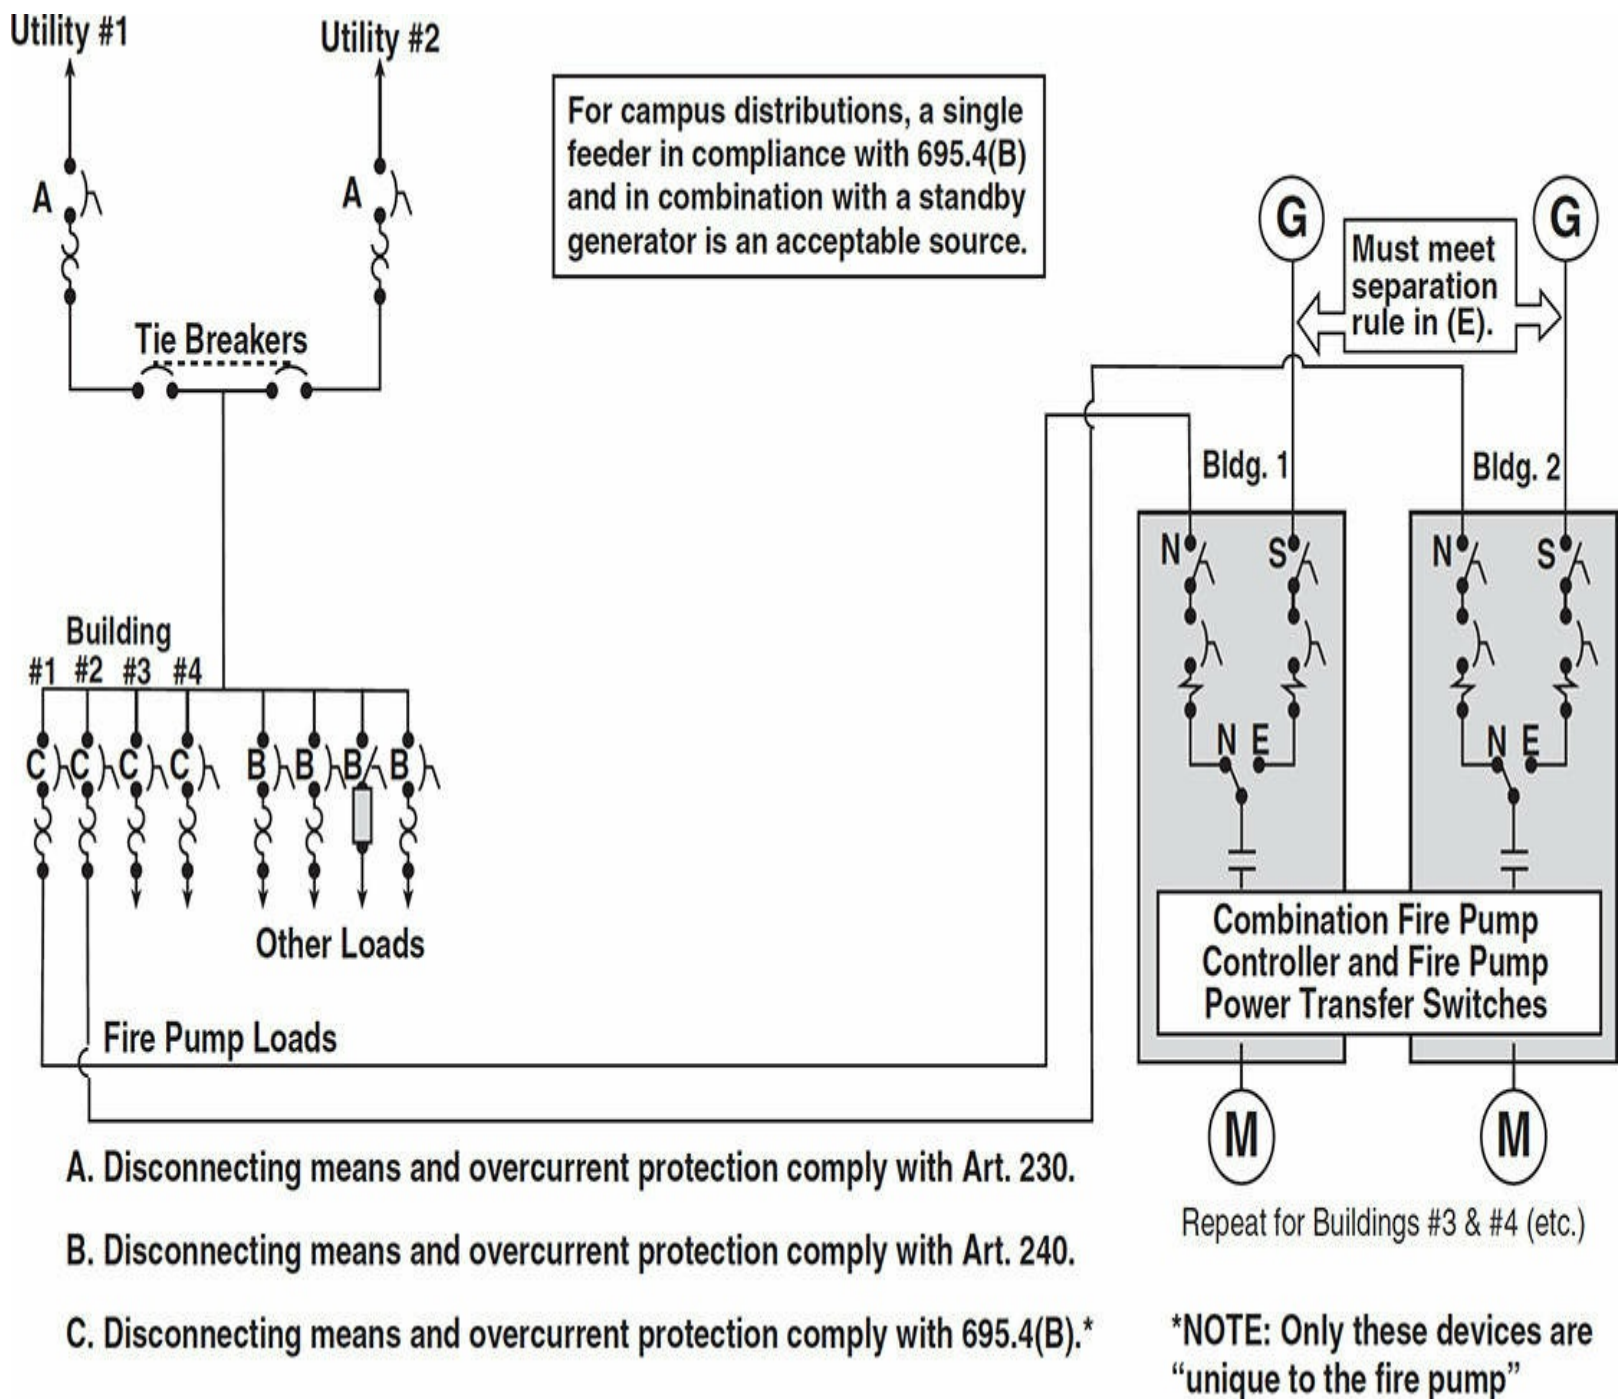

Fig. 695-2. A single feeder can comprise a reliable source if backed up with an alternate source such as the standby generator shown here. The **NEC** no longer requires multiple sets of feeders, so the double-ended service arrangement shown here is not required, but still permitted. The minimum requirement is one service for the feeder, provided an alternate power source is provided.

Part **(D)** covers the usual case where the alternate source of power for a fire pump load is a standby generator, and the requirements are quite reasonable. The generator must be able to pick up the entire fire pump load including associated jockey pumps and controls that have to operate at the same time. It does not have to be sized to carry the locked-rotor current of the fire pump. The generator can supply additional loads in the facility as long as it has the required capacity. Or, it can be fitted with automatic load-shedding controls, similar to what is allowable for emergency generators in 700.4(B), that ensure the fire pump start will not be encumbered by other loads on a generator with insufficient capacity. The connection for the feeder circuit from the generator does not need to be made ahead of the disconnecting means for the generator. The requirement in 430.113 for

plural disconnects near a motor fed from two sources, one for each, does not apply to fire pump supplies. In this case the feed from both sources to the fire pump will be through a transfer switch so it is questionable whether 430.113 is in play, although waiving it does no harm.

Part **(E)** requires that power sources to a fire pump be located and arranged so they are protected against fire damage and “exposing hazards.” This is another performance requirement extracted from **NFPA 20**, so it means what the **NFPA 20** committee says it means and the **NEC** cannot vary it. In this case, there is a note in the Annex to **NFPA 20** that indicates this requirement is to be applied to an “on-site power production facility” as well as the fire pump wiring and components. In addition, the multiple sources must be arranged so a fire at one location does not disrupt the alternate source. Part **(F)** requires that a transfer of power between the “individual source” and one alternate source takes place within the pump room. In this context the “individual source” is one of the three covered in 695.3(A). The selection of sources must be performed by a transfer switch that is specifically listed for fire pump applications. And that transfer switch, if it is configured as a listed assembly to include the short-circuit protection normally required for fire pump circuits, is permitted to use instantaneous circuit breakers as that overcurrent protection. Part **(G)** prohibits phase converters from sourcing a fire pump load because of the effects of voltage imbalances that can occur, particularly in the manufactured phase.

695.4. Continuity of Power. This section tries to make sure that human error will not inadvertently compromise a fire pump connection. Part **(A)** asks for a direct connection to the power supply system, and essentially works for 695.3(A) sources [or (B) sources through a transfer switch] that are therefore reliable. In addition, by virtue of being directly available to the fire pump controls at the point of entry to the building, they are capable of being terminated directly on the fire pump controller (or listed fire-pump power transfer switch) with no intervening overcurrent protection and disconnecting means. However, in more complex systems, it is not always possible to bring those supply conductors to the pump controller without some intervening disconnect and associated overcurrent protection. In such cases, covered in part **(B)**, the disconnect must be installed and conductors protected, but only in the context of additional requirements that ensure that the disconnect will not be opened by human error and that the overcurrent device will not open except under the most extreme conditions. There are three types of installation to address under this topic.

The first is the relatively uncomplicated condition where the fire pump is remote from its supply conductor entry but is otherwise served by a reliable source. In such cases a single disconnecting means, as covered in **(B)(1)(a)**, may be installed. The associated overcurrent device must be sized so that it will only open in the event of a short-circuit or ground fault, but not a simple pump overload condition. As covered in **(B)(2)(a)**, this device must carry the locked-rotor current of the largest fire pump motor, plus the locked rotor current of the pressure maintenance (often referred to as a jockey pump) motor, plus the full load current of all other associated accessory equipment for an indefinite time period without opening. This rule only covers the overcurrent device; it is not necessary to cable the motors based on this calculation or upsize any other devices. The 2014 **NEC** has added another option here. It is now possible to specify “an assembly listed for fire-pump service.” The four performance criteria that follow would be part of the listing evaluation and not judged in the field.

Having assured that the overcurrent device will not open under any condition but the most extreme circumstances, where the supply conductors would actually be creating a fire condition, the next step is to remove human error from the operation of the disconnecting means, as is covered in **(B)(3)(a)**, (c), (d), and (e). Specifically, the disconnect must be SUSE rated, lockable in the closed position, not

located in any equipment, such as a common panelboard or switchboard, that feeds any other loads than the fire pump, and physically located sufficiently remote from such other equipment that inadvertent operation at the same time would be unlikely. It must also be plainly marked with its function (c), the controller must be marked with its location and the location of the key if it is locked closed (d), and its status must be supervised by using one (or more) of the strategies itemized in (e). Note that the 2014 **NEC** added criteria to the lock-out mechanism that has been standardized throughout the **NEC** by references to 110.25. For some reason that reference is still missing here and will need to await action in the 2020 cycle.

The next possibility to address is when the service (or on-site power plant) is not judged reliable, and an on-site generator is required to establish the required reliability. This case also allows for an additional overcurrent device and disconnecting means, as covered in **(B)(1)(c)**. This overcurrent device need only be sized to carry the full fire pump equipment load, as covered in (2)(b). Its disconnecting means, addressed in **(B)(3)(b)**, must comply with 700.10(B)(5) as though it were an emergency circuit, which means it must not be located within the same vertical switchboard section, although that vertical section may share a common bus with other sections. It must not be located in a common panelboard or other common enclosure as other loads supplied by the generator as well. However, the generator may serve as the originating point for other feeders originating at multiple overcurrent devices on the generator, as covered in 445.18. The overall concept is to recognize that many large facilities use highly reliable central generator facilities, and enhanced separation rules only apply at the point where the physical separation of functional feeder conductors, in this case for the fire pump backup supply function, originate and separate from other generator loads. The generator disconnecting means must, however, comply with the supervisory requirements in (c), (d), and (e).

The final possibility is the existence of a large multibuilding campus type distribution, as covered in **(B)(1)(b)** to address 695.3(C) applications. In these cases there will be additional disconnects and overcurrent protective devices in order to comply with various Code rules regarding feeder protection and building disconnects, etc. However, any disconnecting means in the chain of supply “that are unique to the fire pump loads” must comply with the enhanced features and supervisory requirements in **(B)(3)(a)** and (c), (d), and (e).

To reiterate and provide a calculation example for the basic requirement in **(B)(2)**, the overcurrent devices must carry indefinitely the locked-rotor currents of the fire pump, the jockey pump (if used) and all associated accessory equipment when connected. The next higher standard sized protective device must be used. Note that overcurrent devices ahead of fire pump controls, etc., are not part of the locked rotor rule except insofar as their currents add arithmetically to the motor currents in determining the required rating of the next higher sized device.

Example: A 75 hp 575 V fire pump motor and a 5 hp (575 V) jockey pump are protecting a facility along with 15 A of accessory load as supplied on the primary side of a control transformer that supplies 120 V accessories. Calculate the setting of the short-circuit and ground-fault protective device for this feeder.

Solution: From Table 430.251(B), the locked rotor current for the motors is $434\text{ A} + 37\text{ A} = 471\text{ A}$. Add the accessory load of 15 A for a total of 486 A, so a 500 A short-circuit and ground-fault protective device is required for this load.

695.5. Transformers. Transformers are necessary where the service or feeder voltage differs

from that of the fire pump. This rule has a decision tree built into it. If the installation is on a campus distribution as covered in 695.3(B)(2), then the transformer requirements are taken from part (C). If the fire pump supply is from any other source, then the transformer is dedicated to the fire pump load, and the transformer size and the rating of the upstream overcurrent device is calculated here.

Part (A) requires the size of the transformer be rated in terms of 125 percent of the motor load, and 100 percent of accessory equipment. Using the previous example, the motor load from Table 430.250 is $72\text{ A} + 6\text{ A} = 78\text{ A}$; take this at 125 percent = 104 A , and add the accessory load of 15 A for a total of 119 A

$$\text{kVA transformer rating} = \frac{119\text{A} \times 600\text{V} \times \sqrt{3}}{1000} = 124\text{ kVA}$$

The next higher commercially available transformer size is 150 kVA .

Part (B) determines the overcurrent protection based on the locked rotor current determined previously, or 471 A reflected through the winding ratio of the transformer. The primary voltage in this case is 2400 V . $600\text{ V} \div 2400\text{ V} = 0.25$, so the minimum primary side overcurrent protection is $0.25 \times 471\text{ A} = 118\text{ A}$. A 125-A “E” rated fuse for this voltage will provide the appropriate protection.

Part (C) covers campus-style feeder distributions. In these cases, and only these cases, the transformers are permitted to supply other load. However, their minimum size is still based on the same calculation as above, and their primary side protection must still carry the locked rotor currents indefinitely. However, the conductor and the transformer overcurrent protection will be in accordance with normal procedures in 215.3 and 450.3. In other words, for these applications, the locked rotor currents of the fire pumps are carried as loads, with the transformer sizing and wire sizing figured accordingly. Remember that the usual applications for these rules are large institutional and industrial occupancies where the typical transformers are measured in MVA, and even locked rotor current on a fire pump among all the other motors is essentially lost. This is a practical approach, used without incident for almost 10 years now. In terms of reliability, these transformers are the least likely to be out of service, given the likely perceived criticality of other simultaneously connected loads. (See [Fig. 695-3](#).)

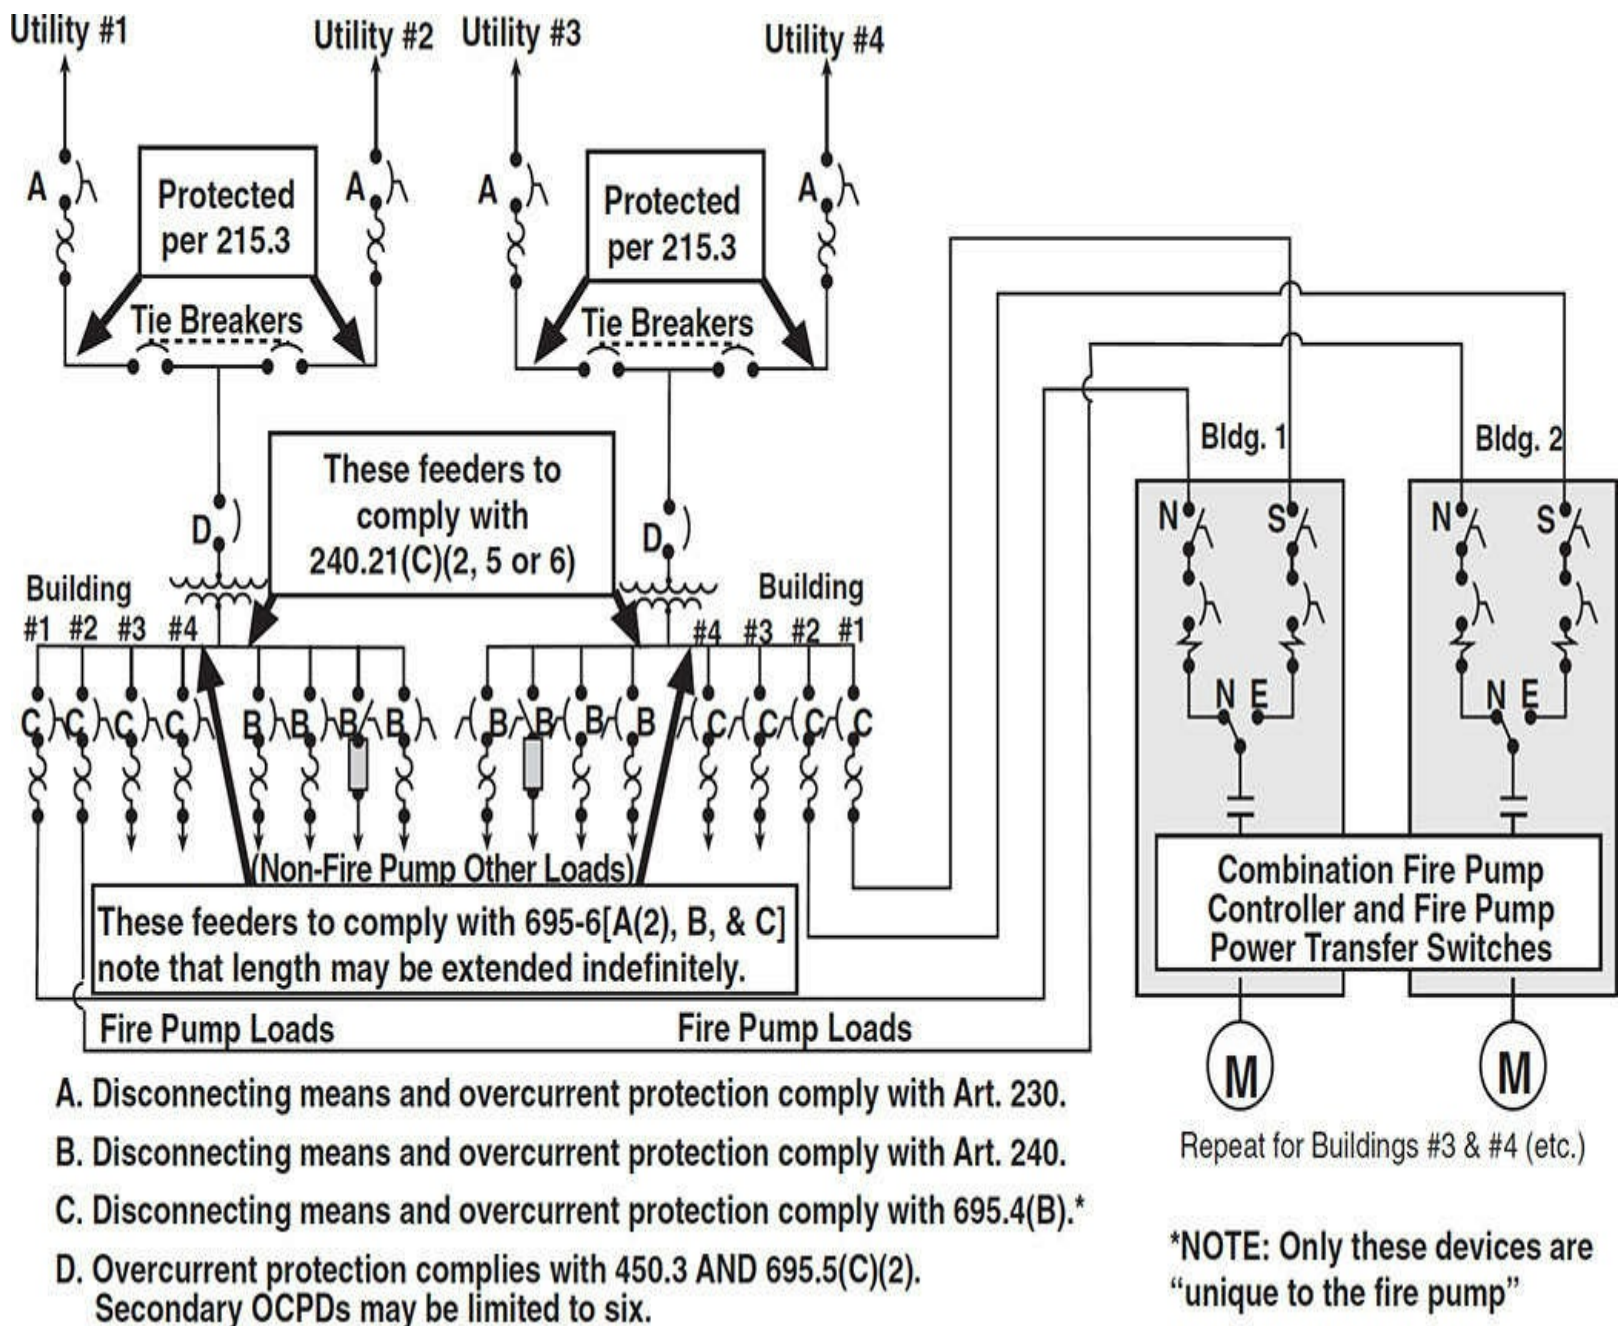

Fig. 695-3. Large transformers and feeders per 695.5(C)(2) with conventional overcurrent protection may supply diverse loads.

695.6. Power Wiring. These are the wiring methods and related requirements. The first set of cross references, contrary to the wording of the sentence, does not involve any requirements because the items are instances of where fire pump wiring receives special dispensation in other Code sections.

Part (A)(1) covers fire pump wiring that is normally connected to a utility supply and therefore consists of service conductors, but it also applies to a separately derived source originating from an on-site power production facility. As is true for service conductors generally, this wiring must be routed outside a building either in fact, or for Code purposes as covered in 230.6, but even there, only where encased in concrete or run below grade. The allowance in 230.6 for installation in a vault does not apply here, since a transformer vault may be the very location of the fire the fire pump will be trying to extinguish.

Part (A)(2) applies to feeder wiring, including wiring from an on-site standby generator on the

load side of the final disconnecting means allowed in 695.4(B). This wiring must be divorced from all other wiring, and supply only fire pump and related loads. This wiring must be arranged to avoid damage by fire, structural failures, and operational accidents. Where routed through the building, they must employ construction methods that provide a 2-h fire separation. Options here include 50 mm (2 in.) concrete encasement or in a listed electrical circuit protective assembly such as MI cable installed in accordance with a special protocol, or construction methods that provide an equivalent separation. However, once the wiring arrives in the pump room, the additional protection can be discontinued unless required by 700.10(D). Note that these rules protect the wiring from the building; the rules in (A), in part, protect the building from unprotected wiring.

Part (B) should remove all doubt that the locked-rotor overcurrent protection rules earlier do not imply oversized motor circuit conductors. The sizing here reflects time-honored standard practice with respect to motor circuit conductor sizing. In the example worked previously, the equipment feeder covered in (A) would use the 119 A load (1 AWG wire), and the motor circuit would use 125 percent of 77 A = 96 A, for a 3 AWG wire.

Part (C) waives the overload requirements, for the fire pump only. The only protection will be the short-circuit protection. This is why a tap off of such a feeder is treated as a service conductor for the purpose of defending the building. However, having now protected the tap in this way, the trade-off is that the distance limitations in 240.21 do not apply. In addition, the vault allowance is restored in this citation of 230.6, so the wiring could run through a vault without additional protection. This correlates this section with the rules for engineered systems. In addition, the last sentence facilitates the placement of a fire pump disconnecting means remote from other disconnecting means in cases where it will be fed from feeder circuits instead of being comprised of service conductors. This makes inadvertent contemporaneous operation by the fire service, as covered in 695.4(B)(3)(4), far less of a possibility. (See also [Fig. 695-3](#).)

An example of the problem is that if conventional tap rules are applied to a 4000 A multiple-ended switchboard, even a 3-m (10-ft) tap would need to be 600 kcmil (at least 400 A). Even if the 600 kcmil conductors could be terminated in the fire pump disconnect, the 3-m (10-ft) length limitation would probably leave the fire pump disconnect in the same room. Remember also, 230.6 protects the building from the least protected of all electrical conductors, namely, service conductors. If the tap is run in the same way, surely the building will be equally protected.

An exception applies to battery wiring for cranking engines. In addition, if the standby generator rated current capacity exceeds 225 percent of the fire pump full load current, the **Code** assumes a short-circuit or ground-fault hazard exists on the order of a service exposure. Therefore, in such cases the conductors running between the transfer switch and the generator must comply with 695.6(B) limitations.

Part (D) covers pump wiring methods, which include RMC, IMC, EMT, LFMC, LFNC-B for raceways, and Types MI and MC cables, the latter with an impervious covering. As of the 2014 **NEC**, twist-on wire connectors, along with insulation-piercing connectors and soldered connections are expressly prohibited from the terminal boxes of fire pump motors. Pick another method, and make sure it is listed. Note that 110.14 will come into play given the fine-stranding leads common with most motors. Refer to the extensive coverage in [Chap. 1](#) of this book on that topic.

Part (E) prohibits a fire pump transfer switch and/or a fire pump controller from being used for any other purpose than operating the fire pump equipment.

Part (F) requires wiring from batteries and engine controllers to be protected from damage and be

installed in accordance with directions.

Part **(G)** forbids the use of GFPE “in any fire pump power circuit.” This is absolutely to be distinguished from any upstream feeder, including upstream feeders in campus distributions. If the upstream wiring is subject to GFPE requirements such as 215.10, and the fire pump power circuit happens to fall underneath them, that protection is unimpeded by this rule, which is specific to the fire pump circuit.

Part **(H)** incorporates some of the specific requirements carried in the electrical circuit protective systems, as mentioned in 695.6(A)(2)(d)(3), and as itemized in **NFPA 20** at 9.8.2 and 9.8.3.

Part **(I)** includes six requirements that apply to a junction or pull box through which fire pump wiring passes, whether from or to the fire pump controller. The pull box must, at a minimum (if in the room, and at least equal to the enclosure type for the controller), be “drip-proof” which presumably corresponds to a **NEMA 2** or better enclosure as shown in Table 110.28. The box must be securely mounted and in a way that does not compromise the integrity of the enclosure for the fire pump controller. Terminals, “junction blocks” [presumably power distribution blocks, as covered in 314.28(E)], and wire connectors must be listed. Item (6) on the list directly recalls 695.6(E) and prohibits the same other load wiring from even passing through it.

Part **(J)** covers raceway terminations, and requires the use of hubs with ratings at least equal to that of the controller enclosure for all raceway entries. All installation instructions of the controller manufacturer must be observed and any other alterations of the enclosure beyond the conduit entries as contemplated by the manufacturer are subject to specific approvals by the inspector.

695.7. Voltage Drop. Fire pump voltage as measured at the controller line terminals must not drop more than 15 percent below the normal, that is, the controller rated voltage, during motor starting conditions. In addition, the voltage at the motor controller load terminals while running at 115 percent of full-load current must not fall below 95 percent of the voltage rating of the motor. However, this limitation does not apply for emergency run mechanical starting. The issue in this section is not the fire pump itself; it is the likelihood that under reduced voltage a magnetic contactor would chatter and drop out, preventing the pump from functioning. This is why a mechanical start is exempted from the rule.

695.10. Listed Equipment. Diesel engine fire pump controllers, electric fire pump controllers, electric motors, fire pump power transfer switches, foam pump controllers, and limited-service controllers are to be listed for fire pump duty.

695.12. Equipment Location. Fire pump transfer switches and controllers must be as close as practical and within sight of the fire pump motors they control, and engine drive controllers must be as close as practical to the engines they control. Storage batteries must be up off the floor, secured, and located where they will not be damaged.

All energized equipment must be not less than 300 mm (12 in.) above the floor level. Fire pump control enclosures must be securely mounted on noncombustible surfaces. Fire pump motors often leak water at their main bearings by design, and their control equipment must be mounted or protected to avoid damage from escaping water.

695.14. Control Wiring. External control circuits that leave the fire pump area (the **NEC** says “room” but a room is not an actual Code mandate under the terms of this article) must be fault-tolerant as defined in 695.2, and the loss of power in a control circuit may cause the pump to run continuously after starting but the controller will still be able to initiate a start. Any control conductors in the room

must be protected. The motor must always try to start, and therefore no phase-loss relay or other sensor is permitted to prevent actuation of the contactor. No remote device can be installed that would inhibit the operation of the transfer switch. Engine drive wiring must be stranded and capable of continuously carrying the charging or control loads, and protected from damage.

For electric fire pump control wiring, only RMC, IMC, LFMC, EMT, LFNC, MI cable, and MC cable with an impervious covering are permitted. Note that this list correlates with the list for wiring to the pump itself in 695.6(D). For generator control wiring connecting the transfer switch and the generator, this wiring must be divorced from all other wiring, and protected in a manner to resist damage from fire or collapse. If run through the building, they must be encased in 50 mm (2 in.) of concrete, or other 2-h fire rated assembly dedicated to the pump circuits, or in an electrical circuit protective system with a 2-h rating, and wired in accordance with the rules for the applicable assembly.

The integrity of this wiring must be continuously monitored, and if compromised, visual and audible alarms must activate and the generator must start. An informational note points to the relevant provision in NFPA 20 regarding “fault-tolerant external control circuits.” The same requirement appears in 700.10(D)(3) for generator control wiring on emergency systems.

695.15. Surge Protection. As of the 2017 **NEC**, surge protection must be arranged “in or on” the fire pump controller.

Chapter Seven

ARTICLE 700. EMERGENCY SYSTEMS

700.1. Scope. Note that all the regulations of this article apply to the designated emergency systems. As defined in Sec. 700.2, these are the systems “legally required and classed as emergency by municipal, state, federal, or other codes, or by any governmental agency having jurisdiction.” *The NEC, itself, does not require emergency light, power, or exit signs.*

The effect of this definition is to exclude from all these rules any emergency circuits, systems, or equipment that is installed on a premises but is not legally mandated for the premises. Of course, any emergency provisions that are provided at the option of the designer (or the client) must necessarily conform to all other **NEC** regulations that apply to the work.

The placement or location of exit lights is not a function of the **National Electrical Code** but is covered in the Life Safety Code, **NFPA** No. 101-2012. But where exit lights are required by law, the **NEC** considers them to be parts of the emergency system. The **NEC** indicates how the installation will be made, not where the emergency lighting is required, except as specified in Part **III** of Art. 517 for essential electrical systems in health care facilities.

An emergency lighting system in a theater or other place of public assembly includes exit signs, the chief purpose of which is to indicate the location of the exits, and lighting equipment commonly called “emergency lights,” the purpose of which is to provide sufficient illumination in the auditorium, corridors, lobbies, passageways, stairways, and fire escapes to enable persons to leave the building safely ([Fig. 700-1](#)).

Fig. 700-1. Exit lights and wall-hanging battery-pack emergency lighting units are covered by Art. 700 whenever such equipment or provisions for emergency application are legally required by governmental authorities. (Sec. 700.1.)

These details, as well as the various classes of buildings in which emergency lighting is required, are left to be determined by state or municipal codes, and where such codes are in effect, the following provisions apply.

As indicated in the informational note following the definition, an emergency system to supply loads classified as emergency in nature by virtue of such a building code or related provision is required to function at all times. Emergency loads do not lose their status as emergency loads just because the generator or other backup source is not running. If a fire is in progress at one end of the building, and the normal wiring system has not yet been compromised, the exit signs still need to work just as well as when the generator is the source of supply. Therefore, all the rules in this article apply to those loads regardless of the status of backup power equipment. This discussion will come up again in 700.32.

700.3. Tests and Maintenance. Part (A) of 700.4 calls for inspection of an operational test at the time of system installation and commissioning, generally referred to as an acceptance test *and* operational testing at periodic intervals thereafter. The frequency of these witnessed tests is to be determined by the local inspection authority [part (B)]. Part (D) requires documentation of such tests. Part (C), broadened in the 2017 **NEC** from a focus on batteries to all emergency system equipment, requires maintenance, to be enforced by the AHJ, of all emergency system equipment, including the batteries that start prime movers and those contained within unit equipment. Emergency systems must be tested “during maximum anticipated load conditions,” as called for in part (E). Testing under less than full-load conditions can be misleading and is not a true test. Part (D) requires written documentation of testing and maintenance.

There has been a requirement, formerly residing in 700.4(B) as a third paragraph, that an alternate source must be available when the emergency generator is out of service for major maintenance or repair. The 2017 **NEC** no longer has that paragraph, and instead includes almost a full column and a half [as Part (F)] of prescriptive text and a graphic to cover the same ground. The basic requirement applies to any location where the alternate source of power is a single generator, and in such cases the site wiring must include a permanently wired switching arrangement and a method of connection of the temporary alternate source. One example would be a permanently wired inlet, with either a conventional or pin-and-sleeve configuration of appropriate rating. The inlet (or other connection point) must be marked to provide notice of the phase rotation and system bonding requirements. The switching can be done manually, but in the event of emergency conditions, the allowable pick-up time for the temporary alternate source must still meet the 10-s parameter in 700.12. The switching method must also preclude an inadvertent interconnection of sources. To add flexibility and ongoing utility for the hard-wired temporary standby connection point, there is express permission to utilize this point for a load bank connection.

These provisions come with a one-line diagram showing a typical compliant arrangement, and also with a detailed exception that provides four options to avoid the new requirement. The first is to demonstrate that for any process or load that relies on the emergency source being available, that function is capable of being disabled during the major maintenance or repair. The second is for an unoccupied building, with the additional condition that any sprinkler (or equal) system will remain operational. For example, a dry system reliant on compressed air would need to qualify under a different provision. Other temporary (unspecified) means are permitted, obviously with the inspector's approval. Finally, and almost not needing to be said, where there is a permanent additional source the need for the connections goes away. In this case, the system would presumably not fall within the triggering provisions ("relies on a single alternate source of power") and qualify for exemption on that basis.

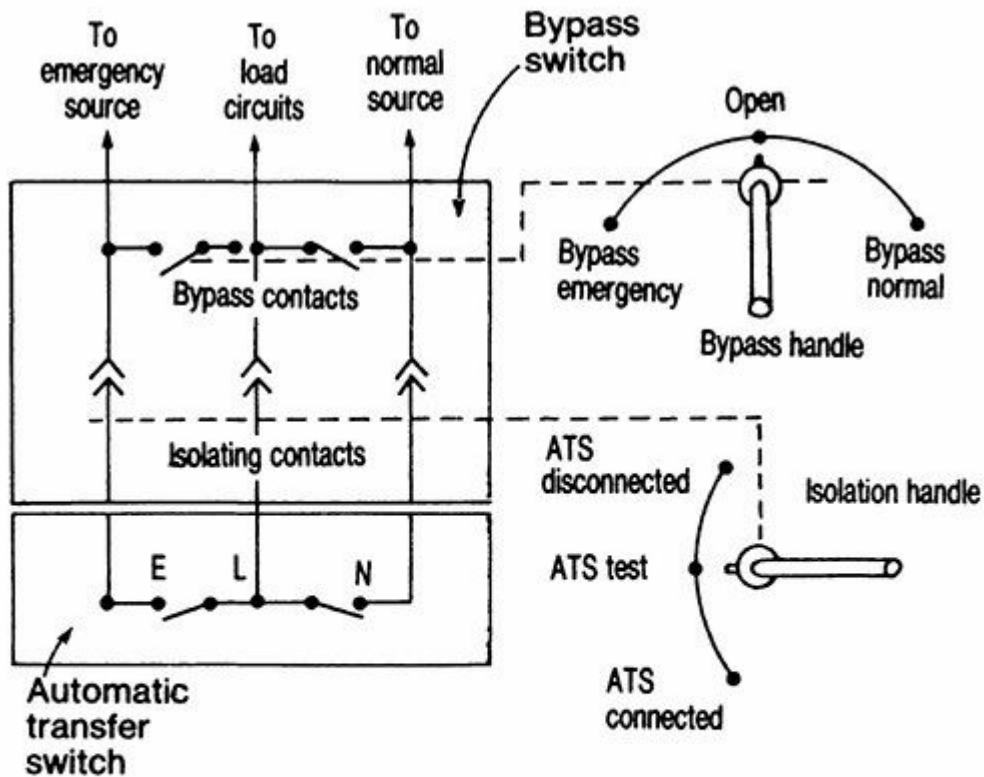

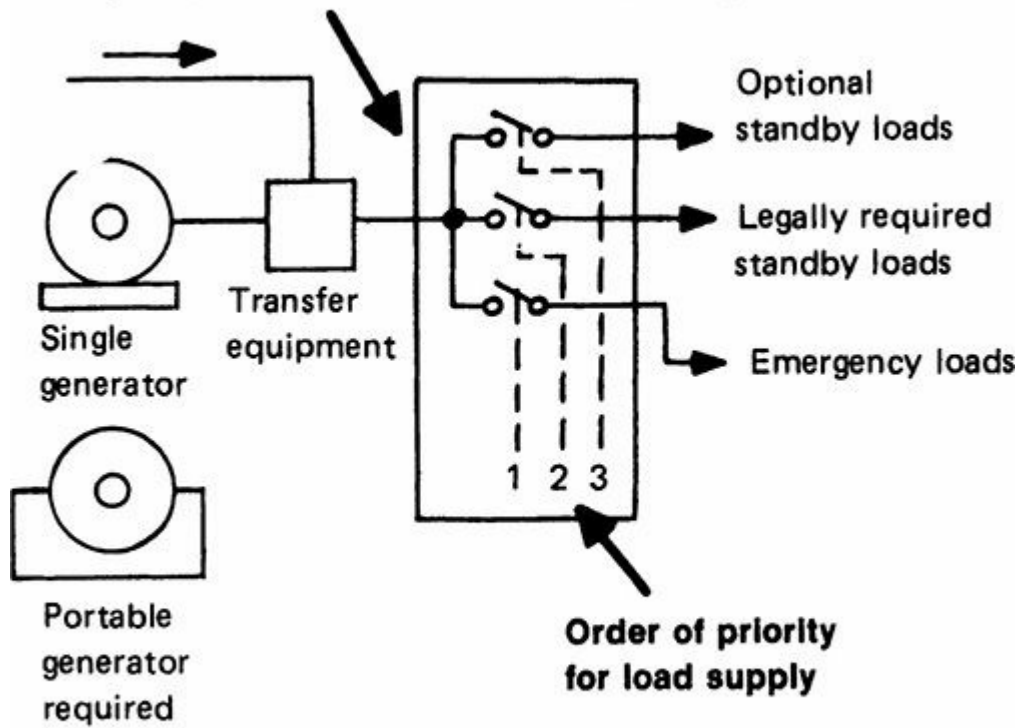

700.4. Capacity. It is extremely important that the supply source be of adequate capacity. There are two main reasons for adequate capacity:

1. It is important that power be available for the necessary supply to exit lights and emergency and egress lighting, as well as to operate such equipment as required for elevators and other equipment connected to the emergency system.
2. In such occupancies as hospitals, there may be a need for an emergency supply for lighting in hospital operating rooms, and also for such equipment as inhalators, iron lungs, and incubators.

It is also essential for safety and effective, long-time, successful operation of emergency system equipment that it be rated to sustain the maximum available short circuit that the supply circuit could deliver at the terminals of the equipment.

Part (B) of this section permits one generator to be used as a single power source to supply emergency loads, essential (legally required) standby loads, and optional standby loads when control arrangements for *selective* load pickup and load shedding are provided to ensure that adequate power is available first for emergency loads, then legally required standby loads, and finally optional standby loads. [See [Fig. 700-2](#) (top) and Arts. 701 and 702.]

Pickup and shedding controller to match generator capacity to load demands—with priority of selection

2-WAY BYPASS ISOLATION SYSTEM

NOTE: Diagram shows only the power (load current) paths through bypass switch and transfer switch.

Fig. 700-2. Special load-control must be used where a single generator supplies emergency and standby loads (top). And a bypass switch may be used to isolate an automatic transfer switch. (Secs. 700.4 and 700.5.)

There is an important difference between how this article and Art. 517 handle the question of automatic load shedding and mandated provisions for selective load pickup. As covered in 517.31(B)(1), if there will be non-Art. 517 loads supplied by a generator, there must be one or more separate transfer switches for those loads [agrees with 700.5(D)] and there must be automatic load control regardless of the generator capacity. That last part of the rule is more severe than the one here, which waives the automatic load control provisions on a showing of adequate capacity, which could be determined by an Art. 220 load calculation.

An on-site generator may be used for peak load shaving, in addition to its use for supplying emergency legally required standby and optional standby loads. The title of part (B) refers to “Peak Load Shaving,” which is recognized as a function of the generator in the last sentence of the paragraph. For peak shaving use, however, the generator must be equipped with the selective load-control equipment described in the paragraph to ensure the order of priority for various purposes. The second paragraph essentially permits the peak load shaving operation to satisfy the testing and maintenance requirements of 700.3.

Generators used for peak load reductions often have the virtue of being routinely exercised under load for significant periods. This increases their overall reliability because any maintenance deficiencies tend to become apparent prior to an emergency.

700.5. Transfer Equipment. Any switch or other control device that transfers emergency loads from the normal power source of a system to the emergency power supply *must* operate automatically on loss of the normal supply. Transfer equipment must also be automatic for legally required standby systems, as covered in 701.5, but a manual transfer switch may be used for switching loads from the normal to an optional standby power source, as in 702.5. The transfer switch must also be listed for emergency use. Listed switches are now available for use on medium-voltage systems, and therefore the voltage limitation on the listing requirement has been removed as of the 2017 **NEC**.

As described in part (B), a bypass switch is recognized on an automatic transfer switch (ATS) to provide for repair or maintenance of the ATS (Fig. 700-2, bottom). Because hospitals and many industrial systems contain transfer switches that cannot be shut down, some means is required to isolate a transfer switch for routine maintenance or for some specific task like contact replacement. When a bypass switch is used, inadvertent parallel operation must not be possible.

Part (C) requires that transfer switches be electrically operated and mechanically held. This ensures that the contacts stay closed in the event of a coil failure, or a temporary loss of voltage in the control circuit directing the emergency connection resulted in a generator running full speed and not picking up the load. This way the switch stays held where it belongs until an affirmative unlatch signal comes in conjunction with a normal system latch command.

Part (D) requires transfer switches that are used in emergency systems to be used exclusively for this purpose and supply no other load. This is the case even in instances where multiple systems are supplied from a single generator. Note that this is a direct conflict with the permission granted in 517.31(B)(2) in small hospital facilities. See the discussion under that heading, and also the discussion at 700.4(B) regarding a related issue where the rule in 517.31(B)(3) is more severe than the requirements here.

Part (E) requires transfer equipment to be field marked on its exterior with its short-circuit current rating. The field marking is required because the characteristics of the applied upstream overcurrent protection will affect the rating.

700.6. Signals. In order to be effective, the signal devices should be located in some room where an attendant is on duty. Lamps may readily be used as signals to indicate the position of an automatic switching device. An audible signal in any place of public assembly should not be so located or of such a character that it will cause a general alarm.

The standard signal equipment furnished by a typical battery manufacturer with a 60-cell battery for emergency lighting includes an indicating lamp, which is lighted when the charger is operating at the high rate, and a voltmeter marked in three colored sections indicating (1) that the battery is not being charged or is discharging into the emergency system, (2) that the battery is being trickle charged, or (3) that the battery is being charged at the high rate. This last indication duplicates the indication given by the lamp.

Part **(D)** of this section requires the use of a hookup for ground-fault indication on the output of a grounded-wye 480/277V generator. 700.31 states that emergency systems do not require ground-fault protection of equipment. Yet when the load is served by the emergency source, the possibility of a ground fault is no less than when the load is served by the utility source. Should a ground fault occur within the emergency system during a power failure, it is debatable whether essential loads should be immediately disconnected from the emergency power supply. However, for reasons of safety and to minimize the possibility of fire and equipment damage, at least an alarm should indicate if a hazardous ground-fault condition exists, so appropriate corrective steps will be initiated. When ground-fault indication is used on the generator output, the fault sensor must be located within or on the line side of the generator main disconnect. For a large facility with multiple generators connected with a paralleling bus, the neutral-ground bond cannot be located at or ahead of the main. The rule also makes it mandatory to have specific instructions for dealing with ground-fault conditions. (Refer to 700.31 and [Fig. 700-17](#).)

700.7. Signs. A sign at the service entrance is required to designate the type and location of emergency power source(s). This sign, however, need not display information regarding individual unit equipment as shown in [Fig. 700-1](#) for obvious reasons. Part **(B)** requires that if the grounded circuit conductor from an emergency source is connected to a grounding electrode conductor anywhere except at that source, then a sign must be posted at the location of the remote grounding connection identifying all emergency and normal sources connected at that location. Figure 700-3 explains the issue.

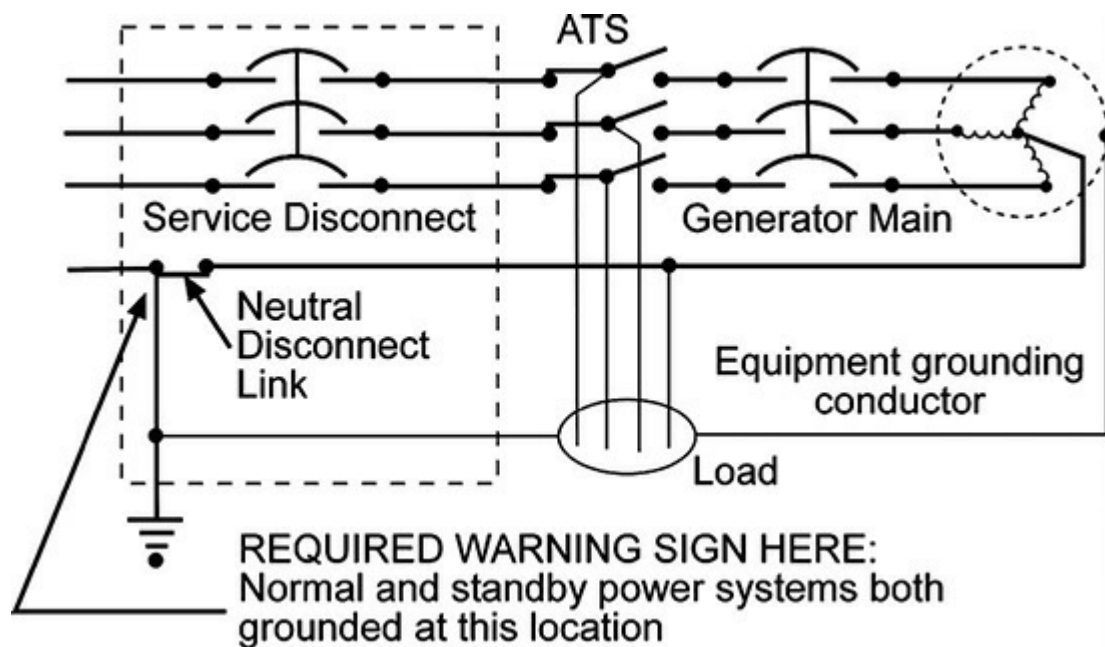

Fig. 700-3. This emergency system is not separately derived and with the generator supplying the load, an open neutral disconnect link will unground the system. [Sec. 700.7(B).]

This requirement resulted from an actual case where the emergency source was supplying power, and during that period maintenance personnel disconnected the normal source grounded conductor for testing purposes. The personnel did not realize that they were also disconnecting the grounding connection for the emergency source at the same time, since the grounded system conductor was only connected to the grounding electrode conductor in the main switchboard. The **NEC** now specifies the wording for this sign.

700.8. Surge Protection. As of the 2014 **NEC**, a listed SPD is required in every Art. 700 switchboard and panelboard. This wording was not correlated with the addition of the term “switchgear” throughout the **NEC**, but the oversight remains to be corrected and it should be applied in any event.

700.10. Wiring, Emergency System. Part (A) requires that all boxes and enclosures for emergency circuits must be readily identified as parts of the emergency system. Labels, signs, or some other *permanent* marking must be used on all enclosures containing emergency circuits to “readily” identify them as components of an emergency system. The “boxes and enclosures” that must be marked include enclosures for transfer switches, generators, and power panels. *All* boxes and enclosures for emergency circuits must be painted red, marked with red labels saying “Emergency Circuits,” or marked in some other manner clearly identifiable to electricians or maintenance personnel (Fig. 700-4, top). The 2017 **NEC** dramatically expanded this rule by requiring any receptacles connected to an emergency system have an equivalent marking, using a distinctive color, either on the device or on the faceplate. In addition, all exposed wiring, whether cable or raceway, must also be identifiable by a periodic marking, at intervals not to exceed 25 ft. At least one manufacturer already has red (and other colors) EMT on the market.

Fig. 700-4. Emergency wiring may not be run in enclosures with wiring for nonemergency circuits, and emergency enclosures must be marked. (Sec. 700.9.)

The bottom of [Fig. 700-4](#) shows a clear violation of the rule of part **(B)** because the wiring to the emergency light (or to an exit light, which is classed as an emergency light) is run in the same raceway and boxes as the wiring to the decorative floodlight.

This section requires that the wiring for emergency systems be kept entirely independent of the regular wiring used for lighting, and it thus needs to be in separate raceways, cables, and boxes. This requirement is to ensure that where faults may occur on the regular wiring, they will not affect the emergency system wiring, as it will be in a separate enclosure.

Part **(B)(1)** for transfer switches is intended to permit normal supply conductors to be brought into the transfer-switch enclosure and to specify that these conductors would be the only ones within the transfer-switch enclosure that were not part of the emergency system. Parts **(B)(2)** and **(3)** permit two sources supplying emergency or exit lighting to enter the luminaire, or a load control relay as covered in 700.26, and its common junction box. Part **(B)(4)** also allows a "common junction box" on unit equipment to contain both emergency and nonemergency circuits.

Part **(B)(5)** allows wiring from a common source location to supply both emergency and nonemergency load distributions. This provision is very poorly written in that there is no parent

language to lay out how the four provisions go together, but based on its history it appears that the four provisions are intended to be read as one rule with differing particulars. In effect, the Art. 700 function is permitted to coexist in the same conductor set with Art. 701 and Art. 702 functions, and the system separation rules do not take effect until that point in the wiring system where the load on a particular set of conductors becomes exclusively Art. 700 in character. Sec. 700.10(B)(5) provides great flexibility as to where that is permitted to occur. This recognizes that many enterprises maintain fully functioning standby power generation capable of serving the entire standby needs of the facility, and any attempt to prematurely divorce emergency circuits from one of these distributions could actually decrease reliability by reducing supply diversity. This follows from the parent wording “to supply emergency and other (nonemergency) loads.” The parenthetical word “nonemergency,” added in the 2017 **NEC**, proves that the separation rules in 700.10 do not apply ahead of the point where a particular set of loads becomes uniquely emergency in character.

Item “a.” recognizes separate vertical switchboard (or switchgear) sections, with or without a common power bus, or in a sequence of disconnects mounted in separate enclosures. In these cases, the separation rules begin at the one or more vertical section(s) of a switchboard that is/are to supply Art. 700 loads, or in the one or more disconnect enclosure(s) that serve(s) Art. 700 loads. The common power bus of the switchboard and the wiring that supplies it are permitted to transmit power for any mixture of power needs, as would the common feeder supplying a line-up of individual disconnects through a wireway with taps extending to each.

Item “b.” says that those switchboard (or switchgear) sections and enclosures, whether singular or plural, can be supplied by single or multiple feeders based on the tap rules in 240.21(G) that do not require overcurrent protection at the line side of a generator tap, provided they are sized at 115 percent of the generator capacity. This is now covered in a separate paragraph with its own graphic (1) to illustrate this point. The second paragraph shows how to achieve the same result with an overcurrent device ahead of the bus, and a graphic (2) to illustrate this arrangement. In this event, the only additional requirement is that the one or more nonemergency overcurrent device(s) selectively coordinate with the upstream device. With that having been established, any fault below the level of the common bus will be isolated from tripping the common OCPD and taking down the emergency system.

Item “c.” clarifies that although the feeders addressed in these provisions can carry a mixture of loads, a vertical switchboard section or a separate enclosure is prohibited from supplying a mixture of loads. At this point of separation, Art. 700 circuits must be fully divorced from other loads, except where otherwise permitted in 700.10(B)(1-4).

Item “d.” is new as of the 2011 **NEC** and carries the basic concepts developed here to another level. In general “distribution equipment” can intervene between an emergency source and where the separation is made. It serves to recognize in particular multibuilding installations with centralized generating facilities, including medium-voltage generating facilities, which have intervening distribution equipment, including transformation, placed well before any subdivision that produces unique Art. 700 load profiles.

Part (C) is motherhood and apple pie wording advising care in the system design to minimize their likelihood of damage. Part (D), however is an entire set of rules regarding the physical separation of emergency system components in order to increase the reliability of the system in higher-hazard exposures. These locations are defined in the parent text as assembly occupancies with an occupancy load of not less than 1000 persons, and also high-rise buildings over 23 m (75 ft) high. As of the 2014

NEC the former list of occupancy classifications (assembly, educational, etc.) has been removed, so the enhanced separation rules apply in any building of the designated height. As of the 2017 **NEC**, two other classifications join the list, educational facilities with an occupancy load over 300 people, and health care occupancies serving patients incapable of self-preservation. The enhanced separation rules divide into two categories, the first for feeder circuits [never branch circuits except as in (D)(3)] and the second for distribution equipment fed by the emergency system feeders. In evaluating the various options do not be confused by beam spray products commonly applied to steel framing. These products are intended to prevent the deflection of those members at high temperatures, and as such keep the steel below temperatures in the range of 540°C (1000°F). At such temperatures an electrical circuit in conventional wiring will be lucky to survive 1 or 2 min.

Part **(D)(1)** on feeders provides five options for protection as follows (somewhat simplified): (1) Run them within an area fully protected by sprinklers. This means the area and not the feeder; an emergency system feeder run above a suspended ceiling does not need the sprinklers to spray on the feeder, only that the area involved meet the requirements in **NFPA 13** or similar as a fully protected space. (2) Run them as a listed electrical circuit protective system with a minimum 2-h rating. These systems require great attention to detail and involve some surprising aspects. Refer to more detailed coverage in this book at 728.4.

Other possibilities include: (3) Install them in a listed fire-resistive cable system. These systems may be evaluated for a 2-h fire exposure, but not necessarily so. The previous wording (2014 **NEC**) mandated a 2-h classification; that criterion was omitted, apparently by mistake, from the 2017 **NEC**. The parent language was under discussion for a global 2-hour requirement, but that did not proceed because the last item (concrete encasement) may not always be, strictly speaking, a 2-h fire barrier. So, the 2-h rule didn't make it into the parent language, and it appears the panel forgot to revisit this line item and include it. It was always intended to be a 2-h condition. Until this is fixed, there is a way to get this back to 2-h. The second informational note in 728.4 specifically identifies fire-resistive cable systems as part of an electrical circuit protective system, and as previously noted here these systems, in turn, are subject to a 2-h minimum requirement. (4) Install them with a listed fire-rated assembly defined in the applicable UL literature as having the required time parameter, such as multiple layers of drywall in accordance with detailed installation criteria. (5) Embed them within 50 mm (2 in.) of concrete.

Part **(D)(2)** on distribution equipment requires panelboard, transformers, transfer switches, and comparable equipment to either be in a space with full sprinkler protection, or in a space with a 2-h fire-resistive rating. Part **(D)(3)** requires generator control wiring running between a transfer switch and its generator to be kept segregated from all other wiring, and to meet one of the feeder protective schemes covered in (D)(1). As of the 2017 **NEC**, the integrity of this wiring must be continuously monitored, and if compromised, visual and audible alarms must activate and the generator must start. The same requirement appears in 695.14 for generator control wiring for fire pumps.

700.12. General Requirements. This section lists and describes the types of emergency supply systems that are acceptable—with one or more of such systems required where emergency supply is mandated by law. It specifies that the normal-to-emergency transfer must not exceed 10 s. It also repeats the generic language of 700.10(C) regarding avoidance of hazards in terms of siting this equipment.

The last paragraph presents important information on protection of emergency power sources for

certain occupancies. Inexplicably, and apparently through oversight, this paragraph has never been correlated with the changes in 700.10(D) that struck out the list of occupancy classes within the high-rise building classification. So, on the literal text, this requirement only applies in the designated occupancy classes. Such protection may be provided by (1) automatic sprinkler or (2) enclosing the equipment in a room with 1-h fire-rated walls. It quite logically makes the generator subject to the same rules as apply to the transformers, transfer switches, and panelboards supplied by it in accordance with 700.10(D)(2), except that the protection parameter is reduced by an hour [1-h fire resistance here, vs. 2-h fire resistance for feeders and equipment covered by 700.10(D)]; in both locations, however, a fully sprinklered building results in a full waiver.

Part (A) recognizes storage batteries for an emergency source. A storage battery for emergency power must maintain *voltage to the load* at not less than 87½ percent of the normal rated value. This was changed from “87½ percent of system voltage” (i.e., battery voltage) because the concern is to keep the voltage to the lamps at 87½ percent. The “electronics” between the battery and the lamps maintain the required “load voltage,” and the battery voltage is not in itself the major concern. Automotive batteries are not permitted.

Part (B) covers use of engine-generator sets for emergency supply as an alternate to utility supply. Engine-driven generators (diesel, gasoline, or gas) are commonly used to provide an alternate source of emergency or standby power when normal utility power fails. Gas-turbine generators are also used. Note that the system may delay a retransfer to normal power for up to 15 min to avoid damaging short-time operation, especially of internal combustion prime movers.

The first step in selecting an on-site generator is to consider applicable requirements of the **National Electrical Code**, which differ depending on whether the generating set is to function as an emergency system, as a standby power system, or as a power source in a health care facility such as a hospital.

For example, an *internal-combustion*-type engine-generator set selected for use under Art. 700 must be provided with *automatic starting and, if required by 700.4(B), automatic load transfer*, with enough on-site fuel to power the full demand load for at least 2 h (Fig. 700-5). If a standby power system selected under the regulations of Art. 701 is *legally* required, it must be provided with enough on-site fuel to power the full demand operation of the load for *not less than 2 h*. Note that 700.12(B)(2) specifically requires that fuel transfer pumps that run fuel to the generator day tank be connected to the emergency system for the obvious reason that if that tank runs out of fuel, the generator stops. This rule had been overlooked for legally required standby systems in 701.12(B)(2), but this was corrected in the 2011 **NEC**.

Fig. 700-5. Generator must have automatic start and adequate fuel supply. (Sec. 700.12.)

In part **(B)(3)**, the engine driving an emergency generator must not be dependent on a public water supply for its cooling. That means a roof tank or other on-site water supply must be used and its pumps connected to the emergency source ([Fig. 700-6](#)).

Fig. 700-6. Engine cooling for an emergency generator set must be ensured for continuous operation of the generator. (Sec. 700.12.)

An exception in part **(B)(3)** permits use of a utility gas supply to the engine of an emergency generator—at the discretion of the local inspector—where simultaneous outage of both electric power and gas supply is highly unlikely.

As required by part **(B)(4)**, a battery used with a generator set must have adequate capacity whether it cranks the generator for starting or is simply used for control and signal power for another

means (such as compressed air) for starting the generator. A separate charging system must be provided, and this system, together with the circuit (if used) powering ventilation dampers for the generator set must be connected to the emergency system. In this way the generator will keep the circuits functioning that are essential to its continued operation.

Part **(B)(5)** of this section requires another power supply to pick up an emergency load in not over 10 s where the main generator cannot come up to power output in 10 s.

Part **(B)(6)** amends the rules in 225.32 that require a disconnecting means for conductors supplying a building or structure to be located at a readily accessible location nearest the point where the conductors enter the building. For emergency generators, the disconnect(s) on the generator, if suitable in accordance with 445.18, can serve as the disconnect at the building, provided the generator (and its disconnect) is within sight (and therefore not over 15 m [50 ft] distant). Remember, 445.18 now allows for a generator shutdown switch as a disconnecting method provided it renders the generator incapable of restarting and it can be locked in the OFF position. A new (2011) exception makes the existing 225.32 Exception No. 1 covering qualified supervision and safe switching procedures apply to emergency generator disconnects. This will provide some flexibility and relief, particularly in crowded real estate markets where the 50-ft limit is difficult. At the point in the building where the generator conductors eventually terminate, they must do so at a switch that is compliant with 225.36. Note that 225.36 has evolved and no longer requires an SUSE rating.

Part **(C)** allows an uninterruptible power supply to supply emergency power, provided battery capacity satisfies part **(A)**, and if a generator is also used—which is generally the case—it must satisfy part **(B)**.

As recognized by part **(D)**, two separate services brought to different locations in the building are always preferable, and these services should at least receive their supply from separate transformers where this is practicable. In some localities, municipal ordinances require either two services from independent sources of supply, auxiliary supply for emergency lighting from a storage battery, or a generator driven by a steam turbine, internal-combustion engine, or other prime mover. Figure 700-7 shows two different forms of the separate-service type of emergency supply. The method at bottom makes use of two sources of emergency input. This method requires the authorization of the AHJ. In many jurisdictions this approval is routinely denied based on common experience that utility outages usually involve significant areas, and even two services from different transformers would seldom make a difference.

Separate Emergency Service

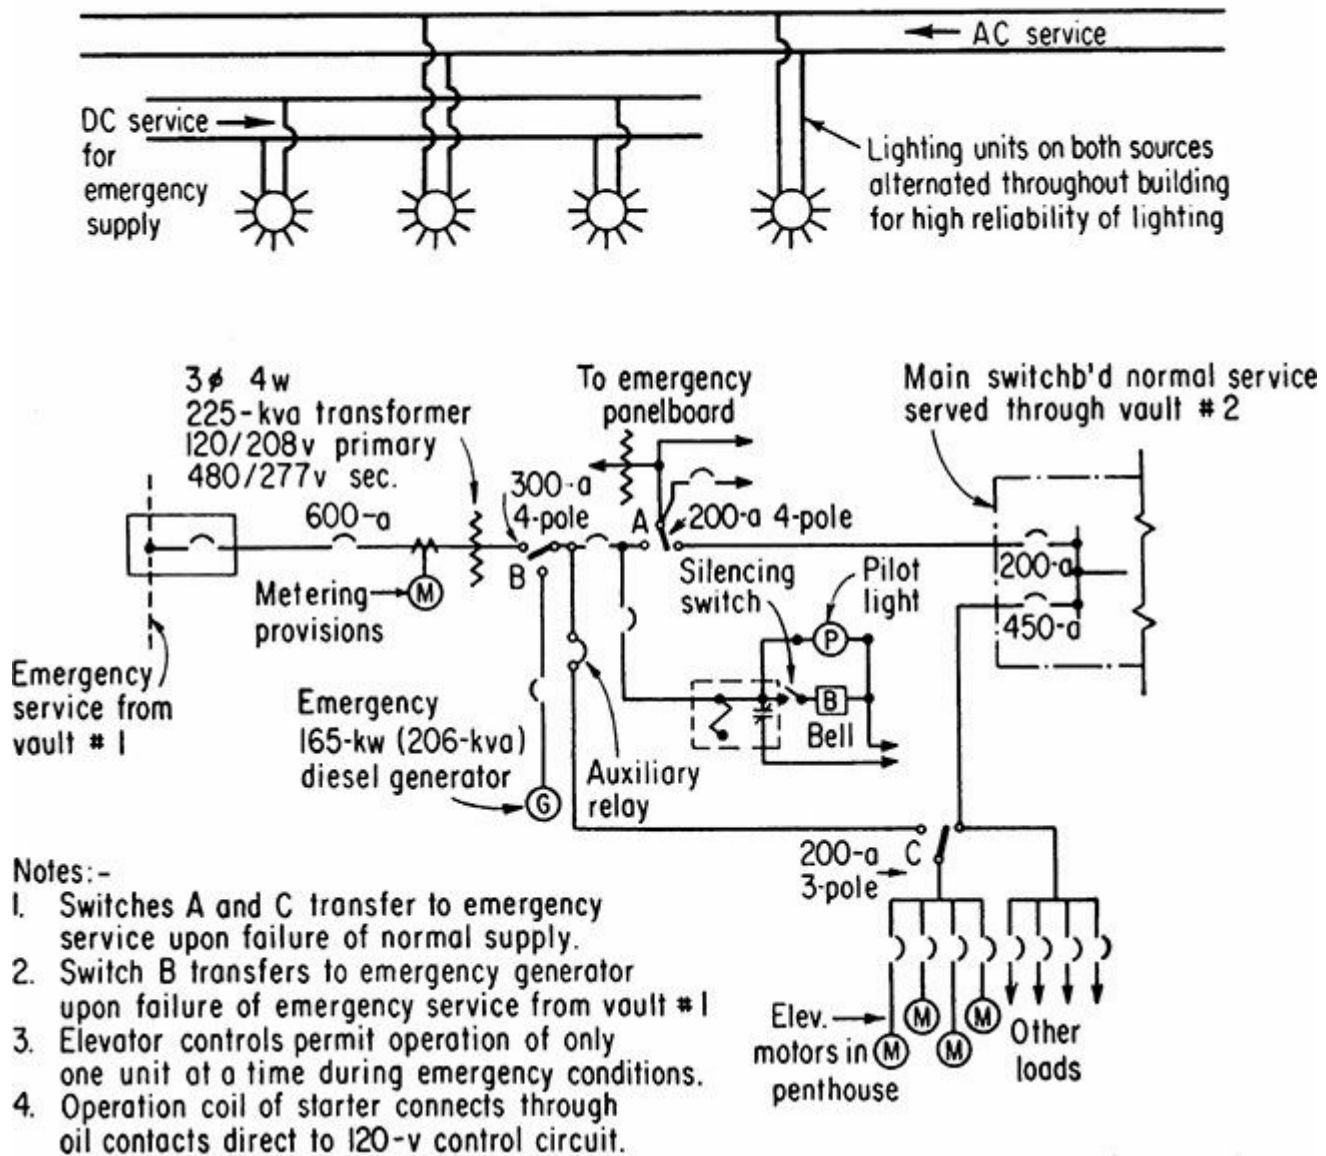

Fig. 700-7. Dual-service emergency provisions can take many different forms. (Sec. 700.12.)

The method shown in [Fig. 700-8](#) was recognized in previous Codes as a means of providing emergency power. However, this permission in the **NEC** was at odds with the **NFPA's Life Safety Code**. In an effort to harmonize the two standards, this permission was deleted in the 1996 **NEC**. Under that arrangement, in [Fig. 700-8](#), the tap ahead of the main could have supplied the emergency panel directly without need for the transfer switch, but this is no longer permitted.

Fig. 700-8. A tap ahead of the service main protects only against internal failures and is no longer recognized. (Sec. 700.12.)

Note that fire pumps use connections ahead of the main routinely in instances where service conductors are accessible to the protected building. Authorities disagree as to whether a fire pump is an Art. 700 load. Fire pumps are generally classified as part of a system for property protection, allowing sprinkler systems to work properly in order to limit the degree of damage from a fire. Sprinklers do not help people find their way out of a burning building. On the other hand, statistics show that buildings protected with sprinklers have better loss experience in terms of fire related injuries and fatalities. Some local regulations do classify fire pump loads as emergency loads, which would require an on-site generator regardless of any finding as to reliability of the local service (review the discussion at 695.3 on this point). Review the local requirements in order to make this decision.

Part (E) recognizes the use of a fuel cell power system to supply the emergency loads provided it has adequate capacity to supply the entire load for not less than 2 h. The second paragraph reiterates the need for compliance with Art. 692, Parts II through IV, which covers the installation of fuel cell systems. The last paragraph of 700.12(E) puts forth a prohibition against using a single fuel cell system as both a normal and emergency source. In such a case, some other means of supply must be provided to power the emergency loads. The source may be another fuel cell system, a generator, a separate service, etc.

Part (F) covers typical wall-hanging battery-pack emergency lighting units, as shown in Fig. 700-9. The 1971 NEC accepted only connection of emergency light units by means of fixed wiring. Part (F) now recognizes permanent wiring connection *or* cord-and-plug connection to a receptacle.

Fig. 700-9. Unit emergency lights may serve as required source of emergency supply. (Sec. 700.12.)

Even though the unit equipment is allowed to be hooked up with flexible cord-and-plug connection, it is still necessary that the unit equipment be permanently fixed in place.

Individual unit equipment provides emergency illumination only for the area in which it is installed; therefore, it is not necessary to carry a circuit back to the service equipment to feed the unit. This section clearly indicates that the branch circuit feeding the normal lighting in the area to be served is the same circuit that should supply the unit equipment.

In part (F) the intent of the 87½ percent value is to ensure proper *lighting output* from lamps supplied by unit equipment. It is generally considered acceptable to design equipment that will produce acceptable lighting levels for the required 1½ h, even though the 87½ percent rating of the battery would not be maintained during this period. The objective is adequate light output to permit safe egress from buildings in emergencies. The UL Guide Card information for this equipment puts it this way: “Emergency power equipment with batteries provides 90 minutes (more if so marked) of rated operating power for emergency lighting equipment (integral or remote) sufficient to meet the illuminance performance requirements of ANSI/NFPA 101 and the IBC, when installed as part of a facility’s emergency lighting system.”

As shown at the top of Fig. 700-10, a battery-pack emergency unit must not be connected on the load side of a local wall switch that controls the supply to the unit or the receptacle into which the emergency unit is plugged. Such an arrangement exposes the emergency unit to accidental energization of the lamps and draining of the battery supply. But, as permitted by the exception, if a panelboard supplies at least three normal lighting circuits for a given area, and they are not part of a multiwire branch circuit, emergency battery-pack lighting units for that area may be connected to a separate branch circuit from the panel, with lock-on provision for that circuit.

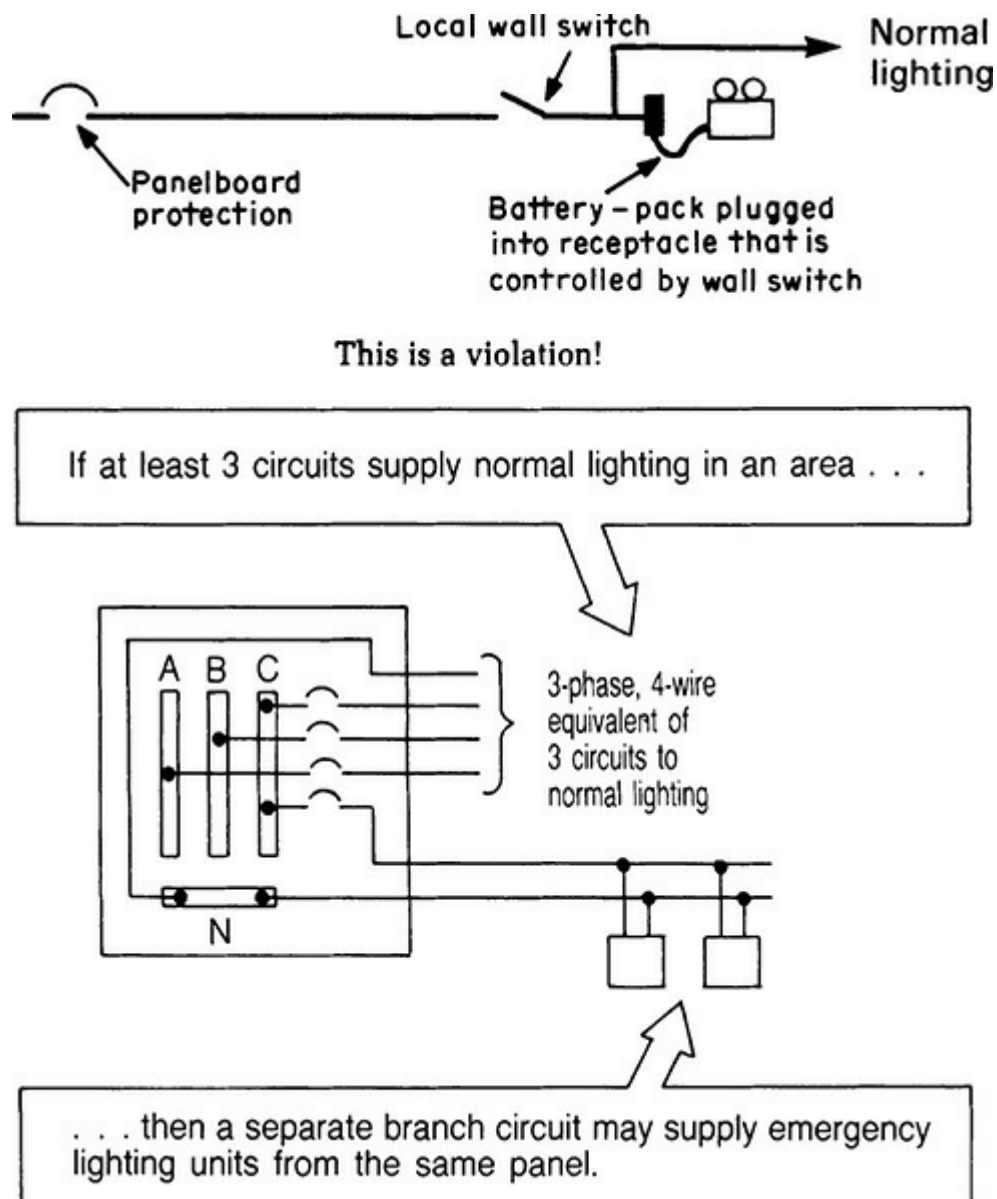

Fig. 700-10. Circuiting of battery-pack emergency lighting may be on normal lighting circuit or separate circuit. The minimum of three circuits must not be multiwired. (Sec. 700.12.)

The multiwire prohibition originated in the 2014 **NEC** and responds to current requirements for multiwire circuits to have a common disconnecting means. When three circuits require three different faults to put an area into darkness, the odds are pretty good that the only time the area is dark is when the panel itself has lost power and the emergency lighting has activated. A common disconnect means that only a single fault would trip the same three circuits, thereby defeating the objective of the requirement.

Note that whatever source is used to supply this equipment, the circuit directory covered in 408.4 must clearly identify the source circuit. The three-circuit allowance is an exception to the rule of the previous paragraph, which says that unit equipment must be connected on a branch circuit supplying normal lighting in the area. By allowing unit equipment on a separate branch circuit from the same panel, the unit equipment will sense loss of power to the panel and activate. The advantage of such application from a design standpoint is that there is no need to observe the rule that the unit equipment must be “connected ahead of any local switches,” which applies when unit equipment is connected on normal lighting circuits. The final paragraph recognizes that a remote head fed from unit equipment is permitted to light the other side (and therefore the egress pathway) of an exit door from a protected

space.

700.15. Loads on Emergency Branch Circuits. Figure 700-11 shows a clear violation of this rule, because appliances are excluded from emergency lighting circuits.

Fig. 700-11. The water cooler may not be on an emergency circuit. (Sec. 700.15.)

700.16. Emergency Illumination. Note that all exit lights are designated as part of the emergency lighting, and, as such, their circuiting must conform to 700.17. As of the 2014 **NEC**, emergency illumination at indoor service and building disconnecting means locations is required if emergency illumination is provided for the interior of the building or structure. Referring to the definition in 700.2, the literal text of this requirement applies even to a building whose sole emergency lighting system is entirely comprised of unit equipment, even a single instance.

Where HID lighting is the *sole* source of *normal* illumination, the emergency light system must continue to operate for a sufficient time after return of normal power to enable the HID lighting to come up to brightness. This rule in the third paragraph is intended to prevent the condition that return of normal power and the disconnect of the emergency lighting leave the building in darkness because of the inherent, normal time delay in the light output upon energizing HID lamps. The exception after that rule permits “alternative means” to keep emergency lighting on. This often involves special HID luminaires that incorporate auxiliary tungsten-halogen incandescent lamps within them that come on immediately and shut off when the HID lamp comes up to brightness.

700.17. Branch Circuits for Emergency Lighting. Figure 700-12 shows the basic rule on transfer of emergency lighting from the normal source to the emergency source. If a single emergency system is installed, a transfer switch should be provided, which, in case of failure of the source of supply on which the system is operating, will automatically transfer the emergency system to the other source. Where the two sources of supply are two services, the single emergency system may normally operate on either source, as in [Fig. 700-13](#). Where the two sources of supply are one service and a storage battery, or one service and a generator set, as in [Fig. 700-12](#), the single emergency system would, as a general rule, be operated normally on the service, using the battery or generator only as a reserve in case of failure of the service. Figure 700-14 shows an emergency hookup that has two separate supplies tied into the emergency lighting system.

Fig. 700-12. Emergency lighting is automatically switched from normal service to the battery or generator. (Sec. 700.17.)

Fig. 700-13. Emergency lighting may be supplied from an emergency service. (Sec. 700.17.)

Fig. 700-14. A single emergency lighting system may be fed from two services. (Sec. 700.17.)

Part (2) of this section provides rules for use of two or more “branch circuits supplied from separate and complete” systems with independent power sources, of which one is from the emergency system, and one is permitted to be part of the normal distribution. If two emergency lighting systems are installed, each system should operate on a separate source of supply, as where each emergency disconnect in Fig. 700-13 feeds a separate, independent emergency lighting system. Either both systems should be kept in operation or switches should be provided that would automatically place either system in operation upon failure of the other system.

Watch Out! Both (1) and (2) as changed in the 2011 **NEC**, together with the addition of the word “Branch” in the section title, make it clear that this rule is a branch-circuit rule. Paragraph (1) requires a transfer and alternate lighting source pickup whenever a normal lighting *branch circuit* fails. More extensive changes in Paragraph (2) require two or more “*branch circuits* supplied from” separate and complete systems with independent power, at least one of which is part of the emergency system.

Consider the common application of this section to lighting outlets in building stairwells, a typical Art. 700 load. It has been commonly believed that Paragraph (1), with its prior wording requiring a transfer in the event of a failure in the “general lighting system supply,” only required a transfer of the feeder to the emergency panel, thereby transferring the “system supply.” Frequently local lighting panels were wired with phase-loss relays that activated the transfer switch upon sensing a power failure in the lighting panel. Now that transfer must operate with a single branch-circuit failure.

The installation of unit equipment wired to the local branch circuit is one way to address these changes; the familiar emergency backup ballasts in fluorescent luminaires in the stairwell are another.

The other option would be to use Paragraph (2) with two supplies to each stairwell luminaire outlet, the circuits being fed from a panel on the normal distribution and a panel on the emergency distribution. This arrangement would clearly meet the “separate and complete systems” rule. Automatic load control relays (see discussion at 700.26) could be installed on each stairwell emergency lighting branch circuit, arranged to sense a failure in the normal branch circuit and energize the luminaire from the emergency panel. If the failure resulted from a building outage, then the transfer switch would have operated and the luminaire would be powered by the generator. If the failure was idiosyncratic to a particular branch circuit, such as a breaker being turned off, the light would still be returned to service through the transfer to the other panel, which would be on normal power.

If the branch-circuit breaker tripped during a wiring fault that was uncleared before the breaker tripped, then the corresponding breaker in the other panel may trip as well because it might close into the same fault. But this does offer a level of redundancy that is a distinct improvement over the way these systems have often been wired previously.

Another possibility, if the remaining illumination meets the minimum brightness required by the applicable building code, would be to wire double-ballasted luminaires to opposite branch circuits, or to alternate branch-circuit coverage by floor level. In any event, it is now clear that emergency branch-circuit lighting coverage now requires fully redundant branch-circuit wiring. Note also that the second paragraph of (2) regarding system transfers, is correctly formatted as of the 2011 **NEC** printings as a second paragraph of (2) and not, as occurred in prior editions, as a second paragraph to the entire section.

700.19. Multiwire Branch Circuits. Again, because of the problems arising from the common disconnect rule for multiwire circuits, they cannot be used to supply emergency circuits.

700.20. Switch Requirements. Figure 700-15 shows a violation of the last sentence of this rule, which follows the exceptions, where use of three- and four-way switches is prohibited. One good example of Exception No. 2 involves a single-pole service switch in parallel with a photocell that turns on luminaires that light secondary egress pathways from multifamily housing. Only the rising sun can turn the lights off after darkness, but the janitor can turn them on during the day to see which lamps need replacement.

These switches are a code violation in this circuit...

... BUT this use of parallel switches is acceptable if one of the switches is accessible only to authorized persons

Fig. 700-15. Watch out for switches in emergency lighting circuits. (Sec. 700.20.)

700.21. Switch Location. The sole switch for emergency lighting control in a theater may not be placed in a projection booth. Figure 700-16 shows the exception, where an emergency lighting switch may be used in a projection booth or on a stage if it can energize such lighting but cannot deenergize the lighting if another switch located elsewhere is in the closed (ON) position.

Control switch for emergency lighting must *not* be in theater projection booth or on stage . . .

. . . but an additional switch that cannot deenergize the circuit if the other control switch is closed *may* be in the projection booth or on the stage.

Fig. 700-16. The sole switch that controls emergency lighting in a theater may *not* be installed in a projection booth or on the stage, with the exception shown. (Sec. 700.21.)

700.23. Dimmer and Relay Systems. This 2008 addition to the **NEC** recognizes dimmer systems comprised of multiple dimmers and listed as an emergency lighting control mechanism. On failure of the normal power, the system energizes selected lighting outlets such that the required degree of illumination is provided. The wiring to the designated outlets must comply with other rules in Art. 700. The 2014 **NEC** has added relays to this concept, because they are commonly employed and provide the same functionality.

700.24. Directly Controlled Luminaires. This new (2014 **NEC**) section is intended to recognize LED luminaires with on-board dimming capabilities, and that can also respond to a change of state in an emergency system transfer switch and turn on to full illumination during the emergency event. The electronics to make this possible are complicated, and for this reason such luminaires together with their external controls must be listed for use in emergency systems.

700.25. Branch Circuit Emergency Lighting Transfer Switch. This is a new term, first defined in the 2017 **NEC**. These devices take automatic load control relays (LCRs) (700.26) to the next level. LCRs are not transfer equipment and for that reason they are not being evaluated in terms of capability for transferring between asynchronous power sources. A special task group was assembled to develop a testing protocol that would allow similar equipment to be evaluated as full-fledged transfer equipment, and this is the result, limited to 20-A circuits. The mechanically held requirement in 700.5(C) is waived for this equipment.

700.26. Automatic Load Control Relay. These devices are defined in 700.2 and provide a relatively inexpensive way to bypass a local switch component and place full voltage on a luminaire during a condition when normal power has been lost. They have a lead or contact point that is connected to the normal source at the relevant upstream transfer switch, and if power is lost, they change state and close the ungrounded conductor across the line. When normal power is restored, they change state again, opening the bypassing ungrounded conductor. As a result, the only power to the luminaire at that point, however, was being controlled before the outage. For example, if the luminaire was on a dimmer and set to 50 percent brightness, a loss of power would force the luminaire to full brightness until normal power was restored.

These devices do not switch the grounded conductor; they do not qualify as and cannot be used for transfer equipment functions. The definition in 700.2 has been revised to emphasize this point. They are used to change the state of a lighting load after a transfer has occurred, including energizing loads within their ratings that had been shut off and needed to be turned on during the outage.

700.27. Ground-Fault Protection of Equipment. Emergency generator disconnect does not require ground-fault protection. This rule clarifies the relationship between 230.95, calling for GFP on service disconnects, and the disconnect means for emergency generators. To afford the highest reliability and continuity for an emergency power supply, GFP is not *required* on any 1000-A or larger disconnect for an emergency generator, although it is permissible to use it if desired ([Fig. 700-17](#)). However, a ground-fault condition must be annunciated as required in 700.6(D) in the event automatic GFPE is not provided.

Ground-fault protection is *not* required for emergency disconnect.

. . . But, 700.7 (D) REQUIRES ALARM ON FAULT.

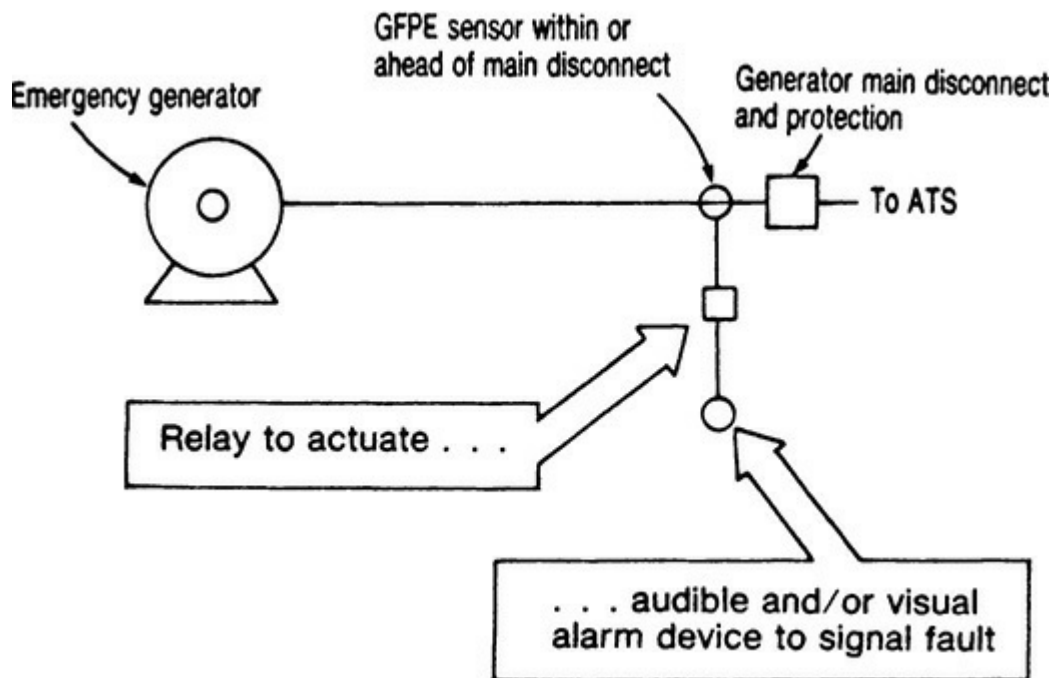

Fig. 700-17. Ground-fault protection is optional for any 480/277V grounded-wye generator disconnect rated 1000 A or more, but ground-fault “indication” is required. (Sec. 700.26.)

700.32. Selective Coordination. The rule put forth in this section mandates “selective coordination” of the emergency system’s overcurrent protective devices, which essentially requires the OC device closest to the fault to operate before line-side devices. This will ensure that any outage is limited to the affected circuit only, and thereby minimize the effect on the overall system supply. The exception addresses circumstances where the loads affected by an upstream outage are identical to an outage from a downstream device, and therefore coordination creates no benefit.

This principle, prior to the 2005 **NEC**, was presented as a desirable condition in a fine print note at this location. As such it could not be literally enforced in all installations. Following a successful proposal from a fuse company employee, however, it is now mandatory and the shortcomings are becoming increasingly apparent, particularly if the choice of overcurrent protective devices on a system operating where exposed to high available fault conditions, was, at least initially, to use circuit breakers.

Circuit breakers of the usual thermal-magnetic type are inverse-time devices until approximately 10 times their nominal ratings. Current somewhat over their nominal ratings takes a long time to clear; and much larger current clears very quickly. Current at or above the 10-times parameter unlatches the breaker in a fraction of a cycle in response to magnetic forces. Further, the unlatch sequences use the same amount of time for all values of fault current within their magnetic trip ranges. This means that a branch circuit experiencing such a fault may trip not just the branch-circuit protection, but upstream feeder protection as well as far up into the system as necessary until and unless the current falls into the range of the inverse time tripping range of a much larger breaker. How far upstream is very difficult to predict, however, because the smaller breaker parts have less inertia and their contacts will begin to open first, introducing the dynamic impedance caused by the internal arcing. This is another wrinkle on the dynamic impedance problem discussed at length in this book at 240.86(B). Note that the 10-times parameter is an oversimplification and actual values will differ between makes and sizes, but the principle holds.

One of the reasons that this is an oversimplification is that it only considers thermal-magnetic breakers. Some electronic-trip breakers include a second instantaneous trip function, in some cases referred to as an instantaneous override, that operates more quickly than the familiar instantaneous settings that are field adjustable. In addition, very high levels of fault current will begin to open breaker contacts even before they actually unlatch. In fact, some breakers rely on this feature and incorporate designs that keep the contacts separated until the full unlatching sequence is completed.

Getting back to conventional thermal-magnetic breakers, and for example, making the oversimplified assumption that the magnetic pick-up points on the devices mentioned are 10 times their ratings, a 5000-A fault on a 20-A branch circuit in a 100-A panel with main fed from a 400-A feeder supplied from a 2500-A service, would trip every overcurrent device downstream of the service protection. Note that this example is true for conventional breaker selections, but there are breakers available that will fully coordinate in this particular fault range. Breaker manufacturers publish coordination tables to assist in this analysis. Fuses, on the other hand, are inverse-time devices over their entire clearing range. For every increase in fault current, there will be some shortening to the clearing time. This is a simple matter of physics; fuses need to see an amount of energy equal to their latent heat of fusion in order to clear. The available energy is a function of the of current squared multiplied by time (I^2t). An increase in current exponentially decreases the amount of time to release the required energy into the link. And, when such functions are plotted logarithmically, the result is a sloping straight line. Further, if the amount of comparable eutectic alloy changes, the sloping line will move to the side, never intersecting one for a different size fuse. Refer to [Fig. 700-18\(B\)](#) for an example. This is what makes the selective coordination of fuses comparatively simple. Fuse manufacturers publish ratio tables to assist in establishing permitted fuse combinations for this purpose and because conventional trip curve data is not published below 0.01 s. [Figures 700-18A](#) and [18B](#) show examples of overcurrent device trip curves in terms of coordination.

Fig. 700-18A. Overlapping trip curves showing three levels of a distribution protected with thermal-magnetic circuit breakers. The right-hand vertical boundaries of the “feet” are the interrupting ratings.

Overcurrent device trip comparison, thermal-magnetic circuit breakers (left) vs. dual-element fuses (right)

The CB example shows no nuisance trip for the 40A breaker because there is no overlap between the 15 hp motor start curve and the breaker trip curve.

The CB example also shows that the 40A and the 150A breakers coordinate down to ~0.5 sec, but only if the instantaneous adjustment is moved to the highest part of its range.

The CB example shows in addition that the 1200A breaker fully coordinates with the other breakers if the time interval is longer than 0.06 seconds.

The fuse curves show no overlap between the 100 A and 400 A fuses over any portion of their ranges. They fully selectively coordinate; the CBs do not.

These graphs illustrate the inherent simplicity in coordinating fully inverse-time devices vs. devices with magnetic (instantaneous) trip components.

Fig. 700-18B. Trip curves for two dual-element fuses. As inverse-time devices, there is little chance of overlap. For example, a 2000-A fault clears the 100-A fuse in ~0.17 sec. and the 400-A fuse in ~13 sec.

The only way to definitively coordinate the circuit breaker sequences mentioned is through the use of circuit breakers equipped with electronic controls that allow for zone selective interlocking, allowing a lower level in the protection hierarchy to restrain the tripping of a higher level until the lower level clears. This is incredibly expensive and not even available in all frame sizes, and it is not practicable under all instantaneous tripping scenarios. It must be noted here that even zone selectivity does not always guarantee coordination without careful attention being paid to the settings

on every protective element in the system. It does, however, offer an important reduction in the amount of energy that can enter the electrical system at feeder levels, because a fault at that level can be cleared quickly since no downstream device will restrain the feeder protection in such cases. This is a very important issue when considering the amount of energy available in an arc flash event, for example. The other way, also not always practical, is to make sure that the next level up is in the inverse-time part of its curve for all fault-currents available. For example, in the above example if the 100-A panel were replaced with a 400-A panel, thereby decreasing the protection levels to three (service, feeder, and branch), and the 400-A breaker selected so its instantaneous (magnetic) response were at 15 times its rating, coordination could be achieved.

This does, however, increase the amount of energy available in an arc blast, so this is not a purely positive design change. In fact the number of distributions with intermediate protective levels being designed upward to deal with phantom coordination issues is becoming so common that we now are having to write special rules regarding breaker controls that turn on the instantaneous trip function during servicing operations so as to reduce incident energy levels, levels that otherwise would be far more difficult because the instantaneous trips were shut off to allow for coordination. See the discussion at 240.87 for more information on this point. If you think this is beginning to look like Rube Goldberg, this author would not disagree.

Economics is not, in and of itself, sufficient motivation to change the **NEC**. If there were numerous field reports of coordination failures that adversely affected the ability of people to escape a dangerous condition, then the adverse affect on circuit breaker market share would be warranted. However, not a single example of such a coordination failure exists in the record of proposals and comments submitted on this change. What is known, however, is the adverse effects of introducing additional energy into the electrical systems under fault conditions. The difference in the arc blast that would be caused by a mishap in that 400-A panel as opposed to one in the 100-A panel originally proposed may well be, and often has been, the difference between life and death for the electrician who dropped the proverbial screwdriver across the proverbial line buses.

Why it can't happen in an occupied building?

There is a good reason for the lack of loss experience around coordination failures. Coordination studies necessarily involve the worst-case electrical fault condition, which is a bolted short circuit, such as can exist on a cross-wired parallel installation. These failures are the sort that are rare and that would be expected to be confined to system startups prior to building occupancy. Buildings do not gradually descend into bolted short-circuit conditions over the years and as a consequence of lack of maintenance. However, ground faults do occur under these conditions, and not infrequently. For this reason, most electrical failures do not involve short-circuits at all, but arcing ground faults instead.

A ground fault frequently involves just enough impedance at the point of arcing contact that the overcurrent device next upstream from the branch-circuit protective device will still be acting within its inverse-time characteristics. Because this is the predominant failure mode on electrical systems, coordination is maintained. Further, it can be shown that even systems perfectly coordinated in terms of short-circuits will fail to coordinate on some ground-fault conditions, even with fuses. For example take a large, heavily loaded feeder, say, 1200 A loaded to 1000 A, with four 400-A subfeeders and a 600-A subfeeder originating at a distribution panel. If the 600-A subfeeder with all loads off sees a 800-A ground fault, it will likely take out the 1200-A main because the other loads

that are making it heavily loaded will continue, and the ground fault will push it over the edge. All things being equal, a 600-A fuse loaded to 800 A (+133 percent) during the ground fault event will take much longer to clear than a 1200-A fuse loaded to 1800 A (+150 percent).

As written, this rule conflicts with **NFPA 110**, *Standard for Emergency and Standby Power Systems*, which only requires that coordination be “optimized.” Many jurisdictions are limiting the reach of this rule in order to achieve practical results. It bears repeating that not a single instance of loss experience supported its inclusion in the **NEC**. You will need to sort this out at the local level with inspectional authorities to see what will be permitted on particular jobs. There is no problem with keeping the selective coordination concept in mind and using it as one consideration in an overall system design, but mandatory application at every level in every distribution is extremely problematic.

The **NEC** promises an electrical system that is “essentially free from hazard” and not one that is absolutely free from hazard. Enforcing absolute selectivity is comparable to relentless enforcement of a 20-mph speed limit on an interstate highway. The costs to the industry do not remotely justify this “benefit,” particularly because it addresses a nonexistent loss experience history.

Were other factors involved in the selective coordinations decision?

The proposal was submitted in the later half of 2002 by a fuse company employee. Prior to that time, fusible panelboards were unusual in occurrence in comparison with circuit breaker panelboards. They were widely used though the middle third of the last century in residential applications, equipped with plug fuses for most of the circuits, and cartridge fuses for the service protection and larger circuits. They were gradually eclipsed by panelboards with circuit breakers. It takes a number of years to develop, test, submit to testing laboratories, and come to market with a new product line. However, a full product line came to market just as the 2005 **NEC** was coming into full effect. The new product line was the subject of a full-color article in *IAEI News*, the March-April issue of 2005. The article featured fusible panelboards that were anything but residential in design (See [Fig. 700-19](#)) and very specifically presented as a solution to selective coordination issues occasioned by the **NEC** change.

Fig. 700-19 A modern fusible panelboard, suitable for a full range of occupancies and applications (700.32). (Adapted from Practical Electrical Wiring, 22nd ed., © Park Publishing, 2014, all rights reserved.)

If there were any doubt as to the motivation and product timing in relationship to the **NEC**, this article, focused on selective coordination, largely removed it. After presenting extensive instruction as to how to selectively coordinate fuses, the article then commenced a discussion of circuit breakers. In the end, the article opined “It is generally difficult to achieve selective coordination with circuit breakers that incorporate instantaneous trip settings.” There is a term in formal economics for this

sort of action, called “rent seeking.” This is a process whereby one generally avails themselves of government action to obtain a greater rent (i.e., return) than would have been possible on the free market.

Transcendent code issues

As of the 2014 **NEC**, the engineering costs involved in providing these systems received an upward click of the ratchet because now a licensed PE or other similarly qualified person must design the system. In fairness, these systems are so complicated that qualified engineering support was almost inevitable.

Certain Code controversies over time become what the author refers to as transcendent issues. These are issues that take on a public policy aspect that attracts the attention of those outside the electrical industry. A classic example was the three-story limit on NM cable, which was in the **NEC** from the 1975 **NEC** edition until it was removed in the 2002 edition. The author recalls being contacted by a representative of the Roman Catholic Archdiocese of Boston regarding eliminating this provision in the Massachusetts Electrical Code because of its adverse effects on the costs of providing affordable housing. The specific issue was moot because Massachusetts never did accept the **NEC** prohibition, but the larger issue was that the Archdiocese of Boston was intently interested in a technical requirement of the electrical code.

The adoption of an electrical code is the exercise of a police power implicitly reserved to the states under the 10th amendment. At any time a legislature can exercise that authority and enact a law that changes the electrical code that is in effect. The author has no problem with a competent group of electrical professionals in a state reaching a different conclusion about what a code provision should say and enacting the applicable code in a transparent manner that supports those conclusions. That is the sort of federalism enshrined in our frame of government. However, once a state legislature gets involved on a purely political level, it is another story. And after the first time such an amendment passes, it is only easier for it to happen a second time. This makes it critical to avoid the first time, and that means watching transcendent issues very carefully. The NM cable limitation provides historical precedent for these concerns.

At the end of the twentieth century, the National Multi-Housing Council realized what the three-story NM cable restriction was costing them in new construction electrical expense and challenged the provision. The electrical industry adamantly refused to support the change, and it failed in the Code-making panel and also at the **NFPA** Annual Meeting. The **NFPA** Standards Council, after looking at the entirety of the technical record, agreed that there was no credible technical substantiation to support the prohibition. The opposition of the electrical industry was motivated by a mixture of romance and self-interest; metallic wiring methods required greater expertise to install and brought the manufacturers more profit. In the author’s opinion, the Standards Council action on the 2002 **NEC**, where the entire prohibition was thrown out and the section rewritten at the Council level, was an act of great courage and integrity, and it saved our industry from itself. No longer would that provision attract the attention of the lay community.

Selective coordination is well on its way to becoming the next transcendent issue. The engineering and design costs to protect against a loss that has never occurred and will never occur during the occupancy of a building using electrical power are in the uncounted millions of dollars and rising. The health care industry was one area particularly hard hit, and it reacted. It has its own standard,

NFPA 99, and the industry ratcheted down the coordination to events longer than 0.1 sec. That time period is a full six cycles, and coordination is simple across almost all ranges of overcurrent devices with that parameter in place (see [Fig. 700-18A](#).)

The history of the **NFPA 99** intervention is important. The final vote on the proposed action in the **NFPA 99** Electrical Systems Committee passed 18-1, with 3 installer/maintainers, 5 special experts, 4 users, 3 manufacturers, 1 consumer, 1 research/testing, and 1 enforcer voting yes and only 1 negative vote (labor). The vote on the action included the following substantiation:

Selective coordination is only one of several competing factors that must be considered in the selection of appropriate overcurrent protective devices (OCPDs) in health care facilities. Other factors that must be considered in the selection of overcurrent protective devices include: arc flash risk hazard, equipment damage, and reduced risk of extended outages; all of which have direct effects on both staff and patient safety. Mandating selective coordination below 0.1 s as the sole determining factor in OCPD selection will result in diminished reliability of the essential electrical system. The method of application of selective coordination directly affects the performance of the essential electrical system in a health care facility. Establishment and management of this type of performance criterion traditionally belongs under the purview of this committee.

The battle went on, however, on the floor of the **NFPA** Annual Meeting. On a vote of 87 yes and 119 no, the attempt, by (who else) the National Electric Fuse Association to overturn the committee action failed. The same association then pursued an appeal to the **NFPA** Standards Council, the highest authority in the **NFPA** Standards process, and lost with all electrical members having recused themselves.

The hospital industry has escaped the selective coordination noose, but once again, only over the entrenched opposition of the electrical industry. Fusible branch-circuit panelboards are once again readily available, and the circuit breaker industry has responded with complicated correction schemes of its own with enormous value added. The vote on the rule in **NFPA 99** did not, however, necessarily bind the **NEC** to follow suit. Now there was a conflict between **NFPA 99** and **NFPA 70**, the **NEC**. In this case the health care industry went to the Standards Council with the argument that coordination was a performance issue belonging to **NFPA 99**. At the bitter end, the fuse industry was in front of the Council with a final appeal against the **NFPA 99** action. And once again, the Standards Council saved the electrical industry from itself. It supported **NFPA 99** and effectively forced what is now 517.31(G) into the 2014 **NEC**. However, the general issue is still very present, still transcendent, and still very dangerous to the autonomy of the Code-making process.

How does this fit with the organizing principles of the NEC?

This entire issue recalls first principles of Code creation and application. The first **NEC** edition to have a written introduction (now Art. 90) was the 1937 major rewrite, which included the following opening sentence of an unnumbered second paragraph: “The requirements of this Code constitute a minimum standard. Compliance therewith and proper maintenance will result in an installation *reasonably free from hazard* but not necessarily efficient or convenient.” [emphasis supplied] This

concept has survived essentially intact of the intervening 80 years; today that provision reads as follows:

(B) Adequacy. This *Code* contains provisions that are considered necessary for safety. Compliance therewith and proper maintenance result in an installation that is essentially free from hazard but not necessarily efficient, convenient, or adequate for good service or future expansion of electrical use.

The **NEC** does not now and never has promised an electrical installation that is without any risk, only one essentially free from hazard. Mandatory selective coordination is an attempt at removing all hazard, and with rent seeking as one of the motivations. The hospital industry has sidestepped the issue, but other users do not have another **NFPA** standard to shield them, and the battle will likely continue above the level of the **NEC** Committee, as this terminology slowly metastasizes across various Code provisions. This entire issue is a wonderful validation of the wisdom of the old French philosopher Voltaire, who famously observed in 1768 that “the perfect is the enemy of the good.”

ARTICLE 701. LEGALLY REQUIRED STANDBY SYSTEMS

701.1. Scope. This article covers *standby* power systems that are required by law. Legally required standby power systems are those systems required and so classed as legally required standby by municipal, state, federal, or other codes or by any government agency having jurisdiction. These systems are intended to supply power automatically to selected loads (other than those classed as emergency systems) in the event of failure of the normal source.

Legally required standby power systems are typically installed to serve such loads as heating and refrigeration systems, communication systems, ventilation and smoke-removal systems, sewage disposal, lighting, and industrial processes that, when stopped during any power outage, could create hazards or hamper rescue or firefighting operations.

This article covers the circuits and equipment for such systems that are permanently installed in their entirety, including power source.

701.3. Tests and Maintenance. These tests are in some ways similar to those for emergency systems. The differences are as follows: Part **(A)** does not require full system tests to be done after the acceptance test after the initial installation. Part **(C)** does not address unit equipment, which is odd given that the article does encompass this equipment in 701.12(G). Part **(E)** requires periodic load testing, but there is no express requirement to test the system under the maximum anticipated load conditions.

701.4. Capacity and Rating. This is also comparable to the standby source for an emergency system. There is no express permission to use the standby source for peak load shaving, nor is there a requirement for an alternate source to be available when the generator for the standby system is out for major maintenance or repairs.

701.5. Transfer Equipment. These requirements are the same as for Art. 700 systems except the product acceptance rules are in terms of standby instead of emergency use. However, there is no part (D) and therefore no limitation that a legally required standby system transfer switch will only supply legally required standby system load. This is logical because Art. 701 circuits need not be divorced from normal circuits, as covered in 701.10.

701.6. Signals. This rule is identical to 700.6, including a comparable requirement for ground-

fault notification. The same additional paragraph as in 700.6(D) regarding paralleling bus applications entered this rule. Refer to the explanatory information at that location for more information.

701.7. Signs. This rule is identical to the one in 700.7. Refer to the discussion and drawing at that location.

701.10. Wiring Legally Required Standby Systems. This is one the few very major differences between this wiring and emergency system wiring, in that there is no separation requirement from ordinary wiring.

701.12. General Requirements. The parent language contains another major difference between these circuits and emergency circuits, that being these systems must transfer to the standby source within 1 minute, as opposed to 10 s for emergency loads, in the event of an outage. Part (A) on storage batteries as a source of supply is identical to comparable requirements in emergency systems. Part (B) omits some requirements that appear for emergency systems, including the requirement that a battery charger needed to recharge the battery and that power to cooling, power-operated dampers connected to the standby system are omitted as well. There is also no requirement for an auxiliary power supply, because the 60 s permitted time delay should be plenty of time to get a generator running. The outdoor generator set rule, at (5), is the same as 700.12(B)(6) but lacks a comparable exception for safe switching procedures under the control of qualified persons. It does, however, carry the same reference to 445.18 and the same reference to 225.36 as covered in 700.12(B)(6). Refer to the comparable material in Art. 700 of this book for a complete analysis. Parts (C) and (D) are the same as their counterparts in 700.12. Part (E) covers connections ahead of the service disconnect, which are permitted here but were removed from 700.12 in the 1996 **NEC**. This provision requires permission of the AHJ; it is discussed at 700.12(D), which gives some of the details and limitations for this type of connection. Part (F) is the same as its Art. 700 counterpart. Part (G) only differs by omitting the circuit identification rule; however, the present language in 408.4 is strong enough to mandate the same result. It also lacks the additional exception for including an exit door light on an interior system.

701.25. Accessibility. Branch-circuit protective devices in legally required standby systems must not be accessible to unauthorized persons.

701.26. Ground-Fault Protection of Equipment. Here again GFPE may be omitted; however, in this, article there is no requirement to sense and annunciate the fact that a fault is in progress, although it is certainly permitted. As in the case of emergency systems, ground-fault indication is required and it must be annunciated in accordance with 701.6(D) in all instances where automatic GFPE shutdown is not provided.

701.27. Coordination. This is the same rule and the same comments apply to it as for the rule in 700.32. The same requirement for professional engineering support applies to these systems; refer to the analysis at 700.32 for extensive commentary on this subject.

ARTICLE 702. OPTIONAL STANDBY SYSTEMS

702.1. Scope. Life safety is *not* the purpose of optional standby systems. Optional standby systems are intended to protect private business or property where life safety does not depend on the performance of the system. Optional standby systems are intended to supply on-site generated power

to selected loads, either automatically or manually.

Optional standby systems are typically installed to provide an alternate source of electric power for such facilities as industrial and commercial buildings, farms, and residences to serve such loads as heating and refrigeration systems, data processing and communications systems, and industrial processes that, when stopped during any power outage, could cause discomfort, serious interruption of the process, or damage to the product or process. To be covered in this article, a system must be permanently installed in its entirety, including any prime movers.

Because of the constant expansion in electrical applications in all kinds of buildings, the use of standby power sources is growing at a constantly accelerating rate. Continuity of service has become increasingly important with the widespread development of computers and intricate, automatic production processes. More thought is being given to and more money is being spent on the provision of on-site power sources to back up or supplement purchased utility power to ensure the needed continuity as well as provide for public safety in the event of utility failure.

At this point a distinction should be clear: Contrary to both common public opinion and frequent trade slang among electricians, the majority of standby power systems are not emergency systems. Just because a system will back up some or all loads on an electrical system, it is not necessarily an emergency backup system. In fact, statistically it is probably an optional standby system. Only a standby system that will supply emergency loads and transfer within 10 s, etc., is an emergency system. This article covers optional standby systems, even those of immense size that may protect millions of dollars worth of data, or extensive plant equipment that would be damaged in the event of a disorderly shutdown, or any other load that the owner may deem a dire emergency should it be disconnected. Until and unless such backup systems also supply life-safety equipment as defined in local laws and regulations [and sometimes they do under the allowances in 700.4(B)], these systems are as presented in Art. 702 and they are not emergency systems. Further, even where one generator, as noted, is the standby source for both optional and emergency systems, only the wiring to the designated emergency loads is part of the emergency system under Art. 700. The rest of the standby wiring, even if it dwarfs the life-safety equipment wiring, is nothing more than an optional standby wiring system, covered here.

The most basic application of standby power is the portable alternator used for residential standby power where electric utility supply is not sufficiently reliable or is subject to frequent outages (Fig. 702-1).

Fig. 702-1. Standby generator with manual transfer is common residential application. (Sec. 702.1.)

702.4. Capacity and Rating. Any standby power source and system must be capable of fully serving its demand load. This can generally be satisfied relatively easily for generator loads. But the task can be complex for uninterruptible power supply (UPS) systems. The UPS is an all-solid-state power conversion system designed to protect computers and other critical loads from blackouts, brownouts, and transients. It is usually connected in the feeder supplying the load, with bypass provisions to permit the load to be fed directly. Figure 702-2 shows a typical basic layout for a UPS system. Such a system utilizes a variety of power sources to ensure continuous power. Circuits are shown for normal power operation. If normal power fails, the static switch transfers the load to the inverter within $\frac{1}{4}$ cycle. The battery is the power source while the engine-generator is being started. When the generator is running properly, it is brought onto the line through its transfer switch, and the static switch transfers the load to the generator supply. The dashed line indicates the synchronizing signal, which maintains phase and frequency of inverter output.

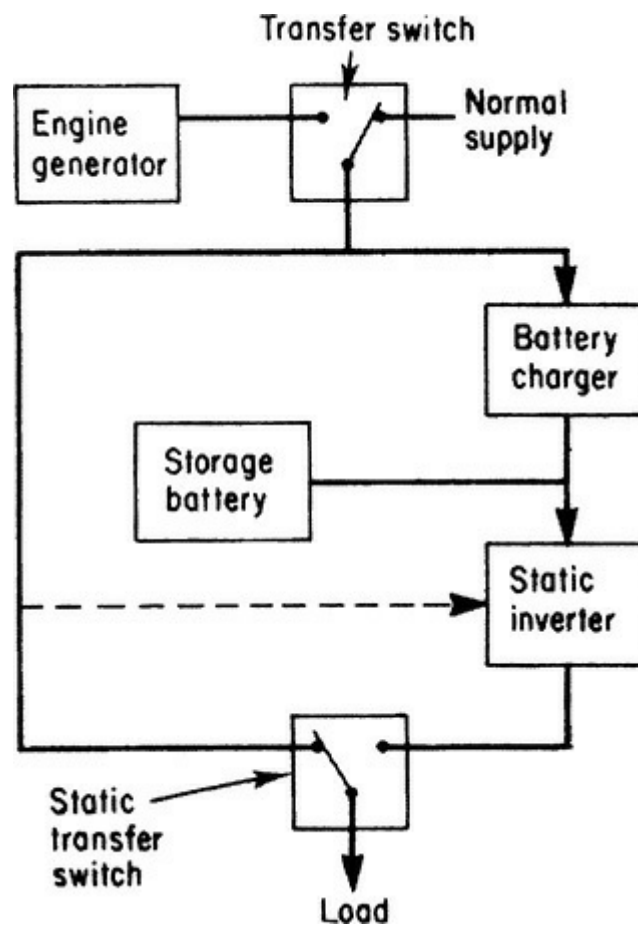

Fig. 702-2. UPS system is a common standby power system. (Sec. 702.2.)

Calculation of the required capacity of a UPS system must be carefully made. Data processing installations normally require medium-to-large 3-phase UPS systems ranging from 37.5 to over 2000 kVA. Some of the typical ratings available from UPS manufacturers are 37.5 kVA/30 kW, 75 kVA/67.5 kW, 125 kVA/112.5 kW, 200 kVA/180 kW, 300 kVA/270 kW, 400 kVA/360 kW, and 500 kVA/450 kW. Larger systems are configured by paralleling two or more of these standard-size single modules.

The necessary rating is chosen based on the size of the critical load. If a power profile itemizing the power requirements is not available from the computer manufacturer, the load may be measured using a kilowattmeter and a power-factor meter. Because UPS modules are both kVA- (apparent

power) and kW- (real power) limited, a system should be specified with both a kVA and a kW rating. The required kVA rating is obtained by dividing the actual load kW by the actual load power factor. For example, an actual 170-kW load with an actual 0.85 power factor would require a 200-kVA-rated UPS. The system should be specified as 200 kVA/170 kW, and the standard 200 kVA/180 kW UPS module should be selected for the application.

The full load requirement applies to the connections as noted in [Fig. 702-2](#) and the preceding discussion because an automatic transfer switch was used and illustrated. Part **(B)(2)** requires this capacity in the standby source if loads are transferred automatically, unless there is an energy management system in place, in which case the system capacity must match the maximum load that the management system will allow to be connected.

On the other hand, if a manual transfer switch is used, as in [Fig. 702-1](#), the only rule, in **(B)(1)**, is that the generator supply the load intended to be operated at one time. This gives a homeowner, for example the ability to turn on a breaker supplying electric heat for a while, and then turn that off and energize a specific appliance for some purpose, and then restore the electric heat, etc. Whether this is advisable is another question. Murphy's law generally results in the most unqualified person being the one present during an outage, and an overloaded generator will not continue in service. At the very least, a qualified person should post instructions advising what combinations of circuits will achieve the desired results without overloading the generator.

702.5. Transfer Equipment. This equipment is mandated for all optional standby systems for which an electric utility is one of the electric supply options. This ensures that a standby source does not backfeed power into a utility system, which can be a source of extreme hazard for utility personnel attempting to cope with an outage. However, for facilities with qualified personnel, a portable generator can be connected without a transfer switch provided the normal supply can be locked out, or where the normal supply conductors are actually disconnected from the distribution equipment. Transfer equipment for single-circuit applications and connected on the load side of the branch-circuit overcurrent protection is also recognized and is permitted to contain supplementary overcurrent devices in recognition of the low available fault currents that are possible from generators of such sizes.

702.7. Signs. These are the same requirements as in 700.7; refer to the discussion and drawing at that location. Large optional standby sources are very important, in size frequently the most important, applications of these requirements. Part **(C)** is new as of the 2014 **NEC** and mandates a sign on a power inlet designed to receive a female cord body attached to a cord-and-plug-connected generator that will be used to power its connected load on a temporary basis. The warning label (the prescriptive language is in the **NEC**) alerts the user whether the transfer switch is arranged for a separately derived source (bonded neutral) or nonseparately derived source (floating neutral). Of course, it remains to be seen if those connecting the cord body from the generator will understand the meaning of the sign. Refer also to the discussion at the new 445.20 for additional background information on this issue.

702.10. Wiring Optional Standby Systems. As in the case of Art. 701 systems, there is no requirement to segregate this wiring.

702.11. Portable Generator Grounding. These rules effectively turn on whether the portable generator will or will not be connected as a separately derived system, and therefore whether it will or will not need a grounding electrode connection in its capacity as a separately

derived system.

702.12. Outdoor Generator Sets. This is the same rule as in 700.12(B)(6) although it lacks a comparable exception for safe switching procedures under the control of qualified persons; refer to the discussion at that point. The reference to 445.18 is there as well, allowing the shut-off switch on the generator to provide this function.

Part (B) allows a flanged inlet and cord body connection to serve as the disconnecting means for portable generators 15 kW or less. Part (C) is new as of the 2017 **NEC** and requires a listed, interlocked disconnecting means for power inlets that are rated 100 amps and up and intended for use with portable generators. If the inlet is listed as a disconnecting means, or if the application is for a supervised industrial installation with permanent space set off for the portable generator(s) that is within line of sight of the power inlets, then these requirements do not apply. The rule is aimed at unqualified persons disconnecting a portable generator connected to an inlet under load.

ARTICLE 705. INTERCONNECTED ELECTRIC POWER PRODUCTION SOURCES

705.1. Scope. This **NEC** article covers interconnected electric power sources, particularly utility supplies, and on-site power sources including solar photovoltaic systems, fuel cell sources, and other sources intended to operate in parallel with an active utility connection. Another common name for this type of connection is “cogeneration.”

The overall intent is to have this article cover issues of utility-interactive, interconnected parallel production sources that apply to all such connections, with technology specific variances addressed in the [Chap. 6](#) articles as required.

705.2. Definitions. There are two new definitions as of the 2017 **NEC** that interface with the equally new Art. 712, which pertain to premises wiring systems. A *microgrid system* is such a system that has electrical generation, storage, and one or more loads or any combination that includes the ability to both disconnect from and operate in parallel with the prevailing primary (presumably usually the utility) source. And the interconnecting device that allows that interconnection to function is the *microgrid interconnect device (MID)*. The term “microgrid” has superseded the prior terminology that referred to intentionally islanded systems. Power production equipment is the term chosen to describe the power sources that provide electricity from other than utility-supplied services, including PV, fuel cells, and wind.

705.8. System Installation. Installation of cogenerating production is to be done by qualified persons, using (Sec. 706.6) listed equipment evaluated for this function.

705.10. Directory. A permanent plaque or directory must be posted at the service equipment showing the location of all local parallel production source disconnecting means capable of interconnection, and reciprocal information must be posted at any remote disconnecting means, if any, for all other power production sources capable of interconnection.

705.12. Point of Connection. Utilities have different policies about where an interactive connection is to be located, either ahead of the service disconnect or after it, and this section covers both. Part (A) covers supply side connections, which are permitted in accordance with 230.82(6). The sum of the ratings of all overcurrent devices connected to power production sources must never exceed the service rating. No further requirement applies to this connection in this section, although

other requirements will apply, the most important being the disconnection rule in 705.22.

Part **(B)** covers load side connections. If the interconnection is through a panelboard or other comparable equipment that is simultaneously supplied by a primary source, and where this equipment also supplies (or is capable of supplying) other circuits, whether feeders or branch circuits or both, then specialized and relatively complicated rules apply to exactly how the supply connections are sized and located. The reasons for this are based in two overarching considerations. First, the busbars of the interconnecting equipment must be protected from overload by excessive loads being taken from those busbars due to the multiple supplies. The second concern is related to the first, but less obvious. The amount of power distributed from the distribution equipment must not exceed the power dispersion that was being taken out of it at the time it was being investigated for its listing. The **NEC** generally allows a 20 percent buffer before drawing the line in this latter area to make the requirements practicable. However, consider a 200-A panel fed with 200-A breakers at both ends, The 400 A that could be taken from intermediate positions in this panel would divide towards both ends and not overload the busbars in terms of amperes. However, the power distributed from this panel would double the amount it underwent during heat rise testing based on the normal configuration of a main OCPD limiting the busbars to the nominal rating.

Interactive inverters and other power sources are permitted to connect to the line side of a service disconnect, as covered in 230.82(6) (and correlated in 230.40 Exception No. 5). Connections on the load side of a service disconnect, as illustrated in Fig. 690-1 for a utility interactive inverter, must comply with a number of requirements, including the requirement at 705.32 to make the connection on the line side of any GFPE. If made on the load side, the inverter output may have unanticipated effects on the GFPE sensor, including damaging the equipment or interfering with the residual current readings. The connections are permitted only if there is GFPE from all sources and the load side equipment must be listed as suitable for backfeeding conditions.

The interconnecting breaker must be suitable for backfeeding, as at (4). Most breakers are tested in both directions. The ones that are not are marked “line” and “load” and if so marked they can only be used in the direction indicated. In [Fig. 690-1](#), a 5-kW inverter operating on a continuous basis on a 240-V system would calculate as a $(5000 \text{ kW}/240 \text{ V}) \times 1.25 = 26\text{-A}$ load for termination purposes, and a 30-A circuit breaker would be used. Note that this would be OK for a 150-A or larger panel, but too large for a smaller panel. The hold-down feature in 408.36(D) designed to prevent breakers with energized bus stabs from getting into trouble while not parked on a busbar is waived in (5) on these installations. If the breaker were lifted from the bus, it would be the same as the ac power going off, and the inverter or other source would immediately shut down anyway, per 705.40. When a panel has multiple sources providing power to the bus, it must be marked to show those sources, as covered in (3). A note following (4) indicates that fused switches are also suitable for backfeed, unless marked otherwise.

705.12(B)(2) was completely rewritten for the 2014 **NEC** in a comprehensive manner to cover every conceivable permutation of busbar connections from interconnected electric power sources. The presentation is so complex that it has to be taken apart a bit at a time in order to be fully understood. At the outset, there is a new requirement in the parent language of (2) to use 125 percent of the inverter output circuit current in calculations to determine the minimum ampacity for conductors and busbars. With this in mind, take the inverter output and land it somewhere. There are three basic possibilities, fully illustrated in the eight figures that follow. Each of the illustrations shows two interconnected power sources, a service (indicated by the breaker fed from a revenue meter [dollar

sign]], and also an interconnected electric power source (abbreviated “IEPS”). The numbers used in this presentation are those in the **NEC**.

(1) Covers landing on a feeder. There are two possibilities in this case, the first being a connection being made at any point along the length of a feeder *that is not the opposite end of the feeder from its point of supply*. There are two logical solutions. The first (Fig. 705-1) is at (a) and requires the ampacity of the feeder now supplied from a normal source and from the inverter to have an ampacity equal to the sum of the normal source OCPD and 125 percent of the inverter-rated output. The second (Fig. 705-2) is at (b) and requires an OCPD on the load side of the inverter connection based on the feeder ampacity for the remainder of the feeder circuit.

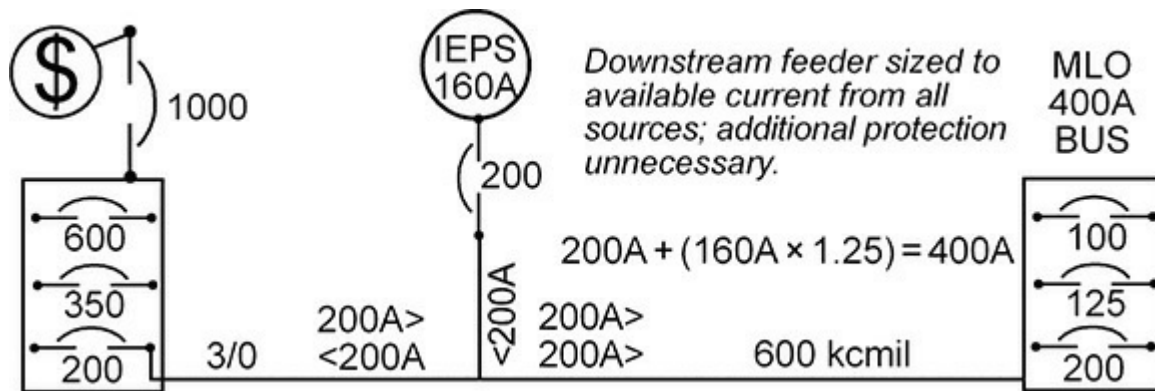

Fig. 705-1. Illustration of 705.12(B)(2)(1)a.

Fig. 705-2. Illustration of 705.12(B)(2)(1)b.

(2) Covers a connection made to a feeder and a tap is extended from such a connection (see Fig. 705-3); the allowable tap size and length are to be based on 125 percent of the inverter output and the current rating of the supply side OCPD with calculations being based (see also Fig. 705-4) on the sum of both taken into the relevant part of 240.21(B).

Fig. 705-3. Illustration of 705.12(B)(2)(2) as used with the 10-ft tap rule.

Fig. 705-4. Illustration of 705.12(B)(2)(2) applied to the 25-ft tap rule.

(3) Covers a connection to a busbar, including a busbar in a panelboard. Such a connection itself presents four connection types, as covered in (3)(a), (3)(b), (3)(c), and (3)(d) below:

For the first type of connection, (3)(a), (Fig. 705-5) 125 percent of the inverter output current plus the rating of the normal source overcurrent device must not exceed the rating of the busbar. As explained in a new informational note, this scenario assumes no limitation on the numbers of loads or sources (and logically no limitation on the positioning of any of the entry or exit points) as applied to the buswork.

Fig. 705-5. Illustration of 705.12(B)(2)(3)(a).

Fig. 705-6. Illustration of 705.12(B)(2)(3)(b), and the connection shown in Fig. 690-1.

The second type of connection, (3)(b) (Fig. 705-6), is a slightly modified presentation of the requirement prior to the 2014 **NEC**: The inverter output connection is made at the opposite end of the busbar from the normal supply protection, and that value, when added to 125 percent of the inverter output current, is not to exceed 120 percent of the busbar rating, and a warning sign is to be placed in compliance with 110.21(B) prohibiting relocation of the inverter connection.

The third type of connection, (3)(c), (Fig. 705-7) requires that the maximum rating of all overcurrent protective devices (other than the main OCPD) installed in a panelboard must not exceed the rating of the busbar. This requirement also specifies that a warning label be provided to indicate that the combined ratings of OCPDs cannot exceed the rating of the panelboard busbars. Fig. 705-8 shows why this section now refers to interconnected sources in general, since no inverter is involved in this application, but the connection requirements raise the same issues.

Fig. 705-7. Illustration of 705.12(B)(2)(3)(c).

Fig. 705-8. A cogeneration installation at a college dormitory in continuous operation for 30 years, it would comply with this section if the required warning label were applied.

The fourth type of connection, (3)(d), (Fig. 705-9) covers center-fed panels that are common in some regions of the country. They often ship as combination equipment with a meter socket to the side. They benefit from the same procedure as at (b), but only one end of the panel is eligible for this treatment. This arrangement has a greater possible load concentration on half the bus, and is limited to dwellings where the likelihood of intensive demand is much less. For no observable reason, and this may very well be a mistake, the requirement for a warning label against repositioning the interconnected power source connection breaker was not repeated in this provision.

Fig. 705-9. Illustration of 705.12(B)(2)(3)(d).

The remainder of this discussion focuses on the connections made in accordance with 705.12(B)(2)(3)(b), which has become the usual mode of connection, and for that reason it deserves a bit more attention by way of explaining the concepts. Most panelboards have busbars with ratings equal to the rating of the main overcurrent protective device ahead of them in the panel. Refer to [Fig. 690-1](#), which shows a common 200-A panelboard. The **NEC** now requires, at (3)(b), that the input breaker from the inverter be at the opposite end of the bus from the normal main. In this way, no configuration of branch circuit or feeder loads could draw more than the current the busbars were designed to carry. In addition, the panel must be marked with a warning label advising against repositioning this breaker. There is, however, still a 20 percent limitation on the size of the interconnecting breaker, also at (3)(b). This is because, although the busbars could not be overloaded, the panel would still be delivering more power than the conditions under which it was tested. The 20 percent is a reasonable limit until more testing is carried out.

Note that what this refers to as a 20 percent rule is actually stated in the **NEC** as a requirement that all input breakers must not have a combined rating not over 120 percent of the busbars—which makes the effective limit on the branch to be 20 percent of the bus after taking out 100 percent of the main. Note also that main lug (MLO) panels in higher busbar ampere ratings are available. For example, in reference to [Fig. 690-1](#), it is possible to obtain a 200-A MLO panel and then install a comparable 150-A breaker (with hold-downs) as a side-feeding device at the upper end. Now an inverter requiring a 40-A interconnecting circuit breaker could be connected.

705.14. Output Characteristics. The interconnecting source must be controlled so as to be compatible with the applicable utility system. A note indicates that it is not necessary to match the wave shape exactly and still have a compatible system for interconnection.

705.16. Interrupting and Short-Circuit Current Rating. Cogenerating sources will, to varying degrees, elevate the available fault current on the system being connected to; as such sources are added this section requires a reevaluation of compliance of existing circuit components in terms of their ability to break currents at fault levels (110.9) and in terms of the required short-circuit current ratings of various types of equipment.

705.20. Disconnecting Means, Sources. Cogenerating sources must be disconnectable using a qualifying device under 705.22.

705.21. Disconnecting Means, Equipment. Equipment in the power train of a cogeneration source must be disconnectable from applied voltage on either side. In the case of the inverter in [Fig. 690-1](#), that would be the PV disconnect to its left, and the 30-A circuit breaker in the

panel to its right.

705.22. Disconnect Device. There is a seven-part rule covering the system disconnects from a cogeneration source, as follows: (1) They must be readily accessible; (2) They must be externally operable by hand even if their power supply fails; (3) They must be indicating; (4) They must be fully rated in terms of load and available fault current; (5) They must be equipped with a warning sign that all contacts can be energized if that is the case (and it usually is on these systems); (6) They require simultaneous action across all poles when the disconnect opens; and (7) They require a lock-open capability.

705.23. Interactive System Disconnecting Means. A readily accessible means must be installed to separate the interactive system from all other wiring systems on the premises. The point is to differentiate between the equipment disconnecting means that have their own requirements, and the system disconnecting means.

705.30. Overcurrent Protection. Conductors must have protection at both ends to cope with the multiple supplies that are inherent to this article. Part (A) (PV systems) and part (C) (Fuel cells) defer to those articles, as discussed at length in [Chap. 6](#) of this book. Transformers, covered in part (B) are considered from both sides as both primary and secondary in terms of overcurrent protection provided in accordance with 450.3. Interactive (and not just utility-interactive) inverters, per part (D), must comply with 705.65 and generators [part (E)] must comply with 705.130.

705.31. Location of Overcurrent Protection. This rule is new as of the 2014 **NEC**. Where premises power production sources interconnect on the supply side of the service equipment as covered in 705.12(A) and 230.82(6), overcurrent protection must be arranged within 10 ft of the connection. If that dimension is not met, then cable limiters or current-limiting circuit breakers must be located at the connection point. The likely difficulty and expense of applying that exception means that probably 10 ft will be the limit for these connections. These conductors have been unlimited by any express Code rule because they are not, strictly speaking, service conductors, but they are subject to the full utility available fault current should they fail. This change addresses that hazard.

705.32. Ground-Fault Protection. The preference is to make cogeneration connections on the line side of GFPE sensors; however, if there is GFPE arranged so as to offer protection from all current sources, then the cogeneration output may enter on the load side of the sensors. This may prove problematic on large cogeneration systems connected to remote panels.

705.40. Loss of Primary Source. When the primary source is interrupted, the cogenerating source must cease power production. If this were not to happen for any reason, the cogenerating source would be exporting power out into utility lines that are subject to service by utility line crews, an extreme hazard. Remember that these systems normally do not operate through transfer switches. There is an exception that allows for the development of listed interactive inverters that are capable of continuing to produce ac power, but without any power reaching the service conductors and beyond. In this way the cogeneration facility becomes, in effect, an Art. 702 optional standby system.

705.42. Loss of 3-Phase Primary Source. If the primary source is a 3-phase system, and a phase is dropped, the entire interactive system must disconnect unless it is a listed interactive inverter as in 705.40 Exception that will not export power back into the utility system, but will function instead as an island, at least until all utility phases are restored. If the parallel production source is supplying an Art. 700 or Art. 701 load, however, the requirement to shut down on a utility phase drop does not apply.

705.50. Grounding. Interconnected power production sources must follow the usual system and equipment grounding provisions that normally apply from Art. 250. However, for interactive dc systems connected through an inverter to a grounded ac system, equivalent methods using equipment listed to provide comparable system protection are permitted.

705.60. Circuit Sizing and Current. These systems are presumed to be continuous loads and the calculations must be done with the usual 125 percent factor.

705.65. Overcurrent Protection. Overcurrent protective devices are sized according to usual procedures, unless the source current is inherently so limited that the conductor ampacity will not be exceeded, and there are no parallel source connections, such as from batteries or inverter backfeed. Transformers also follow the usual overcurrent protection considerations, but the protection chosen must work as if either side could be primary or secondary, depending on conditions.

Because this topic now involves power sources not so inherently limited in capacity, (C) now creates a more open-ended calculation procedure that will work for any interactive source. The approach here marries the result in 705.60(B) with the feeder tap rules in 240.21(B).

705.70. Interactive Inverters Mounted in Not Readily Accessible Locations. This section covers utility-interactive inverters mounted in difficult locations such as rooftops. In such cases dc and ac disconnects must be mounted in sight of, and on the appropriate sides of the inverter. Then an additional ac disconnect must be mounted in accordance with the usual rules in 705.22 for a readily accessible location, and reciprocal labeling as required in 705.10 must be applied to this accessible disconnect and at the service equipment.

705.80. Utility-Interactive Power Systems Employing Energy Storage. Such systems must have a marking showing the polarity of the grounded circuit conductor, and the maximum operating voltage including the equalizing voltage if any.

705.82. Hybrid Systems. These systems are defined in 705.2 and involve multiple power production sources from PV to micro-hydro generators. They may include energy storage, but if so, the storage equipment is not a power source within this definition. This section allows hybrid systems to be connected to an interactive inverter.

705.95. Ampacity of Neutral Conductor. If a single-phase 2-wire inverter output is connected phase or line to neutral in a 3-wire or a 3-phase 4-wire system, the maximum connected load between the neutral and any one ungrounded conductor of that system, plus the inverter contribution, must not exceed the ampacity of the system neutral. This prevents such an inverter connection from overloading a neutral. For example, if a 100-A panel is wired with 3 AWG copper and has 80 A of line-to-neutral load and a 30-A line-to-neutral inverter input, 110 A of current can be taken out of the panel on line-to-neutral loads, overloading the busbar if the inverter connection is made at the same end as the service neutral connection.

A neutral used strictly for instrumentation and sized equal to or larger than the equipment grounding conductor is permitted to be sized smaller than its associated ungrounded conductors.

705.100. Unbalanced Interconnections. Single-phase hybrid inverters and ac modules in interactive systems must not be connected to a 3-phase system unless the interconnected system is designed to avoid significant unbalanced voltages. Three-phase interactive inverters must automatically deactivate if there is a loss of or unbalanced voltages in one or more phases, unless the system is designed to avoid significant unbalanced voltages. As of the 2014 NEC, when single-

phase inverters are connected to a 3-phase system, it must be done in such a way as to limit the unbalanced voltages to not over 3 percent. An informational note references an ANSI document that provides guidance on this point. The prior Code language was routinely interpreted as effectively prohibiting a practice that utilities routinely apply on their systems.

705.130. Overcurrent Protection. This is a reiteration of 705.30, with a sentence tacked on at the end requiring generators to be protected in accordance with 445.12. Because the rules in [Chaps. 1 through 4](#) apply unless modified here, this rule technically adds absolutely nothing to the NEC. The material here was copied from 705.30 in order to begin the population of a new Part III of the article so rotating sources would be grouped together.

705.143. Synchronous Generators. This requires controls on synchronous generators to maintain their synchronicity while in operation. This is not new material; it was relocated from its former location to group rules for rotating sources in a common location.

Part IV. Microgrid Systems.

705.150. System Operation. This is the first recognition of systems that can intentionally separate themselves from the normal power environment and then reconnect as needed. They are receiving increasing attention as a way to increase resiliency in premises wiring systems.

705.160. Primary Power Source Connection. These connections must comply with 705.12.

705.165. Reconnection to Primary Power Source. Intentionally islanded systems, as these were formerly known, that then intentionally reconnect must do so in a synchronous manner that does not disrupt the surrounding connections.

705.170. Microgrid Interconnect Devices (MID). These devices must be listed or field labeled for this use and comply with requirements that reflect 705.30 regarding overcurrent protection from all available directions. The key here will be the listings. There is an informational note at this point advising that these functions may be found in multimode inverters and other systems involved with interactive operation.

ARTICLE 706. ENERGY STORAGE SYSTEMS

706.1 Scope. This article, new in the 2017 NEC, applies to energy storage systems operating over 50 volts ac or 60 volts dc whether acting on a stand-alone basis or interactive with other electric power production sources. There is an extensive list of definitions, but key to the scope is the definition of energy storage system itself. It is:

- 1) comprised of one or more components
- 2) capable of storing energy
- 3) operational using electrical equipment (batteries, capacitors, etc.) or kinetic energy storage (flywheels, compressed air, etc.)
- 4) may have either ac or dc output
- 5) may include inverters or other components for interconnection

Energy storage systems are classified into one of three general forms:

- 1) Self-contained, pre-assembled into a single container or unit (ESS, self-contained)

- 2) Pre-engineered using matched components, intended to be field assembled (ESS, pre-engineered of matched components)
- 3) Other systems, that would be completely field assembled as a system from constituent parts (ESS, other)

These systems form points of mediation between variable sources of power, such as day vs. night for PV, windy vs. calm for wind, and variable demands for power. This will make them an important part of the future of energy distribution, on both sides of the service point.

706.5 Equipment. The components, with the exception of lead-acid batteries, must be listed, or a self-contained ESS can qualify for an overall listing.

706.7 Disconnecting Means. This section is inspired by 480.7 for batteries. Refer to the commentary in this book at that location for details. An exception to (D) waives some of the prescriptive information for the labeling if an arc label of the sort specified in NFAP 70E is applied. The informational note describes the requested content as falling entirely within the parameters of such labeling. In addition, the primary safety objective of the label is the ability to properly anticipate and mitigate the hazards of arc flashes. Large battery banks are a classic source of extremely high available fault current exposures. Part (E) is unique to this article and covers instances where the ESS is on the other side of a partition or at a distance and otherwise out of sight. Disconnects then become mandatory at both ends of the circuit; a lock-open alternative is not offered. Reciprocal placards are required advising of the location of the relevant disconnects.

706.8. Connection to Other Energy Sources. A load disconnect with multiple sources of power supplying it must disconnect all such sources from its load when it is in the OFF position. Inverters and ac modules that will be used in an interactive system must be listed for this duty. The remainder of this section points to material in Art. 705 and is discussed at that location in this book.

706.10. Energy Storage System Locations. This section is completely based on 480.9, but with some additional text that makes necessary allowances for pre-engineered and self-contained ESS applications.

706.11. Directory. Part (A) requires the usual power source reciprocal labeling at the service and at all locations where power production sources are capable of interconnection. This largely duplicates 705.10. If a facility has a stand-alone system, then a directory must be provided on the outside of the building as approved by the inspector. It must advise that there is a stand-alone electrical power system is on site, and specify the location for its disconnecting means. It copies 690.56(A), and it is somewhat surprising that this requirement is not in Art. 710.

706.20. Circuit Sizing and Current. These requirements are what might be expected, and were taken from other locations and adapted for this equipment. For example, 706.20(A)(1) comes from 692.8(A) and simply points to the nameplate; the inverter parameters all come from 690.8(A) and 705.60(A). The conductor ampacity rules are copied from 692.8(B) and (C).

706.21. Overcurrent Protection. This section, in part (A), effectively makes all tap rules off limits for ESS circuit conductors, because they must “be protected at the source.” Part (E) includes an unusual, but understandable requirement for fuses in this context. If a fuse is accessible to unqualified personnel, then it must be replaceable without exposing the operator to live parts, even where energized in both directions. The paragraph goes on to mention pullouts and other suitably rated devices. The location rule in (F) (not over 5 ft and within view) matches the disconnect location rule in 706.7(E).

706.23. Charge Control. Charge controllers are required and their controls must be accessible only to qualified persons.

Part (B) covers diversion charge controllers. If they are the sole means of controlling the charge, then a second, independent method must be in place to prevent overcharging. If there is also a diversion load, that load must have a higher voltage rating than that of the batteries, and it must not exceed the current rating of the diversion load charge controller. The power rating of the diversion load must be at least half again the power rating of the PV array. The conductor ampacity and overcurrent device ratings for the charging circuit must be at least half again the maximum current rating of the diversion charge controller.

If an ESS is utility interactive, and is using interactive inverters to control battery charge by diverting excess power into the utility system, then the charge regulation circuits do not have to comply with these rules. However, these systems must also have a second, independent means of preventing battery overcharging if the utility is off line, or if the primary charge controller fails for any reason.

Part (C) covers dc charge controllers used for battery charging or comparable converters. For example, a PV system might produce 5 A of current at 250 V, and the equipment could pass that on to the storage batteries as 24 V, 50 A. The output conductor ampacity must be based on the continuous rated output current for the selected voltage range, and the output voltage rating must be based on the maximum voltage of the charge controller or converter-selected output voltage setting.

706.30. Installation of Batteries. Any parts of an ESS for a dwelling unit that are accessible during routine maintenance must not exceed 100 V (double the voltage of prior codes). Any series battery string with a combined voltage exceeding 240 V, either between conductors or to ground, must have provisions to subdivide the string so the voltage limitation can be met. The disconnecting means do not require a load break rating.

Storage systems exceeding 100 V must have a similar switch, accessible only to qualified persons, that will open both grounded and ungrounded conductors for maintenance. The ESS can operate on an ungrounded system, provided there is a ground-fault detector in place that will detect a ground fault.

706.31. Battery and Cell Terminations. As recommended by the manufacturer, antioxidant compound must be used on terminals, and the wires landing on them must be arranged so as to prevent mechanical stress on the terminals. The wire size selected for terminal jumpers and rack take-offs must have been evaluated for temperature rise during full load conditions to avoid overheating of insulation or conductor supports.

706.32. Battery Interconnections. Single-conductor flexible cord is permitted, in sizes not smaller than 2/0 AWG, to be used as interconnecting cables on batteries, or to run from battery terminals to nearby enclosures to connect to normal building wire. The cord must be listed for hard service and identified as moisture resistant. The cord terminations must be made using components that are listed and marked for the use. Refer to the discussion at 110.14 for more information on this topic.

706.34. Battery Locations. This material comes straight from 480.10, for which there is additional information in this book.

706.40. General. This section and the ones that follow address flow batteries. These are defined in 706.2 and consist of an enclosed reactor surface that separates two liquids that create a potential difference on either side of the membrane as they flow past and react. This means they can be

instantly recharged by renewing the chemicals as they flow, while removing the spent chemicals for renewal (Fig. 706-1). The process has similarities to fuel cells, and Art. 692 provisions are incorporated into these rules by reference. The reagent tanks must be clearly identified by chemical compound, and posted at any point where it can be inserted into or removed from the system. The installation must also provide a method for electrolyte containment in the event of a spill, and the system must be alarmed in the event of such a failure. In addition, in the event of a blockage, the system must be arranged to shut down. The equipment must be evaluated for the chemical exposure, and all wiring must be routed to avoid contact with the chemicals.

Fig. 706-1. Flow battery components. Flow batteries store/release charge in/from the electrolyte solutions, instead of the electrodes.

706.50. General. Other ESS technology must comply with the **NEC** in general, and specifically Part III of Art. 705.

ARTICLE 708. CRITICAL OPERATIONS POWER SYSTEMS (COPS)

708.1. Scope. This new 2008 **NEC** article covers wiring in facilities that must be kept in operation in a “designated critical operations area (DCOA)” in the event normal operations are disrupted. This is a response to studies of infrastructure that followed the 9-11 attacks. These systems must be so classified by a governmental authority, or even by a facility engineering document establishing the need. For example, it would certainly be plausible for an oil refinery, for example, to document and provide such coverage that would be expected to survive a major conflagration. The scope of this article includes both power systems and also HVAC, communications, security, and alarm systems in such locations.

708.2. Definitions. Often seen in its acronym, *supervisory control and data acquisition*

(SCADA) is an electronic system that monitors and controls the operation of the critical operations power system. This includes start and stop functions in the power system, annunciation and communications to personnel, both within the facility and for remote operators. Annex G provides additional information on this topic.

708.4. Risk Assessment. Risk assessment must be documented with respect to identifying and quantifying the likelihood of various hazards to the electrical system, and assessing the vulnerability of the electrical system to those hazards. Then, based on the foregoing, a strategy must be implemented to mitigate hazards deemed insufficiently addressed by the applicable requirements of the **NEC**, both within this article and elsewhere. A note points to [Chap. 5](#) of **NFPA 1600-2007**, *Standard on Disaster/Emergency Management and Business Continuity Programs*, for guidance concerning risk assessment and hazard analysis.

708.5. Physical Security. Based on the risk assessment, a strategy for physically securing COPS must be developed, documented, and implemented. Electrical circuits and equipment for these systems must be made accessible exclusively to qualified persons.

708.6. Testing and Maintenance. This rule is the same as 700.4 except part (C) on maintenance applies to the entire COPS and not just the batteries, and a note points to **NFPA 70B-2006**, *Recommended Practice for Electrical Equipment Maintenance* for guidance on testing and maintenance procedures.

708.8. Commissioning. This is a defined term in 708.2. It includes the acceptance testing, operational tune-up work, and start-up testing in order to create a baseline of testing results that verify the proper operation and sequencing of electrical equipment operation, as well as creating a set of data such that future trends analysis can be applied to identify deteriorating equipment. This section requires a commissioning plan to be developed and documented, and a note here also points to **NFPA 70B**, this time for guidance on developing a commissioning program. The remainder of this section requires component and system tests to ensure proper functioning, and the documentation of all baseline test results. The section concludes with a requirement to create, document, and carry out a functional performance test program upon completion of the initial installation to provide the definitive baseline for future performance criteria. Annex F provides additional information on creating and carrying out a functional performance testing program.

The annex material includes formulas that use failure statistics, such as mean time between failures (*MTBF*). The IEEE has been accumulating this sort of data for several decades, as published in its *Gold Book*. In addition, the U.S. Army Corps of Engineers funded an exhaustive reliability survey in order to support its own mission. These are potential sources of information that can be used to perform the mandated statistical analysis. This article will require an extensive learning curve because it breaks new ground in the **NEC** by the extent it relies on performance-based rules, rather than the usual prescriptive requirements elsewhere. This in turn means that a heavy emphasis will be placed on the judgments of qualified engineering staff, because it will not be possible to compare their analysis with black-letter code. The AHJ will be in the position of umpiring analytical techniques few in that position have been traditionally familiar with.

708.10. Feeder and Branch-Circuit Wiring. All boxes and enclosures must be marked with permanent methods so they are readily identifiable as components of the COPS, but only in the event that a particular building has both COPS and normal power systems present. If the building is classified as entirely a COPS facility, then specific identification of boxes and enclosures is

pointless. Receptacles must also be so identified using a distinctive color or marking; however, in a stand-alone facility where all the receptacles are necessarily part of the system, no special identification scheme is required. As of the 2017 **NEC**, nonlocking 15- and 20-A. receptacles (no voltage parameter provided, therefore, literally applies to any voltage) must have either a lit face or an indicator light that shows the receptacle is powered.

COPS wiring must be completely divorced from any other wiring; however, if there are two distinct COPS in a particular location, then wiring from those two systems may share the same location. COPS wiring and normal wiring may enter the same transfer switch for obvious reasons.

The wiring methods are robust, consisting of heavy-wall steel conduit, or Type MI cable. PVC, RTRC, EMT, and LFNC or LFMC are permitted, but only where embedded in not less than 50 mm (2 in.) of concrete. A jacketed metallic cable assembly is also permitted in concrete if so listed for concrete embedment. If flexibility is required at a termination, flexible metal fittings, flexible metal, and liquidtight flexible metal conduits are permitted.

Feeders must have a fire separation generally using one of the same strategies enumerated in the list of techniques in 700.10(D)(1); specifically items (2), (3), (4), or (5). There is no waiver if the facility is fully sprinklered (1). If the facility is below the level of the 100-year floodplain, the conductors and wiring methods must be suitable for wet locations.

The wiring methods and fire separation rules for feeders also apply to branch circuits that are part of the system, if they are outside the DCOA. If they are inside the DCOA, then any methods in [Chap. 3](#) are permissible.

708.11. Branch-Circuit and Feeder Distribution Equipment. Branch circuit distributions must be within the same DCOA as is supplied by the circuit. Feeder circuits, including transfer equipment, panels and transformers, must be in spaces with a 2-h fire resistance rating and located above the 100-year floodplain.

708.12. Feeders and Branch Circuits Supplied by COPS. No equipment shall be supplied by either unless it is a required element of the COPS.

708.14. Wiring of HVAC, Fire Alarm, Security, Emergency Communications, and Signaling Systems. All such circuits must use rigid or intermediate metal conduit, or Type MI cable unless embedded in concrete. The former requirement for exclusively shielded cables has been relaxed, as of the 2014 **NEC**, in view of the reality that they are inconsistent with some data transmission protocols. The enclosing raceway methods are not changing, and it is now generally left to the performance requirements of the system and the published instructions of the manufacturer to determine the characteristics of the preferred cable assemblies, with fiber required between buildings on a property under single management. Listed primary protectors must be applied to all communications circuits. Listed secondary protectors are required on communications cable terminations. All control circuits operating over 50 V must use 600-V wiring. Relay contact ratings must exceed the control voltage and currents in the controlled circuit. Riser emergency communications cables must be Type CMR-CI or be run in a 2-h listed electrical circuit protective assembly. All fire alarm, security, and signaling systems must be riser rated and utilize a listed 2-h rated electrical circuit protective system.

HVAC system control and monitoring, as well as the power circuits to this equipment, must be in a qualifying 2-h electrical circuit protective assembly. Note that even concrete encasement, or routing within a listed assembly of building materials with a 2-h rating, does not comply with this rule.

708.20. Sources of Power. The permitted sources of power in the event of failure in the normal supply largely line up with emergency systems in 700.12. Part (A) is the first paragraph of 700.12 minus unit equipment. A major difference, however, is the absence of an arbitrary time-for-restoration parameter. In this location, the rule is the system must function in the “time required for the application.” Part (B) is the enhanced system for distribution and generation equipment in high-hazard occupancies as covered in the fourth paragraph of 700.12.

Part (C) on grounding is unique to Art. 708, and requires a COPS to be wired as a separately derived system with its own grounding and bonding equipment within it. However, if the service equipment containing the main bonding jumper meets the enhanced reliability provisions of 708.10(C) and 708.11(B), then an additional step of converting to a separately derived system is not required. Note that this exception also points to the location of a system bonding jumper. Since a system bonding jumper only pertains to a separately derived system, it is difficult to see how a system bonding jumper for a separately derived system belongs as an exception to a rule that requires a separately derived system. The panel failed to substantiate its insertion of this wording, so the importance of this particular reference remains unclear.

Part (D) is also unique to this article, and requires surge protection devices at all distribution levels within a COPS.

Part (E) covers storage batteries, using the language in 700.12(A). The first paragraph of the Art. 700 materials addresses the 1½-h rule, which is not appropriate for facilities that may need to be running for days or more.

Part (F) covers on-site generator sets, largely the same as in Art. 700. The following seven differences apply: (1) The 2-h fuel source rule is not brought over because these systems may need to run far longer. (2) There is no exception for an off-site fuel delivery system. (3) There is no provision for an auxiliary power supply for cases where a generator will not start in 10 s, which is appropriate given the provisions of the first paragraph. (4) There is no requirement for the generator disconnect in an outdoor set to be rated as suitable for use as service equipment. (5) There is an additional requirement that if a single generator is the alternate supply for a COPS, then permanent provisions must be made to connect a portable or vehicle-mounted generator. (6) There is an allowance for a portable generator to power the facility through a flanged inlet; this is new as of the 2014 **NEC**. (7) If internal combustion engines constitute the prime mover, the fuel must be stored on site, secured and protected as covered in the risk assessment documentation.

Part (G) covers UPS systems, and where they are the sole supply of a COPS, they must comply with the applicable rules of (E) and (F) just discussed. Part (H) recognizes fuel cell systems installed per Art. 692, but with no express performance requirements as appear in 700.12(E), which is somewhat unexpected. The original proposal contained this language, which the panel deleted without documenting its action.

708.21. Ventilation. The standby power source must be equipped with sufficient ventilation such that it will be able to operate continuously on even the hottest day.

708.22. Capacity of Power Sources. Part (C) drives much of the differences between these rules and their counterparts in 700.5, because these systems must be able to run for at least 72 h at the

full load of the DCOA while holding voltage to within 10 percent, plus or minus, of the nominal utilization voltage. This number was recommended by the U.S. Army Corps of Engineers based on what can be expected in terms of the replenishment of fuel, and the system may well be expected to function for longer periods. With that in mind, part (A) requires full load capacity for an indefinite period, and a redundant source available whenever the normal standby source is out of service for maintenance or repair. Note that this requirement is here instead of (B) as is its counterpart in 700.4, and also that it applies at any time the standby source is down, not just for occasions of “major” maintenance or repair. Part (B) is the same as 700.4(B) except that the COPS wiring is co-equal with the emergency system in the pecking order, and they are both to be energized first.

708.24. Transfer Equipment. These rules are the same as 700.6, although the requirements for listing and for electrical operation/mechanical holding are waived if the sources are inherently synchronized. This can occur in large facilities with multiple switchboards supplied from multiple power sources with other methods in operation to assure that the sources are synchronized. Part (E) requires the short-circuit current rating applicable to the transfer equipment under the extant types and settings of overcurrent protection to be field-marked on its exterior.

708.30. Branch Circuits Supplied by COPS. This, with respect to branch circuits, is a duplication of 708.12.

708.50. Accessibility. Only qualified persons are permitted access to overcurrent devices, a concept already essentially covered in 708.5(B).

708.52. Ground-Fault Protection of Equipment. This is a requirement for a second level of GFPE when a first level is installed to meet 230.95 or 215.10. It is similar to 517.17.

708.54. Selective Coordination. This correlates with 700.32 and 701.27. Refer to the discussion at 700.32 for more information on this controversial requirement. The same requirement for professional engineering support applies to these systems.

708.64. Emergency Operations Plan. A facility with a COPS must have an emergency operations plan, properly documented. NFPA 1600-2007 provides the guidance for developing and implementing emergency plans.

ARTICLE 710. STAND-ALONE SYSTEMS

710.1. Scope. This is the new home for stand-alone systems, which have inherently common features even though they have come up in several articles over the years, most notably former 690.10. Not all systems are utility interactive like the one in Fig. 690-1. Many such systems serve off-grid occupancies, and the NEC had to decide what to tell people wiring homes that were off-grid, but that might later be on-grid. The decision was to have all the branch-circuit wiring installed as if the occupancy were supplied with a normal service, including the panelboard. However, the supply arrangements at the panel would reflect the realities of a PV system. The feeder size from the off-grid source and the main overcurrent protection (to be located at the inverter) would be based in accordance with the size of the source output. The only limitation on the local source is that it be able to handle at least the highest single connected utilization equipment. The other general rule (710.6) is for all equipment to be listed or field labeled.

This raises the question of what to do with a 120/240-V panelboard, because inverters are usually single-voltage equipment, and in this case would usually be 120-V rated. Feeding only one of the

ungrounded buses would waste half the capacity of the board. The decision here was to allow both buses to be connected to the same line. This is contingent on the rating of the inverter overcurrent device being less than the current rating of the neutral bus, there being no 240-V outlets connected, and there being no multiwire branch circuits connected. There must also be a warning sign against such circuit connections, because if they were made, the grounded conductor would carry up to double its expected load. Although PV systems are well known for overriding the hold-down rule for back-fed panel mains in 408.36(D) [See 705.12(B)(5)], this does not happen for stand-alone systems, as clarified in 710.15(E).

ARTICLE 712. DIRECT CURRENT MICROGRIDS

712.1. Scope. This article, new as of the 2017 **NEC**, and in reference to the definition, covers dc power distribution systems that are powered by at least two interconnected dc power sources and that actively supply dc loads (which can include dc-to-ac inverters that supply ac loads). These systems do not generally have a connection to an ac primary power supply such as a utility service entrance. However, some are equipped with dc-ac bidirectional converters or dc-ac inverters. These systems offer inherent energy efficiency, because many renewable energy sources are inherently, or easily configured as, dc sources, including wind turbines, fuel cells, and photovoltaic systems. Every time dc is changed to ac (or vice-versa) there are inherent losses in the conversion that are avoided with direct dc load utilization. LED lighting is a classic example of the potential use of dc distributions, especially since part of the process of making an LED luminaire turn on is the rectification of ac to dc, and a dc circuit eliminates that step.

These systems are ever increasing in size and number, driven by steady advances in energy storage systems (Art. 706), reliable methods for large-scale dc power transformation, and decreasing costs of PV as a dc power source. The substantiation cited such seemingly unlikely examples as an auto assembly plant in Michigan and a jail in California that is currently integrating power from four dc sources (PV, fuel cells, wind, and diesel generators).

712.2. Definitions. Most topics on this list are described within the context where they are discussed here. However, one definition will be key to understanding a good deal of what applies generally, “Reference-Grounded dc System.” This is exactly the same as the “Functional Grounded PV System” that is discussed at great length in Art. 690, except it is not a photovoltaic system. However, many of these systems will be powered by exactly that sort of system. Understand that the two concepts are identical and completely compatible. Undoubtedly a common term will be agreed on by the end of the next Code cycle.

712.3. Other Articles. If a dc microgrid has the capacity to operate in parallel with a conventional utility source, it must do so in accordance with the provisions of Art. 705. Key to this type of arrangement will be some sort of, presumably listed, Island Interconnection Device (IID) that will serve as the gatekeeper. See also 705.170, which covers the ac counterpart, the MID.

712.10. Directory. This is a reciprocal labeling requirement, with all potentially primary dc sources included.

712.25. Identification of Circuit Conductors. The usual rules for dc conductors apply. However, there is a semantic conflict between Art. 690 and this article. This section refers to “ungrounded conductors” as following 210.5(C)(2). In many cases, one of the conductors in the circuit will be “reference grounded.” It is not an ungrounded conductor subject to the red and black

default color code in Art. 210. So now, suppose the negative (and therefore black) wire on a PV supplied microgrid is functionally grounded, and in accordance with 690.31(B)(1) it is, indeed, not colored white. When it arrives at the microgrid it is powering, now it might become a white wire. This will obviously need to be sorted out with the inspector. It should, in fact, remain a black wire. This is why 712.35 correctly insists that this wire be disconnected along with its red brother at any disconnecting means. It is not a grounded circuit conductor for these purposes. Note also that reidentification is permitted for 6 AWG and smaller wires; this is to assist retrofitting this technology into existing wiring.

Part III. Disconnecting Means. One of the most interesting and important sections here is 712.37, and its informational note. This section actually reaches beyond simple disconnect switches and covers control equipment as well. It turns out that there is a great deal of dc-rated equipment that is extremely polarity sensitive, and must be installed accordingly.

712.52. System Grounding. Part (A) requires grounding in accordance with 250.162. That is not particularly enlightening, because, the only system grounding requirement conferred by that reference is one for 300 volts and below, which must be grounded. However, it is far from clear whether a reference ground satisfies this rule, and that may rule out reference ground connections at lower voltages. Note that reference (or functional) grounding is essential for the ground fault detection requirement in 712.55 to proceed. The PV ground fault requirement in 690.41(B) functions through a ground reference that the literal text here compromises at lower voltages. Above 300 volts, there are no issues with 250.162 and reference/functional grounding is mandatory.

712.55. Ground-Fault Detection Equipment. This section builds on the long-standing success that has come from PV systems covered in 690.41(B). Any system operating over 60 volts must have this equipment. The actual grounding system must be identified and marked “in accordance with 250.167(C).” There may be a problem with that reference. 250.167(C) comes with an informational note pointing to the list of dc grounding systems in **NFPA 70E**. That list is reproduced in this book, and it does not include reference (or functional) grounding. This may be another topic of conversation with the inspector.

712.57. Arc-Fault Protection. This protection is required “where required elsewhere in this Code.” The type of protection the input submitters had in mind is clear; it is the type required for PV systems by 690.11. It is unclear whether any other section in the **NEC** requires dc arc-fault protection. This rule is presumably a placeholder to drive market interest in an expansion of the applicability of the technology supporting 690.11.

Part V. Marking. The maximum available dc short-circuit current on the microgrid must be determined and field-marked at the dc source equipment, together with the date the calculation was made. The calculation is to be revisited if changes that would affect the result take place.

Part VI. Protection. For multiple sources of power (and remember, the definition insists that there be more than just one) there must be overcurrent protection from all of them. The contributions of all sources must be considered in determining the applicable available fault current and the required short-circuit current ratings of all equipment for which that is relevant, principally equipment intended to break current at fault levels.

ARTICLE 720. CIRCUITS AND EQUIPMENT OPERATING AT LESS THAN 50 VOLTS

720.1. Scope. This article covers low-voltage applications that are not power-limited circuits as defined in 725.2 and are not remote-control or signal circuits. Determination that Art. 720 applies to any circuit or equipment must be carefully made on the basis of the particular load being supplied and circuit conditions. This article covers circuits operating at more than 30 V but not over 50 V—such as 32-V circuiting. Be aware that any low-voltage lighting system that specifically is “listed” as a “low-voltage lighting system” must comply with the requirements given in Art. 411. If, however, the low-voltage lighting in question is not listed as a complete system, then the requirements given here must be observed. Other installations that are exempted from the requirements given here are those covered by the articles indicated by 720.2.

This article looks very much the same today as it did in the 1930s, when it was introduced to deal with rural farms wired on 32-V battery systems charged with windmills. Since the advent of the Rural Electrification Administration (REA) in the later part of that decade, this article has become increasingly irrelevant.

720.4. Conductors. The minimum No. 12 conductor size, rather than No. 14 as permitted for standard power and light wiring, is aimed at the higher current required for a given wattage load at low voltage. For instance, at 32 V, the current corresponding to a given wattage is 3.6 times the current for the same wattage at 115 V. It should also be noted that for a given load in watts and a given size of wire and circuit length, the voltage drop in percentage is about 13 times as great at 32 V as at 115 V.

720.5. Lampholders. Where medium-base sockets are used, there is no good reason for using any but those having a 660-W rating. The ampere ratings of candelabra and intermediate-base sockets would permit the use of 25-W lamps at 32 V, but it is not considered safe to allow the installation of these low-wattage sockets on circuits operating at 50 V or less.

720.7. Receptacles Required. Receptacles must be rated 20 A where used in kitchens, laundries, and other locations where portable appliances are likely to be used. This is a good example of a section in this article that is unchanged since at least as far back as the 1937 **NEC**, and that largely dates the article.

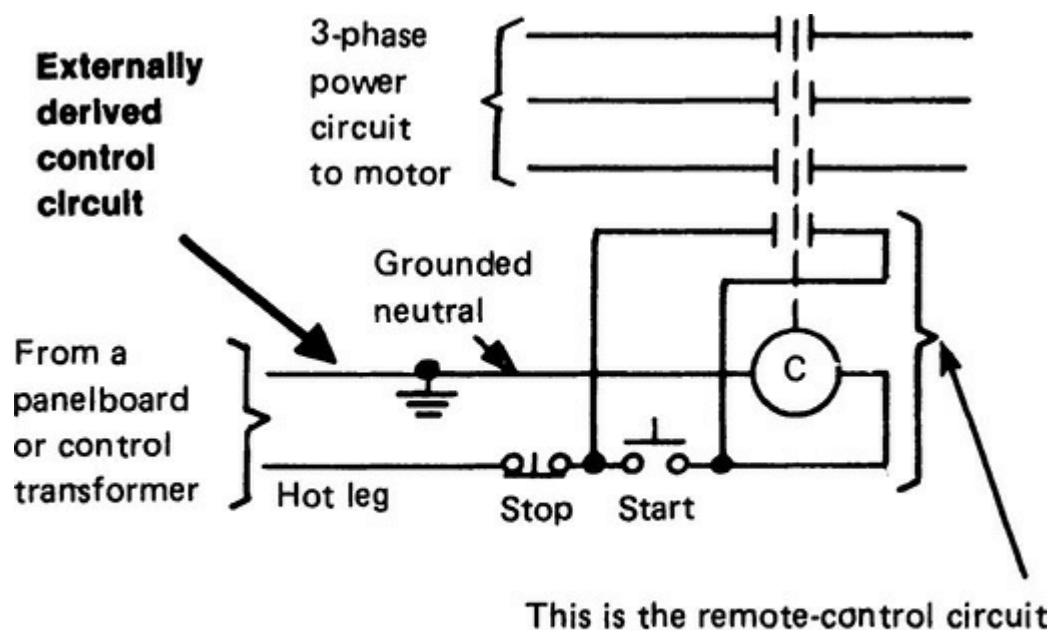

720.11. Mechanical Execution of Work. This section essentially reiterates the requirement given in 110.12. Although, according to 90.3, all requirements given in [Chaps. 1 through 4](#) generally apply to installations and equipment covered by [Chaps. 5 through 7](#), the inclusion of this requirement here, clarifies that applicability of the general requirement given in 110.12 to the work covered by Art. 720. Cables must be supported in a way that ensures they will not be damaged by normal building use.

ARTICLE 725. CLASS 1, CLASS 2, AND CLASS 3 REMOTE-CONTROL, SIGNALING, AND POWER-LIMITED CIRCUITS

725.1. Scope. Article 725 of the Code covers power-limited circuits and remote-control and signal circuits. A signal circuit is defined as any electrical circuit that supplies energy to an appliance or device that gives a visual and/or audible signal. Such circuits include those for doorbells, buzzers, code-calling systems, signal lights, annunciators, fire or smoke detection, fire or burglar alarm, and other detection indication or alarm devices.

A “remote-control” circuit is any circuit that has as its load device the operating coil of a magnetic

motor starter, a magnetic contactor, or a relay. Strictly speaking, it is a circuit that exercises control over one or more other circuits. And these other circuits controlled by the control circuit may themselves be control circuits or they may be “load” circuits—carrying utilization current to a lighting, heating, power, or signal device. Figure 725-1 clarifies the distinction between control circuits and load circuits.

ARTICLE 725 APPLIES

Fig. 725-1. A control circuit governs the operating coil or some other element, to switch the load circuit. (Sec. 725.1.)

The elements of a control circuit include all the equipment and devices concerned with the function of the circuit: conductors, raceway, contactor operating coil, source of energy supply to the circuit, overcurrent protective devices, and all switching devices that govern energization of the operating coil. Typical control circuits include the operating-coil circuit of magnetic motor starters (**NEC** 430.71 and 430.72), magnetic contactors (as used for switching lighting, heating, and power loads), and relays. Control circuits include wiring between solid-state control devices as well as between magnetically actuated components. Low-voltage relay switching of lighting and power loads is also classified as remote-control wiring ([Fig. 725-2](#)).

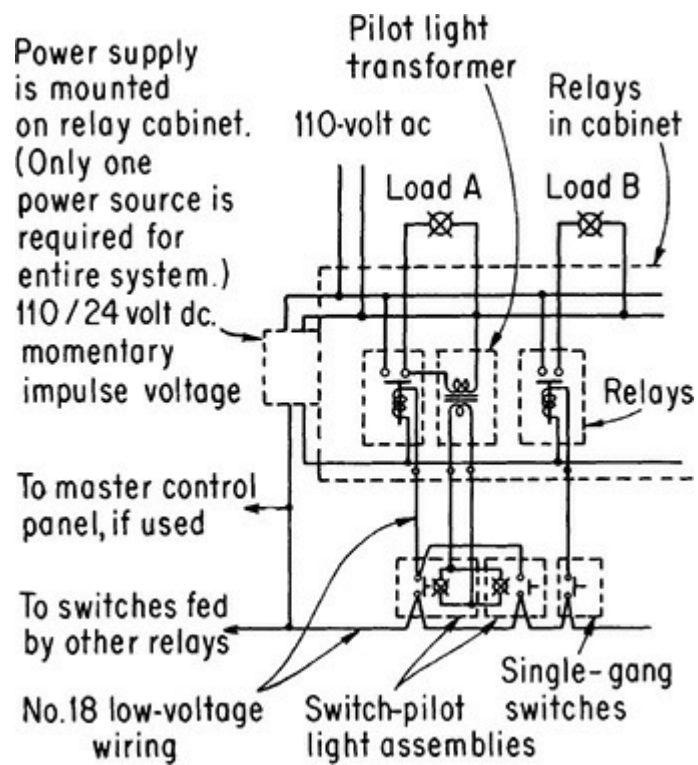

Fig. 725-2. Low-voltage switching involves typical “remote-control circuits.” (Sec. 725.1.)

Power-limited circuits are circuits used for functions other than signaling or remote control, but in which the source of the energy supply is limited in its power (volts times amps) to specified maximum levels. Low-voltage lighting, using 12-V lamps in fixtures fed from 120/12-V transformers, is a typical “power-limited circuit” application.

725.2. Definitions. The provisions of this section divide all signaling and remote-control systems into three classes.

Class 1 includes all signaling and remote-control systems that do not have the special current limitations of Class 2 and Class 3 systems.

Class 2 and Class 3 systems are those systems in which the current is limited to certain specified low values by fuses or CBs, and by supply through transformers that will deliver only very small currents on short circuit, or by other means that are considered satisfactory. All Class 2 and 3 circuits must have a power source with power-limiting characteristics as described in parts (A)(1) through (4) in 725.121. Class 2 circuits consider power limitation in terms of both shock and fire hazard; Class 3 circuits have higher power ratings and consider power levels largely in terms of fire initiation.

725.3. Other Articles. All the applications under this article must observe the specified sections that also rule on use of general power and light wiring.

Part (B) prohibits any installation of remote-control, signaling, or power-limited wiring in such a way that there is an appreciable reduction in the fire rating of floors, walls, or ceilings.

Part (C) requires that Class 1 circuits covered by this article must be run in metal raceway or metal cable assembly when used in an air-handling ceiling, as required by 300.22. Class 2 and/or 3 circuits (as defined in 725.2) are permitted to be used without a metal raceway or metal cable cover in ducts, plenums, or ceiling spaces used for environmental air *provided that the conductors are “listed” as Type CL2P or CL3P, as required in 725.154.* Because of the definition of the word “listed” (see Art. 100, “Definitions”), this rule would require that any such nonmetallic assembly of

conductors for these circuits must be specifically described in the relevant UL product documentation (or with similar third-party certification) as having the specified characteristics for use without a metal raceway or covering in ducts, plenums, and air-handling ceilings.

Note: For any such application, check that the conductors of the circuit are definitely listed by UL or others.

Part (F) notes that Art. 725 does not apply to control circuits tapped from line terminals in motor starters. As described under 430.72, the control circuit for the operating coil in a magnetic motor starter where the coil voltage supply is tapped from the line terminals of the starter is regulated by the rules of 430.72 and not by the remote-control rules of Art. 725. Where a control circuit for the operating coil of one or more magnetic motor starters is derived from a separate control transformer, one that is not fed from a motor branch circuit, the control circuit(s) and all components are covered by the rules of Art. 725. In the same way, a control circuit that is taken from a panelboard for power supply to the operating coil of one or more motor starters is also covered by Art. 725 and not by the rules of 430.72. (See [Fig. 725-1](#).)

Part (G) correlates control circuits wired under the provisions of Art. 727, which is a wiring method used for certain industrial control circuits, with this article.

Part (H) incorporates the rules in 300.7(A) for sealing raceway interiors that are subject to convective air migration, particularly where condensation is a likely result.

Part (I) brings in the vertical support rules for cables run in raceway, but only for the circuit-integrity (CI) cables. This makes sense because in a fire condition, these cables become extremely brittle and vertical supports can easily make a significant difference in how long they survive. These cables must be used in close agreement with the directions that come with them from their manufacturer in terms of installation methods, and these may be more restrictive than the limits in 300.19.

Part (J) requires a bushing in accordance with 300.15(C) where cables emerge from being sleeved in a raceway riser for physical protection. Note that the actual 300.15(C) rule requires a fitting to protect the cable from abrasion, which could be some sort of change-over fitting, and does not mention a bushing.

Part (K) brings in the requirements on 300.8 to divorce electrical raceways from any conveyance of nonelectrical systems. Part (L) brings in corrosion-resistance provisions in [Chaps. 1](#) and [3](#) and applies them to Class 2 and Class 3 circuits.

Parts (M) and (N) bring in cable routing assemblies and communications raceways as suitable for use with Art. 725 cabling.

725.21. Access to Electrical Equipment Behind Panels Designed to Allow

Access. It is contrary to the **NEC** to drape endless quantities of these cables across suspended ceiling panels in a way that limits the intended access to the ceiling cavity above them.

725.24. Mechanical Execution of Work. In addition to the usual neat and workmanlike manner requirement, this section also requires exposed cabling (which includes the area above a suspended ceiling) to be supported to structure such that normal building operations will not damage the cable. In addition, if the wiring is run parallel to framing, it must meet the 32 mm (1¼ in.) spacing requirement from the leading edge of the framing.

725.25. Abandoned Cables. The last sentence here has the effect of requiring that any “abandoned” conductors—as defined in 725.2 as not being terminated or identified for future use

with a tag—must be removed. It is no longer permissible to leave abandoned Class 2 and Class 3 conductors in place when they are no longer in use, unless they have been “identified” for future use. See 725.2.

725.30. Class 1, Class 2, and Class 3 Circuit Identification. Circuits covered by this article must be identifiable at terminations so as to prevent inadvertent interference with other systems during service and testing.

725.31. Safety-Control Equipment. The application of this rule is illustrated by Fig. 725-3, which is a simplified diagram of a common type of automatic control for a domestic oil burner. Assuming a steam boiler, the safety control is a switch that opens automatically when the steam pressure reaches a predetermined value and, preferably, also opens if the water level is allowed to fall too low. The master control includes a transformer of the current-limiting type that supplies the thermostat circuit at a voltage of 24 V. When the thermostat contacts close, a relay closes the circuits to the motor and to the ignition transformer.

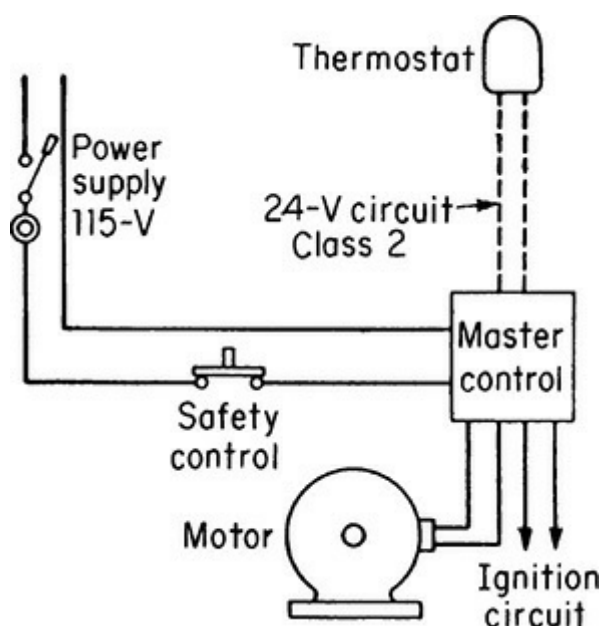

Fig. 725-3. Remote-control circuit *must* be Class 1 if failure would create a hazard. (Sec. 725.31.)

Failure of the safety control or ignition to operate would introduce a direct hazard; hence, the circuits to this equipment are Class 1. Part (B) gives the permitted wiring methods to be used if the safety-control rule applies and the control circuit is reclassified as Class 1.

The thermostat circuit fulfills all requirements of a Class 2 circuit and can be short-circuited or broken without introducing any hazard. The wiring of this circuit can therefore be done with any type of wire or cable that is sufficiently protected from physical damage to ensure serviceability.

725.41. Class 1 Circuit Classifications and Power Source Requirements. Class 1 systems may operate at any voltage not exceeding 600 V. They are, in many cases, merely extensions of light and power systems, and, with a few exceptions, are subject to all the installation rules for light and power systems.

Part (A) requires that Class 1 power-limited circuits must have energy limitation on the power source that supplies them. And such circuits may be supplied from either a transformer or another type of power supply—such as a generator, batteries, or manufactured power supply. Note that a Class 1 power-limited circuit must be supplied at *not over* 30 V, 1000 VA. There are other sources

for these circuits, as presented in the second numbered topic. These rules set the power limitations for these alternate sources.

Part **(B)**, however, permits Class 1 remote-control or signaling circuits to operate at up to 600 V, and no limitation is placed on the power rating of the source to such circuits (Fig. 725-4).

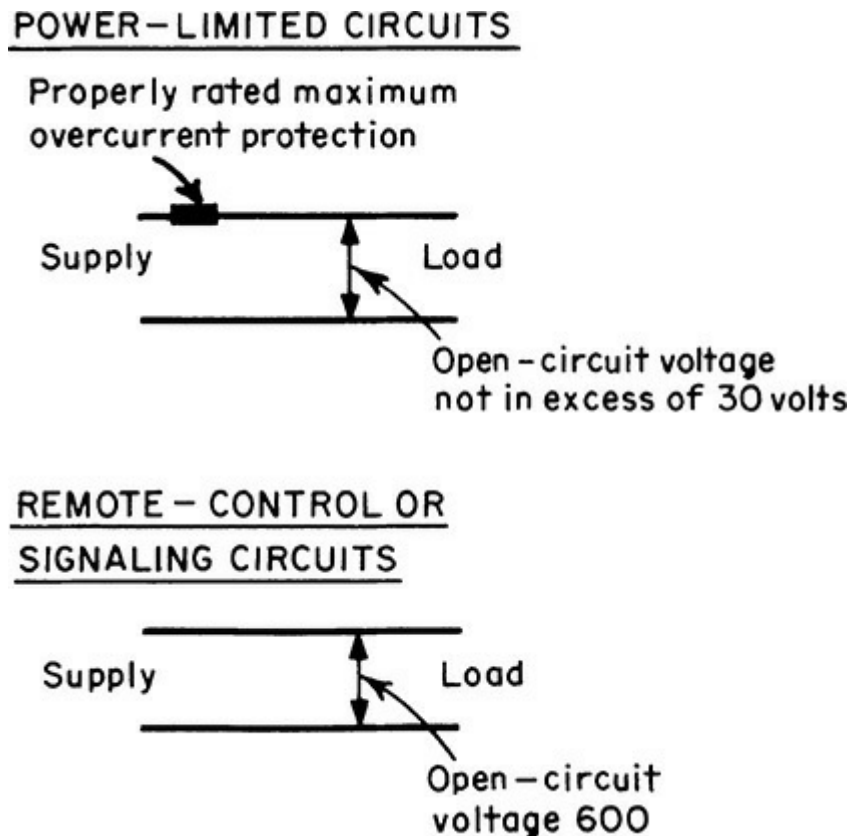

Fig. 725-4. Class 1 circuits are divided into two maximum voltages. (Sec. 725.41.)

The most common example of a Class 1 remote-control system is the circuit wiring and devices used for the operation of a magnetically operated motor controller. The term *remote-control switch* is used in various Code references to designate a switch or contactor used for the remote control of a feeder or branch circuit, with the operating-coil circuit as a Class 1 remote-control circuit.

The signaling systems that are included in Class 1 operate at 120 V with 20-A overcurrent protection, although they are not necessarily limited to this voltage and current. Some of the signaling systems that may be so operated include electric clocks, bank alarm systems, and factory call systems. An example of a lower-voltage Class 1 signaling system is a nurses' call system, as used in hospitals. Such systems commonly operate at not over 25 V.

Most control circuits for magnetic starters and contactors could not qualify as Class 2 or Class 3 circuits because of the relatively high energy required for operating coils. And any control circuit rated over 150 V (such as 220- or 440-V coil circuits) can never qualify, regardless of energy.

Class 1 control circuits include all operating-coil circuits for magnetic starters or contactors that do not meet the requirements for Class 2 or 3 circuits. Class 1 circuits must be wired in accordance with the requirements of Part II of Art. 725.

725.43 and 725.45. Class 1 Circuit Overcurrent Protection and Location. In general, conductors for any Class 1 remote-control, signaling, or power-limited circuit must be protected against overcurrent. No. 14 AWG and larger wires must generally be protected at their

ampacities from **NEC** Table 310.15(B)(16). In the second clause of this rule, an important statement indicates that it is *not* necessary to take any ampere derating—for either elevated ambient temperature or for more than three wires in a conduit or cable. The wires may simply be used and protected at the ampacity values given in the table.

Important: The clause “without applying the derating factors of 310.15 to the ampacity calculations” is a strange permission, which can be disregarded without violating this or any Code rule. And there seems to be a conflict between this clause and the requirement in 725.51 that Class I conductors must be derated under some conditions. Actually, there is no conflict. This rule says derating factors need not be applied in figuring the size of the overcurrent protection; however, they must be applied in evaluating acceptable loading on those wires, as covered in 725.51. Figure the overcurrent protection on the table numbers, but be sure to factor any derating into the size of the wires selected.

It is important to note that Nos. 18 and 16 control or signal-circuit conductors must always be protected at not over 7 or 10 A, respectively. These smaller sizes of wire may be used for control and signal circuits supplying coils, relays, or signal devices. Note that these are OCPD limits; the actual load must not exceed the limits in Table 402.5 (6 A and 8 A, respectively) as provided in 725.49(A).

The rule of 725.45(D) is the same as that of 240.3(F), but applies to the case where the 2-wire transformer secondary supplies a control circuit to one or more operating coils in motor starters or magnetic contactors. A properly sized circuit breaker or fuses may be used at the supply end of the circuit that feeds the transformer primary and may provide overcurrent protection for the primary conductors, for the transformer itself, and for conductors of the control circuit, which is run from the transformer secondary to supply power to motor starters or other control equipment, as follows:

1. The primary-side protection must not be rated greater than that required by 450.3(B)(1) for transformers rated up to 600 V. For a transformer rated 9 A or more, the rating of the primary CB or fuses must not be greater than 125 percent of (1.25 times) the rated transformer primary current. And if 1.25 times rated primary current does not yield a value exactly the same as a standard rating of fuse or CB, the next-higher-rated standard protective device may be used. Where the transformer-rated primary current is less than 9 A—as it would be for all the usual control transformers rated 5000 VA and stepping 480 V down to 120 V—the maximum permitted rating of primary protection must not exceed 167 percent of (1.67 times) the rated primary current. For a transformer with a primary rated less than 2 A, the primary protection must never exceed 300 percent of (3 times) the rated primary current. With most control transformers, with primary ratings well below 10 A, fuse protection will be required on the primary because the smallest standard CB rating is 15 A, and that will generally exceed the maximum values of primary protection permitted by 450.3(B)(1). (See [Fig. 725-5](#).)

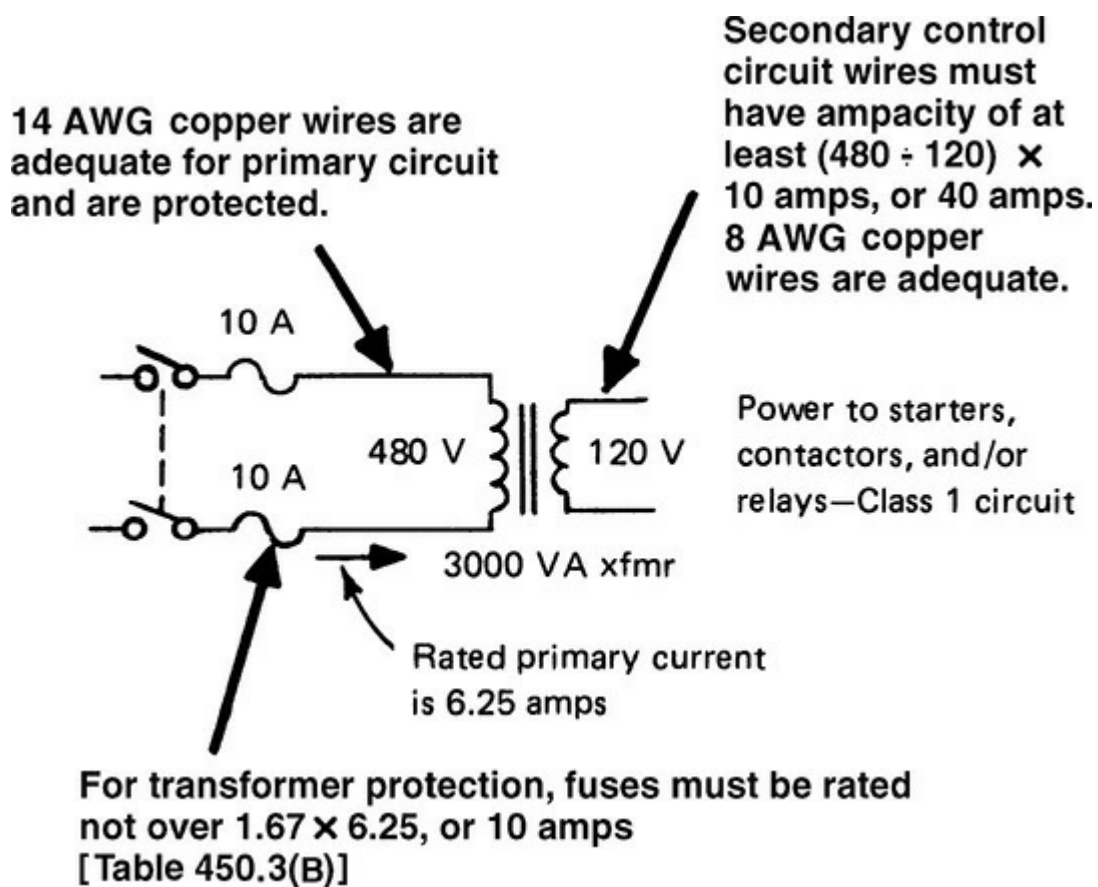

Fig. 725-5. A separate control transformer supplying a number of coil circuits for motor starters or magnetic contactors must have primary protection that protects the secondary control conductors as well as the transformer. (Sec. 725.43.)

2. Primary protection must not exceed the amp rating of the primary circuit conductors. And when protection is sized for the transformer, as previously described, 14 AWG copper primary conductors will be protected well within their 15-A rating.
3. Secondary conductors for the control circuit can then be selected to have an ampacity at least equal to the rating of primary protection times the primary-to-secondary transformer voltage ratio. Of course, larger conductors may be used if needed to keep voltage drop within limits.

In [Fig. 725-6](#), covering use of a magnetic contactor, 14 AWG and larger remote-control conductors may be properly protected by the feeder or branch-circuit overcurrent devices if the devices are rated or set at not more than 300 percent of (3 times) the ampacity of the control conductors. If the branch-circuit overcurrent devices were rated or set at more than 300 percent of the rating of the control conductors, the control conductors would have to be protected by separate protective devices located within the contactor enclosure at the point where the conductor to be protected receives its supply.

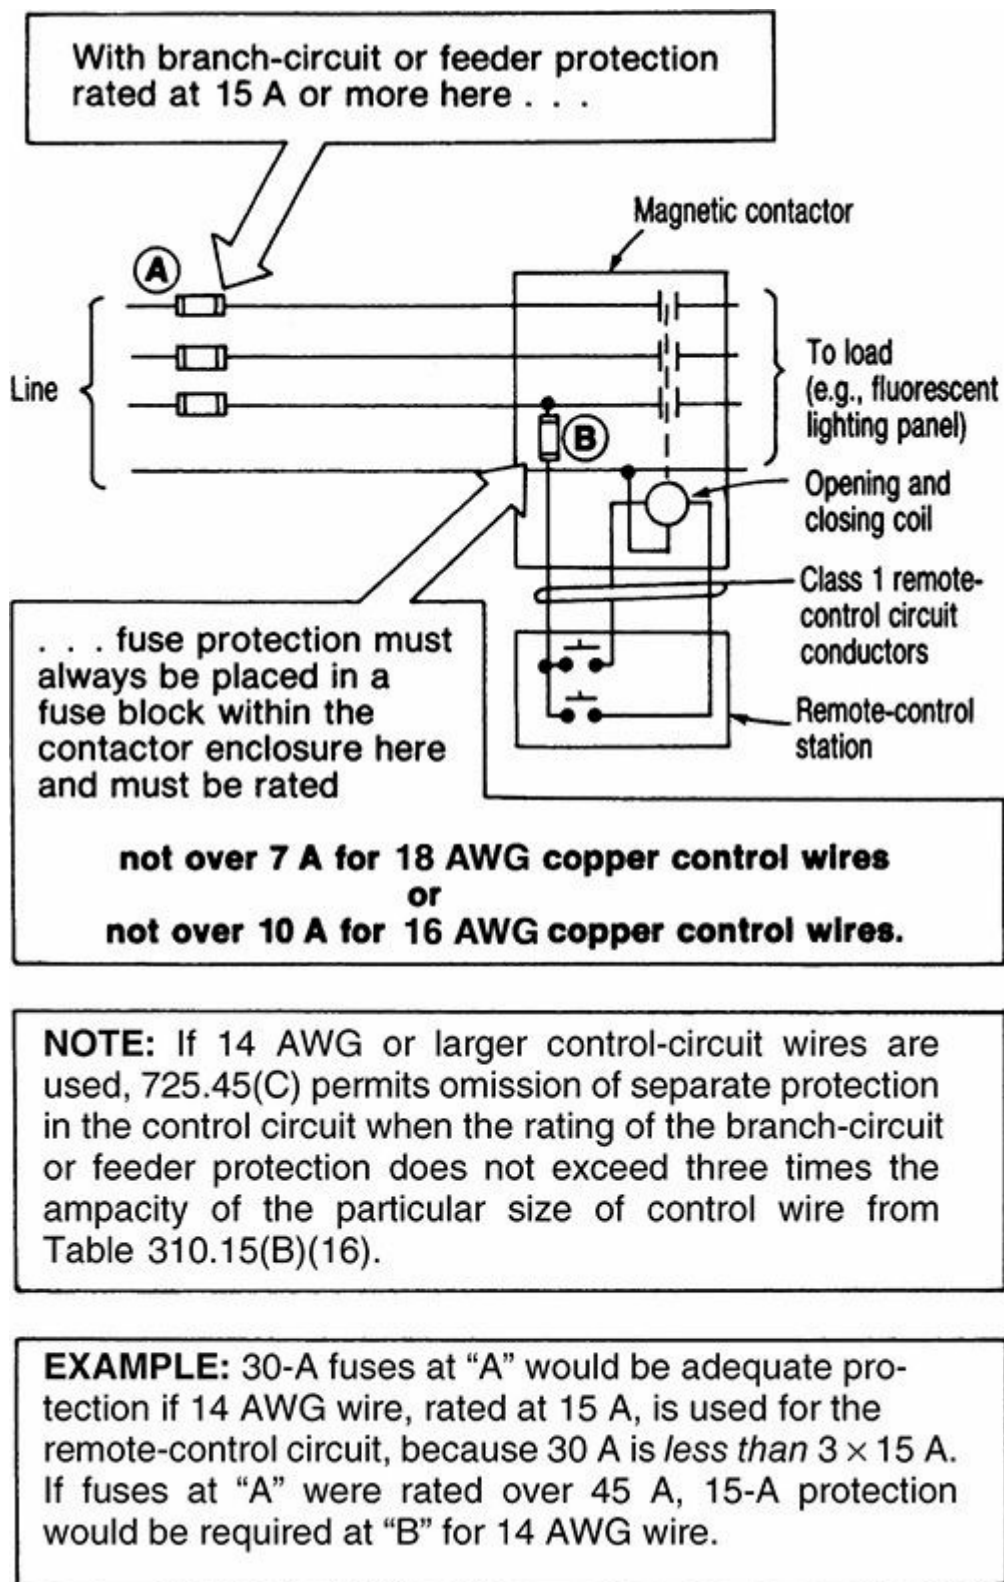

Fig. 725-6. Protection of coil circuit of a magnetic contactor is similar to that of a starter. (Sec. 725.43 and 725.45.)

This is covered by 725.45(C), which applies to the remote-control circuit that energizes the operating coil of a magnetic contactor, as distinguished from a magnetic motor starter. Although it is true that a magnetic starter is a magnetic contactor with the addition of running overload relays, part (C) covers only the coil circuit of a magnetic contactor. That applies to control wires for magnetic contactors used for control of lighting or heating loads, but not motor loads. 430.72 covers that requirement for motor-control circuits.

In Fig. 725-6, for instance, 45-A fuses at A in the feeder or branch circuit ahead of the contactor

would be adequate protection if 14 AWG wire, with its ampacity of 15 A [reduced from 20 A in Table 310.15(B)(16) for 75°C and 90°C conductors by 240.4(D)(3)], were used for the remote-control circuit, because 45 A is not more than 300 percent of (3 times) the 15-A ampacity. Larger fuses ahead of the contactor would require overcurrent protection in the hot leg of the control circuit, at B, rated not over 15 A. [See 240.4(D).] Similar calculations apply to electronic sources, as covered in (E).

Note that the overcurrent protection is required for the control conductors and not for the operating coil. Because of this, the size of control conductors can be selected to allow application without separate overcurrent protection. When overcurrent protection is added in the enclosure, its rating must be such that it conforms to the first paragraph of this rule.

725.46. Class 1 Circuit Wiring Methods. In general, wiring of Class 1 signal systems must be the same as power and light wiring, using any of the cable or raceway wiring methods that are Code-recognized for general-purpose wiring. The two exceptions refer to the details of wiring permitted by 725.48, 725.49, and 725.51.

725.48. Conductors of Different Circuits in Same Cable, Cable Tray, Enclosure, or Raceway. Any number and any type of Class 1 circuit conductors—for remote control, for signaling, and/or for power-limited circuits—may be installed in the same conduit, raceway, box, or other enclosure *if* all conductors are insulated for the maximum voltage at which any of the conductors operates.

Class 1 circuit wires (starter coil-circuit wires, signal wires, and power-limited circuits) may be run in raceways by themselves in accordance with the first sentence of this section. A given conduit, for instance, may carry one or several sets of Class 1 circuit wires. And 725.46 says use of Class 1 wires must conform to the same basic rules from [NEC Chap. 3](#) that apply to standard power and light wiring.

But note that two specific sections of the **NEC** cover the use of Class 1 circuit conductors in the same raceway, cable, or enclosure containing circuit wires carrying power to a lighting load, a heating load, or a motor load ([Fig. 725-7](#)). 300.3 covers the general use of “conductors of different systems” in raceways as well as in cable assemblies and in equipment wiring enclosures (i.e., cabinets, housings, starter enclosures, junction boxes). But Class 1 circuit wires are also regulated by this section, which strictly limits use of Class 1 wires in the same box and/or raceway with power wires. Figure 725-8 shows a clear violation, if the annunciator has no relationship to the motor load.

Fig. 725-7. This is permitted by 300.3(C) and 725.48. (Sec. 725.48.)

Fig. 725-8. Class 1 wires must generally *not* be used in raceways with “unrelated” wires. (Sec. 725.48.)

Note that 725.48(B)(1) permits Class 1 circuit wires to be installed in the same raceway or enclosure as “power supply” conductors *only* if the Class 1 wires and the power wires are “functionally associated” with each other. That would be the case where the power conductors to a motor are run in the same conduit along with the Class 1 circuit wires of the magnetic motor starter used to control or to start or stop the motor. Refer to the commentary in 300.3.

The same permission would apply to the hookup of a magnetic contactor controlling a lighting or heating load, as shown in Fig. 725-9. There the circuit wires for the Class 1 remote-control run to the pushbutton station may be run in the same conduit carrying the wires supplying the lighting fixtures. A typical application would have the magnetic contactor adjacent to a panelboard, with the control and power wires run in the same raceway to a box at some point where it is convenient to bring the control wires down to the control switch and carry the power wires to the lighting fixtures being controlled. The contactor can be located at the approximate center of its lighting load to keep circuit wiring as short as possible for minimum voltage drop, and the control wires are then carried to one or more control points. In such a layout, the control and power wires are definitely “functionally associated” because the control wires provide the ON-OFF function for the lighting. *But* other control or power wires are prohibited from being in the same conduit, boxes, or enclosures with the single set of associated Class 1 and power wires.

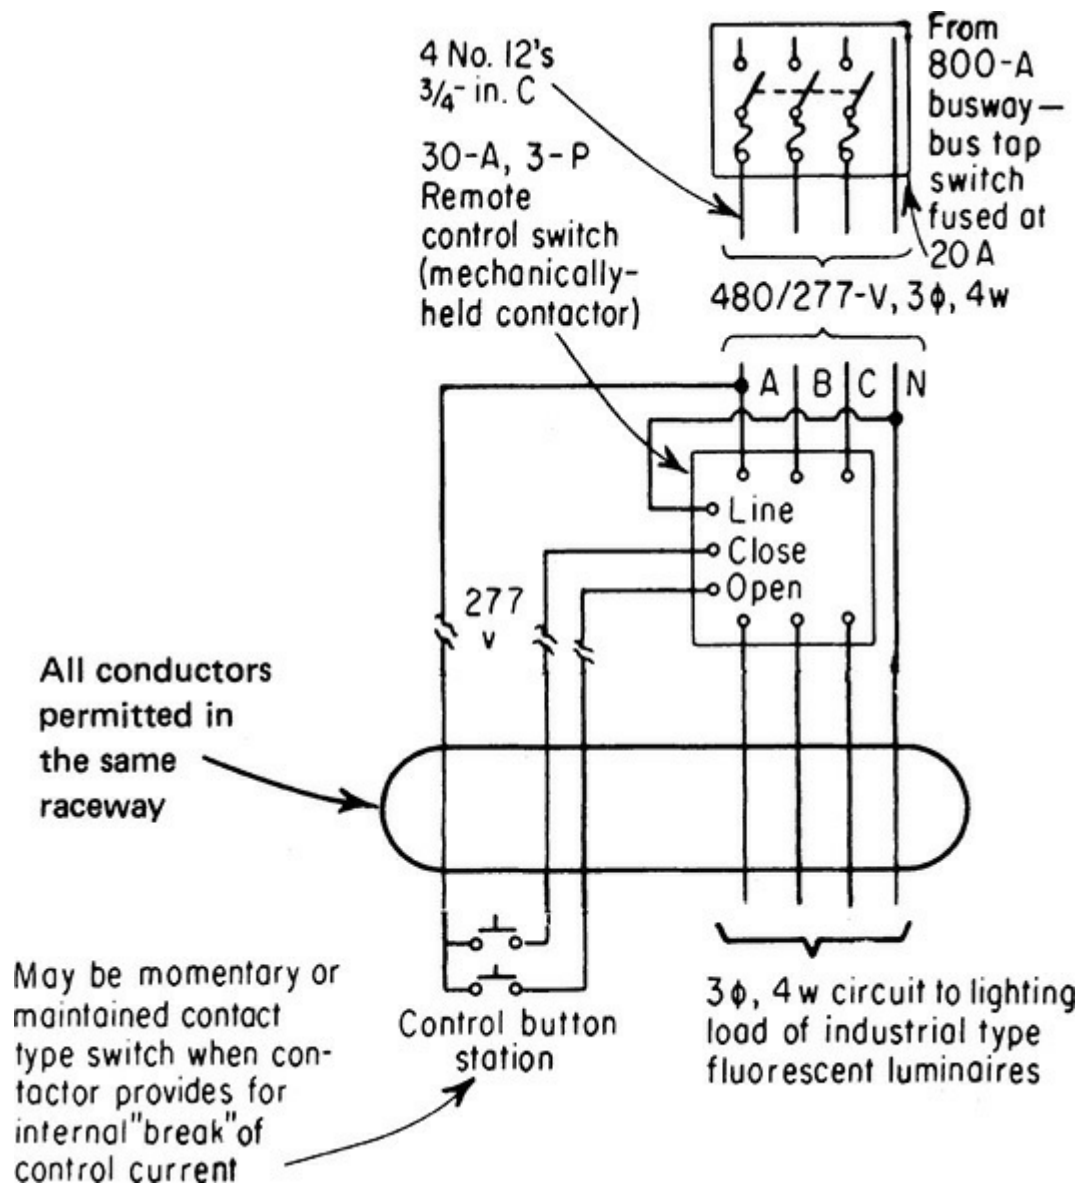

Fig. 725-9. Class 1 wires and power wires may be used in same raceway for “functionally associated” equipment. (Sec. 725.48.)

There is another issue, for which the **NEC** offers no clear answer. First, some background; if you have two unrelated motors at the same general location, it is beyond question that the two sets of branch-circuit conductors to the two motors can run in a common raceway. Now, add a set of control conductors for each motor to the same conduit. Are these control conductors functionally associated with the power conductors? Obviously. However, is every control conductor functionally associated with every power conductor? Obviously not. Is this, therefore, a violation of 725.48(B)(1)? The words of the **NEC** say “functionally associated” and leave it at that, so every inspector gets to make a call here. The answer cannot be determined based on the literal text of the **NEC**.

This is a very important question, so it is worth exploring the technical merits of this question. The usual objections to this practice run to the undesirability of exposing unrelated control conductors to a fault and thereby disabling multiple motor functions in unrelated processes. Although that is a reasonable design argument, there are serious limitations to this argument as a matter of **NEC** minimum standards. The power and control wiring that goes to those two motors can originate in the same vertical motor control center section, as covered in 725.48(B)(2). There are no limits on running the two power circuits together to the motors, as already covered. And a fault in one of those

motor circuits will certainly disable the other motor, yet that is clearly allowed. Why then object to the control conductors? There is no supportable argument that multiple functions in a single raceway (other than very rare exceptions as with fire pump and emergency circuits) rise to the level of a fire or electrocution hazard, which, as covered in 90.1, is and ought to be the controlling principle. Nevertheless, some inspectors will turn it down, so be sure to ask before committing yourself to a particular circuit design.

Note: Part **(B)(2)** in 725.48 permits power and control wires for more than one motor in a common raceway. Factory- or field-assembled control centers may group power and Class 1 control conductors that are not functionally associated. This rule recognizes the use of listed motor control centers that have power and control wiring in the same wireway or gutter space supplying motors that are *not* “functionally associated.” The basic rule generally prohibits that condition when hooking up motor circuits.

Part **(B)(3)** of 725.48 says that Class 1 circuit conductors and unassociated power-supply conductors are permitted in a manhole if either of them is in metal-enclosed cable or Type UF cable *or* if effective separation is provided between the Class 1 conductors and the power conductors. This rule covers the conditions under which Class 1 conductors and unrelated power conductors may be used in the same enclosure (a manhole).

Part **(B)(4)** covers the same issues in cable tray. Item (1) is a functional association rule that raises the same issue as covered in (B)(1). Item (2), which applies in the event there is no functional association as illustrated in [Fig. 725-8](#), avoids a barrier if all the wiring is in separate multiconductor cables, including Type TC. This is an improvement over prior versions of this rule that asked for, exclusively, cables with metal armor.

725.49. Class 1 Circuit Conductors. Figure 725-10 shows this basic rule of part **(A)**, which accepts use of building wire to a minimum 14 AWG size. But 16 or 18 AWG fixture wires of the types specified in part **(B)** *may* be used for running starter coil circuits, signal circuits, and any other Class 1 circuits. Of course, use of 16 or 18 AWG fixture wire for Class 1 circuits depends on such conductors having sufficient ampacity for the current drawn by the contactor or relay operating coil or by whatever control device is involved. Wires larger than 16 AWG must be building types (TW, THW, THHN, etc.). Class 1 circuits may not use fixture wires larger than 16 AWG. And ampacity of any Class 1 circuit wires larger than 16 AWG must have that value shown in Table 310.15(B)(16).

EXAMPLE :

If branch-circuit protection is rated at 15 A or 20 A . . .

. . . the Class 1 remote-control wires may be No. 18 or No. 16 fixture wire or No. 14 building wire, depending upon the ampere load of the starter coil.

Fig. 725-10. 16 or 18 AWG fixture wire may be used for Class 1 circuits. (Sec. 725.49.)

Note: 402.5 shows that the ampacity of any 18 AWG fixture wire is 6 A and the ampacity of any 16 AWG fixture wire is 8 A. Any 18 or 16 AWG fixture wire or 14 AWG building wire used for a Class 1 circuit is considered adequately protected by a fuse or CB rated not over 20 A. See 725.43 and 240.4.

725.51. Number of Conductors in Cable Trays and Raceway, and Derating. The number of Class 1 remote-control, signal, and/or power-limited circuit conductors in a conduit must be determined from Tables 1 through 5 in [Chap. 9](#) of the **NEC**, or Annex C, where all conductors are of the same size.

When more than three Class 1 circuit conductors are used in a raceway, ampacity derating of 310.15(B)(3)(a) applies only if the conductors carry continuous loads in excess of 10 percent of the ampacity of each conductor ([Fig. 725-11](#)). This rule is aimed at relieving the need to derate conductors that are usually carrying very low values of current (such as up to 2 A for most coil

circuits of contactors and motor starters). The wording does not spell out whether all the conductors are carrying continuous current or if only some of them are.

Fig. 725-11. Determining conductor ampacity for more than three Class 1 circuit wires in a raceway requires careful evaluation of conditions and the Code rule. (Sec. 725.51.)

The same concept of “10 percent of the ampacity of each conductor” has been applied in part **(B)** **(1)** and **(2)** of 725.51. This number was chosen because based on the I^2R relationship, a wire carrying 10 percent of its ampacity is putting out 1 percent of the heat it would be putting out at full load, a number low enough to comfortably ignore.

When power conductors and Class 1 circuit conductors are used in a single conduit or EMT run (as permitted by 725.48), the derating factors of Table 310.15(B)(3)(a) must be applied as follows:

1. Table 310.15(B)(3)(a) must be applied to all conductors in the conduit when the remote-control conductors carry continuous loads in excess of 10 percent of each conductor’s ampacity and the total number of conductors (remote-control and power wires) is more than

three. For example, in [Fig. 725-12](#), the conduit size must be selected according to the number and sizes of the wires. Because two of the control wires to the pushbutton and the power wires to the motor will carry a continuous load that is usually less than 10 percent of conductor ampacity, a derating factor of 80 percent [from Table 310.15(B)(3)(a)] does not have to be applied. This drawing shows the most important impact of the 10 percent rule, namely, where the control circuit wiring would impose a significant penalty on power conductor sizing, perhaps changing wire and conduit sizes.

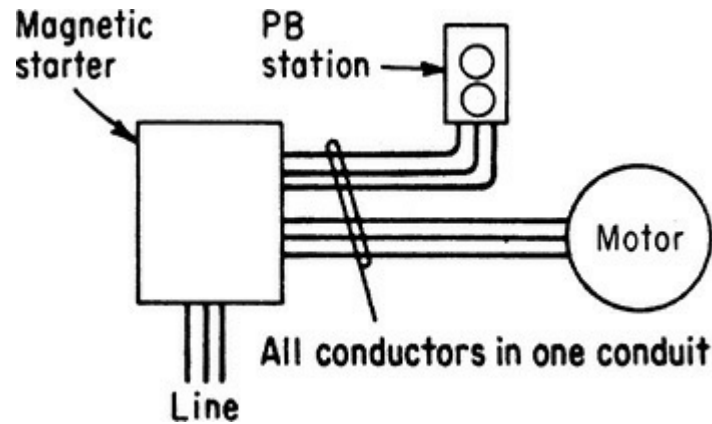

Fig. 725-12. Derating of conductor ampacity is usually not required for this circuit makeup. (Sec. 725.51.)

- Table 310.15(B)(3)(a) must be applied only to the power wires when the remote-control wires do not carry continuous load and when the number of power wires is more than three. In [Fig. 725-13](#), no derating at all is applied because the control wires do not carry continuous current (only for the instant of switching operation), and there are only three power wires.

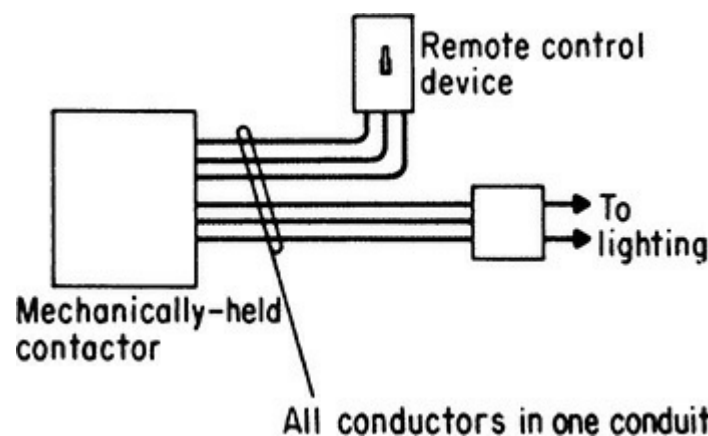

Fig. 725-13. Derating is not required here if Class 1 conductors do not carry continuous load. (Sec. 725.51.)

These rules of part **(B)** have created controversy. It usually starts with this question: If a conduit from a starter carries the three power wires of a motor circuit and also contains three control wires run from the starter to a pushbutton station, is it necessary to derate any of the conductor ampacities?

Answer: 725.51(B) covers this. (Read that rule several times.) If the starter is the usual magnetically held type of contactor, the two control wires to the STOP button at the pushbutton station will carry the holding current to the coil as long as the starter is closed. 725.51(B)(1) says that all

conductors in the raceway must be derated in ampacity if the total number of conductors (power wires plus control wires) is more than three—but *only if the Class 1 circuit conductors carry continuous loads* of more than 10 percent of conductor ampacities. The continuous control current in this case is the sealed current for the contactor, likely a fraction of an ampere. As noted in the explanation of where the 10 percent rule came from, the effect on the adjacent conductors is negligible.

725.52. Circuits Extending Beyond One Building. Class 1 circuits that extend aerially are subject to the requirements in Art. 225.

725.121. Power Sources for Class 2 and Class 3 Circuits. Specific data regarding maximum current and voltage ratings for Class 2 and 3 circuits are given in Tables 11(A) and 11(B) in [Chap. 9](#). These tables were removed from this part of the Code and sent to [Chap. 9](#) in order to avoid the frequent misinterpretation that Class 2 and Class 3 power supplies can be manufactured in the field, given appropriate fuses and transformers, etc. This is not and has not been true for many decades, if ever. These circuits normally require a power supply that has been investigated by a qualified testing laboratory. As far as installation is concerned, the marking on any listed piece of equipment will be the determining factor as to how a power source is classified. And the installation must satisfy all rules related to that classification. Note that Class 2 and Class 3 power supplies must not have their outputs paralleled or interconnected, unless listed for this application. To do so would likely exceed the allowable power limitations for the circuits, creating a hazard.

There are some exceptions to the requirement for listed power sources. Thermocouples are a Class 2 source without a specific marking, as are limited power circuits from listed equipment with energy levels as in Tables 11(A) and 11(B); this is explained in an extensive note that gives examples of circuit cards in listed assemblies, and listed computer equipment circuits such as the Ethernet cable leaving desktop #1 and talking to desktop #2. Also, No. 6 carbon-zinc dry cells, 1½ V each, can be wired in series up to 30 V and still be considered a Class 2 source.

With regard to the computer wiring allowance, as of the 2017 **NEC**, this category has been expanded by inserting “audio/video” ahead of “information technology (computer),” and also adding “communications, and industrial” after it, so it now reads “Listed audio/video information technology (computer), communications, and industrial equipment limited power circuits.” Unfortunately a comma was omitted after the word “video,” which literally makes “audio/video” a modifier of the phrase “information technology (computer).” The intent was to address the current title of the applicable UL standard (referenced in the panel statement), which does have a comma after audio/video. The clear intention was to cover audio/video equipment as an expansion of the reach of this provision, and not a reduction of the types of computers that (4) covers.

725.124. Circuit Marking. Equipment supplying these circuits must be plainly marked as to the classification of the circuits supplied.

725.127. Wiring Methods on Supply Side of the Class 2 or Class 3 Power

Source. Conductors and equipment on the line side of devices supplying Class 2 systems must conform to rules for general power and light wiring. Transformers that are Class 2 or Class 3 sources must be protected by supply side overcurrent protection not over 20 A; if fed with pigtails, however, the supply leads can be as small as 18 AWG if fully insulated and not over 305 mm (12 in.) long.

725.130. Wiring Methods and Materials on Load Side of the Class 2 or Class 3 Power Source. There is a decision point here, namely, whether or not to use limited energy

wiring methods. Part (A) covers the option to use Class 1 wiring methods and materials, as covered in 725.46. Two exceptions immediately bear on this practice. The first waives all mutual conductor heating derating penalties. The second, although written as a permissive exception is actually a mandatory part of the reclassification decision, because the reclassification is effectively conditioned on the obliteration of the Class 2 and/or Class 3 markings as covered in 725.124. Note also that the exception correctly mandates Class 1 “wiring methods and materials.” The wiring method is only the first issue; equal attention must be paid to the equipment on which the wiring is terminated. A Class 2 thermostat circuit run in EMT will satisfy the wiring method rule, but when it arrives at the thermostat there will be a problem unless it is rated for a Class 1 wiring connection. Further, once this is done, the circuit is forever Class 1 even though the source will have been listed as a Class 2 (or 3) source.

This procedure is widely used in industrial wiring, where all the wiring is Class 1 to begin with, and the reclassification allows these control circuits, usually run with 14 or 12 AWG 600 V THHN, to run with other control wiring with which it is functionally associated. The normal circuit separation rules for power-limited wiring in 725.136 no longer apply. The overcurrent protection rules in 725.43 admittedly do apply. Nevertheless, the majority of industrial control panels with wiring duct between relays and other control components employ large numbers of Class 1 circuits, both native and manufactured under this rule and all mixed together and terminating on the same control equipment; it would be nearly impossible to do this kind of wiring otherwise.

Some equipment manufacturers deliberately avoid having their components evaluated as Class 2 or 3 for similar reasons. For example, a major producer of automated gasoline station dispensing equipment has its circuits routinely evaluated with Class 1 spacings just so its equipment can be retrofitted in older stations that only have a single conduit going out to the dispenser.

Part (B) requires that conductors be installed in accordance with 725.133 and 725.154, using insulation recognized in 725.179. There are three exceptions. The first (unclear because not written as a complete sentence as required in the Style Manual) apparently removes all limitations on this wiring when it is run in the various elevator wiring methods detailed in 620.21. The second exception is apparently intended to recognize equivalent wiring that complies with 725.3, including [Chap. 3](#) methods where the installer does not wish to reclassify the circuit, but only to extend or replace something existing. The third exception recognizes small bare wires as part of a listed intrusion-protection system.

725.135. Installation of Class 2, Class 3, and PLTC Cables. When power-limited cabling began to be subject to fire and smoke performance criteria in the 1987 **NEC**, it was extremely controversial, because the cables were never the source of a fire or an electric shock. It raised serious questions about whether this was appropriate in terms of the scope and history of the **NEC**. In the end, actual loss experience persuaded the **NEC** Committee to add these criteria, and with them, logically, coverage of optical fiber cables, many of which have no metallic parts whatsoever. The loss experience that provoked this change in policy was a severe fire in a telephone company facility where the major issue in the severity of the fire was the fuel load represented in the enormous quantity of cables present. In effect, the **NEC** Committee decided that the mere existence of certain types of cable jackets and conductor insulation was a fire hazard, thereby meeting the implicit test in 90.1. This same thought process also supports the recent requirements to remove abandoned cables.

A hierarchy of cable insulation was established, with essentially four levels. The low-smoke, low-flame type suitable for plenum cavity ceilings (“P” suffix designation) was at the top. The next

step down was a cable that would not carry fire from floor to floor, designated a riser (“R” suffix designation) cable. The next step down was a cable suitable for general commercial use (no suffix), and the bottom of the totem pole went to a cable, constructed much like cables before the rule changes went forward and suitable for exposed areas in individual dwelling units (“X” suffix designation). Each level in the hierarchy included in the testing all lower-level tests, so any cable listed for an upper level could substitute for one in a lower level, and within any level, a cable tested for a higher voltage could substitute for a lower-voltage application. This general approach still holds today, although there are many complications.

This section is a new method of presenting this information, with the various classifications of installation circumstance listed in lettered subsections, roughly in order of decreasing levels of resistance to flame and smoke. So this list begins with actual ductwork (no suffix, only special rules) and then plenum installations (suffix “P”), then riser installations (suffix “R”), then a catch-all of intermediate industrial/commercial installations, then general building installations (no suffix), and finally residential applications (suffix “X” mixed, and then all “X”). In theory this approach supposedly separates installation requirements from application requirements, which remain in 725.154. However, that appears to be a distinction without a difference, because the same information largely appears in both locations, only formatted differently. For example, riser cables in vertical runs are now covered in 725.135(D), and at that location (1) cover the eligible naked cables, and (2) cover allowable uses in various raceways. Moving over to Table 725.154 in the horizontal block “In risers” one reads “In vertical runs” and/or then the sub-row for the raceway of interest to read off where what cable can be used. Whether this has been a useful exercise is far from proven.

725.136. Separation from Electric Light, Power, Class 1, Non-Power-Limited Fire Alarm Circuit Conductors, and Medium-Power Network-Powered

Broadband Communications Cables. Part (A) of 725.136 says that Class 2 or 3 conductors must not be used in any raceway, compartment, outlet box, or similar fitting with light and power conductors or with Class 1 signal or control conductors, unless the conductors of the different systems are separated by a partition. This section sets out the separation rules that cope with one of the most fundamental requirements for installing power-limited cables, namely, that it is not permitted to establish the required system separations between power-limited wiring and non-power-limited wiring through the use of insulation alone. Some additional affirmative step must be taken, and this section provides different ways to meet this requirement.

Part (B) allows for a common enclosure where the conductors of different systems are separated through the use of a barrier.

Part (C) allows a raceway to run within an enclosure, where the raceway wall is, in effect, a barrier. This approach is often used when a power circuit must enter at an inconvenient point and it is necessary to route the power conductors to a set of terminals on the other side; a run of flexible metal conduit run from the entry point around to the power terminals will maintain system separation.

Part (D) allows a common enclosure where the power-limited and non-power-limited wiring must terminate on the same equipment, as in the case of a small power contactor whose 24-V coil is being controlled by a Class 2 circuit. In this case there is a general solution and a limited alternative. The general solution is to restrain the wiring with duct, tie-downs, or other methods such that a 6-mm (¼-in.) air separation is maintained between systems. The limited solution only applies if the non-power-limited wiring is operating not over 150 V to ground, and the limited energy cabling uses Class 3 rated cabling under the further condition that the individual control conductors, where they extend

outside the cable jacket, maintain additional separation by maintaining not less than a 6-mm (1/4-in.) air separation, or they are separated by a nonconductive sleeve or barrier from other conductors. Note that this provision is for dead-end wiring only, not daisy chains (“solely to connect” does not mean to connect and then to feed another piece of equipment).

This rule also presents the option of installing these wires as Class 1 conductors. This provision has effectively been superseded by the requirements of 725.130(A), and should probably be deleted from this rule. It came into the **NEC** before 725.130(A), and apparently has been overlooked.

Part **(E)** covers the case where an enclosure containing equipment requiring multiple system connections only has a single conduit entry point, so the connection will take place through a tee with the different systems arriving through opposite sides. In this case (another instance of dead-end wiring only) the power-limited wiring must be enclosed in a “firmly fixed nonconductor” such as loom of some sort or other flexible tubing.

Part **(F)** covers manholes, and multiple systems are permitted provided one of three options is applied. The first is that the non-power-limited wiring is running in a metal clad cable assembly or in Type UF cable. The second is that the power-limited wiring runs in loom of some sort or other firmly fixed non-conductive tubing in addition to the cable jackets. The third is that the power-limited wiring is secured to racks or insulators in the manhole such that effective separation is maintained.

Part **(G)** covers cable tray and requires separation through the use of a divider within the tray, unless the power-limited wiring is run within Type MC cable.

Part **(H)** covers hoistways, and conductors must be installed in rigid conduit, IMC, PVC, RTRC, LFNC, or EMT, except as provided for elevators in 620.21.

In part **(I)**, Class 2 or 3 circuit conductors must be separated not less than 2 in. (50 mm) from conductors for light, power, Class 1, or non-power-limited fire-protective signaling circuits. The present wording of 725.136(I) clarifies many past misunderstandings about the intent of the rule. Previous Code editions only mentioned raceways, porcelain tubes, or “loom” as a means of separating Class 2 circuits, such as “bell wiring,” from conductors of light and power systems where such systems were closer together than 2 in. (50 mm). And on that basis, some inspectors required such bell wiring or similar Class 2 wires to have a 2-in. (50-mm) clearance from any type of cable (NM, UF, ac, etc.) that contained conductors for power or lighting circuits. The old rule was also commonly applied to prohibit bell wires and NM cables in the same bored holes through studs, and so on. With the present wording, the 2-in. (50-mm) clearance from Class 2 wiring applies only to “open” light, power, and Class 1 circuit conductors. Power and light circuits or Class 1 circuits that are in raceway or cable do not require 2-in. (50-mm) separation from Class 2 and/or 3 circuits ([Fig. 725-14](#)).

Fig. 725-14. Class 2 or 3 wiring must be separated from open wiring for power and light. (Sec. 725.136.)

Note, however, that there is no express permission to include Class 2 or Class 3 conductors within a common cable assembly with power conductors. Paragraph (2) here comes the closest, because it recognizes a “continuous and firmly fixed nonconductor.” This is crucial to the production of hybrid cables, where additional separation beyond the conductor insulation is applied to the power-limited conductors in accordance with the spirit of these principles. For example, 334.116(C) expressly recognizes this type of construction for Type NMS cable, and UL has been listing such constructions for many years.

There is another close approximation, with several available cable assemblies based on Type MC cable and Type TC cable that include a twisted pair of control wires (could be shielded) intended as Class 2 and run within an overall plastic jacket. This jacket is being evaluated for conformity to the chemistry and thickness (30 mil) of Type NM cable of equivalent diameter. In effect, this construction complies with the literal text of Paragraph (1) that allows (among others) “nonmetallic-sheathed ... cables” for the power-limited wiring. There are obvious applications including 0-10V dimming controls for luminaires. Once out of the cable assembly at both ends, the Class 2 wiring needs to be run and terminated in accordance with other applicable rules in Sec. 725.136.

725.139. Installation of Conductors of Different Circuits in the Same Cable, Enclosure, Cable Tray, Raceway, or Cable Routing Assembly. Class 2 circuits can coexist in a common location, as can Class 3 circuits. The rule of 725.139(C) requires separation of Class 2 and 3 circuits, *unless* the Class 2 wires have insulation that is at least equivalent to that required for Class 3 wires. Part (D) covers instances such as a cable made up with eight-conductor Ethernet data wires cabled with a four-conductor, Art. 800 telephone connection; in such cases the combination is allowed but the entire assembly becomes reclassified as a communications cable; and the Class 2 or Class 3 circuit is now an Art. 800 circuit. On the other hand, there are composite cables comprised of jacketed signaling cables along side of jacketed communications cables, all within a common overall jacket, and in this case the signaling circuit is permitted, but not required, to be reclassified as a communications circuit.

Part (E) covers the common enclosure rules between power-limited wiring under this article and

wiring under related power-limited articles. The following systems can share an enclosure with jacketed Class 2 and Class 3 cables: (1) Power-limited fire alarm wiring—Art. 760; (2) Optical fiber cabling both conductive and nonconductive—Art. 770; (3) Communications circuits—Art. 800; (4) CATV systems—Art. 820; and (5) Low-power network-powered broadband communications—Art. 830.

Part (F) forbids co-locating power-limited cabling under this article and comparably marked audio circuits as detailed in 640.9(C); the testing protocols showed they should not run together.

725.141. Installation of Circuit Conductors Extending Beyond One

Building. Aerial extensions (the type vulnerable to contact with light and power wiring, or exposed to lightning) must meet comparable requirements for Art. 800 wiring, as covered in a list, or Art. 820 wiring, as covered in a list for comparable coaxial wiring exposures.

725.143. Support of Conductors. Class 2 and Class 3 cables must not be tie-wrapped to or otherwise supported by electrical raceways, as also disallowed in 300.11(B). However, the allowance for a Class 2 cable to run on the outside of a power raceway where the control cable is functionally related to the power conductors within the raceway remains valid.

Low-voltage relay switching is a common application of Class 2 remote control circuits regulated by Art. 725. Low-voltage relay switching is commonly used where remote control or control from a number of spread-out points is required for each of a number of small 120- or 277-V lighting or heating loads. In this type of control, contacts operated by low-voltage relay coils are used to open and close the hot conductor supplying the one or more luminaires or load devices controlled by the relay. The relay is generally a 3-wire, mechanically held, ON-OFF type, energized from a step-down control transformer.

In some cases, all the relays may be mounted in an enclosure near the panelboard supplying the branch circuits, which the relays switch with a single transformer mounted there to supply the low voltage. Where a single panelboard serves a large number of lighting branch circuits over a very large area—such as large office areas in commercial buildings—a number of relays associated with each section of the overall area may be group-mounted in an enclosure in that area.

Figure 725-15 shows 24-V control of 277-V fixtures, with constantly illuminated switch plates alongside doorways to define interior exit routes and practical hollow-partition clip-in switch boxes in interior labs of a medical research center. Control relays are in compact boxes atop luminaires. Relays are connected to switches and to 50-VA continuous-duty 120/24V transformers by Class 2 remote-control circuits routed through overhead non-air-handling ceiling plenums and supported by insulator rings attached to fixture hangers by spring clips. Wiring of the Class 2 circuits may be done with multiwire low-voltage cable, such as 3- or 4-conductor thermostat cable. Interior-area route indicating lights and general lighting switches are mounted together in thin boxes set in partitions.

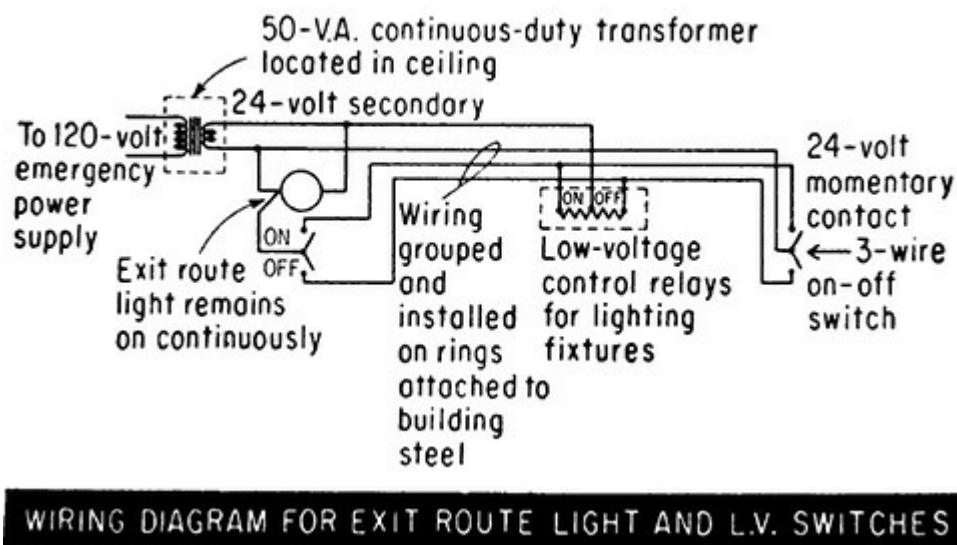

Fig. 725-15. Low-voltage relay switching is a typical application of Class 2 conductors. (Sec. 725.154.)

725.144. Transmission of Power and Data. There is now a comprehensive set of requirements for what is widely known as “power over Ethernet.” There are many electronic devices for which this is applicable. Although the word “power” sounds incompatible with the limited power circuits covered in this location, in fact even the most restrictive voltage and current limits for the Class 2 envelope are large enough to allow for small electronic equipment to be powered. This section sets the ground rules for how all this is to be applied. The current must not exceed the ratings of the connectors, with presumably points to the normal RJ45 jacks used for terminations. An informational note suggests a default ampere rating for these jacks would be 1.3 amperes. For conventional cables, the ampacities of typical Ethernet cables are displayed in the table, with the four usual conductor sizes at the left, and number of cables in the bundle running across the top. The notes at the bottom address the frequent circumstance where only half the wires (4 out of 8) in a cable are current carrying. At higher temperature ambients, the rules invoke the temperature adjustment rules in 310.15(B)(2).

Part (B) recognizes a new cable construction (for limited power, denoted by the marking suffix of LP after the cable type). For small bundles this wire would not be helpful, but for large bundles, it could be very helpful because its ampacity never falls below the numerical value that follows the “LP” marking. For example, as covered in the second informational note, the marking “CL2-LP(0.5A)” means a Class 2 cable evaluated for a highly populated bundle, and rated to carry 0.5A. The other rules, including the cable substitution hierarchy, are unaffected by this and still apply. The listing requirements for PoE equipment are in 725.170, and that new section correlates with this new section. The listing requirements for these cables now appear in a new (re-purposed) Sec. 725.179(I).

725.154. Applications of Listed Class 2, Class 3, and PLTC Cables. Almost all the narrative subsection material that was located here has been relocated to Sec. 725.135 in the 2014 NEC, where it has been reformatted as a series of lists. What remained behind is a table of applications of questionable utility. Three important subsections did not make the trip, however.

Part (A) and its associated table presents visually the cable hierarchy discussed at length in the commentary on 725.135. This part authorizes a substitution table that covers that discussion. Communications cabling has a comparable voltage capability to CL3 cabling, and therefore can be used in lieu of CL3 where otherwise ranked on an equal level, for example, CMR can be used in a CL3R application, but CMR cannot substitute for CL3P.

Part (B) covers circuit integrity (CI) cabling. This cable has a ceramifiable insulation that when heated turns into a glassy compound that, although brittle, will maintain the insulation values between the enclosed conductors for the specified fire exposure period. Some must be installed in raceways, and if so, that fact will be included in the instructions. These cables can be substituted for others without this designation but with equivalent evaluations in the hierarchy. Rounding out the list, cables that are part of a listed electrical circuit protective system, such as Type MI cable with enhanced installation specifications, can also be used.

Part (C) recognizes a style of Type PLTC that uses thermocouple extension wire for Class 2 circuits. As implicitly recognized in 725.121(A)(3) Exception No. 1, thermocouples are sufficiently power-limited to automatically qualify as a Class 2 source.

That general principle survives, and shows clearly in the cable substitution hierarchy table, Fig. 725.154(A). However, the specific rules that once resided here have been transferred to 725.135, and all that remains is a table that summarizes the uses permitted.

725.179. Listing and Marking of Class 2, Class 3, and Type PLTC Cables; Communications Raceways; and Cable Routing Assemblies. This section covers the listing requirements for the cables used in the applications just covered, as follows:

Part (A) covers Types CL2P and CL3P for plenum cavity applications.

Part (B) covers Type CL2R and CL3R for riser applications.

Part (C) covers Type CL2 and CL3 for general-purpose applications.

Part (D) covers Type CL2X and CL3X for limited-use residential applications.

Part (E) covers Type PLTC for cable tray and some additional applications.

Part (F) covers cables additionally rated for circuit integrity (CI). This part is now split in order to make a useful distinction between CI cable itself and CI cable as a component of an electrical circuit protective system. Any given CI cable that relies on a raceway to protect it must be

specifically listed and marked as part of such a system. Refer to the coverage of this topic in this book at 728.4 for more details on this protective technique.

Part **(G)** covers the required voltage ratings on Class 2 and Class 3 cables, that being not less than 150 V and 300 V respectively.

Part **(H)** Class 3 single conductors must be no smaller than 18 AWG and Type CL3. Fixture wire covered in 725.49(B) can also be listed in this category.

Part **(I)** covers the new limited power cable constructions for power over Ethernet as covered in 725.144 and 725.170.

Part **(J)** summarizes the marking rules, and the associated table reinforces the earlier comments about the cable hierarchy. This rule also disallows marking voltage ratings on power-limited cables because they may lead unqualified users to confuse them with the ratings on actual power cables covered in [Chap. 3](#). Some cables have multiple listings and if such a listing requires a voltage marking, then that marking can appear.

ARTICLE 727. INSTRUMENTATION TRAY CABLE: TYPE ITC

727.1. Scope. This is a specialized cable used for control circuit applications, particularly in industrial occupancies. It is limited to 150 V and 5 A. It uses power levels that are in a range between Class 3 and Class 1, and was originally conceived as a fourth class of wiring within Art. 725. That proved too complicated, and in the 1996 **NEC** it entered as a stand-alone article for what is in effect a power-limited Class 1 control cable with power limitations even more severe than the ones in 725.41(A). It originated as a work-around for control circuiting limitations for power-limited circuits in Art. 725 that were unacceptable, particularly in industrial occupancies. It also has a far less severe system separation requirement than other power-limited wiring. When it went into the **NEC**, it was only after a pitched battle that resulted in a vote at an **NFPA** Annual Meeting that effectively overruled a decision of the Technical Correlating Committee.

Review the commentary at 725.130(A) on this point, because the ability to reclassify control circuits as Class 1 now addresses some of the concerns with respect to system separation that led to the creation of this article. From a true Code purist point of view, this article should never have been necessary and the necessary accommodations should have been made in Art. 725. However, with this now in place, the major industrial players adamantly refuse to give it up, and several serious attempts to eliminate it have failed. So now Art. 725 gives it a grudging, half-hearted recognition, in 725.3(G). Every circuit running on Art. 727 cabling is, in fact, classifiable under the provisions of Art. 725. That is a fact, and because that is so, this article is an ongoing contradiction in terms given a very thin veneer of consistency through the 725.3(G) reference.

727.4. Uses Permitted. This cable is permitted to be used roughly where Type PLTC cabling is permitted to be used, as covered in 725.135. It even has an –ER variant that matches up to 725.135(J), along with the usual 6-ft out-of-tray exception.

727.5. Uses Not Permitted. The cable can't be used above 150 V or over 5 A. It can run with other cabling unless the other cabling rules say it can't, and none of them do. This cabling must be divorced from power or non-power-limited Class 1 circuits unless it is of the metal-armored variety, and it is also permitted to enter common enclosures with power circuits when mutual terminations must be made; in such cases a separation must be maintained. Note that it is permitted to be used with Class 1 power-limited circuits limited only by the 30-V 1000-VA parameters in 725.41(A) (but see

727.7 below).

727.6. Construction. The size range for this cable is 22 AWG up to 12 AWG, copper (or thermocouple alloy) with 300 V insulation, with optional shielding, and with recognition of a metal-clad type of cable armor.

727.7. Marking. The markings are the same as for comparable cables, as set forth in 310.120(A) (2 through 5). As in 725.179(L), voltage ratings must not be marked on the cable.

727.8. Allowable Ampacity. This cable is not permitted to exceed 5 A down to 20 AWG conductors, and 3 A on the 22 AWG size conductors.

727.9. Overcurrent Protection. The overcurrent protection permitted matches the allowable ampacity.

727.10. Bends. Bends must not damage the cable.

ARTICLE 728. FIRE-RESISTIVE CABLE SYSTEMS

728.1. Scope. This new article (2014 **NEC**) is designed to centralize the requirements for fire-resistive cable systems, which are defined as a cable and components employed to ensure survivability of critical circuits for the prescribed period of time during a fire.

728.4. General. One of the most important concepts in this area is that every single component of a designated system must work with all other components in a tested and predictable way. These systems require great attention to detail in order to install properly, particularly when one considers that the only test after installation will likely be their performance under the one and only fire event they will be subjected to. This section includes two informational notes. The second identifies the cables addressed in this article as components of an “electrical circuit protective system.” This is defined in Art. 100 as “a system consisting of components and materials intended for installation as protection for specific electrical wiring systems with respect to the disruption of electrical circuit integrity upon exterior fire exposure.” These systems are evaluated by UL and other laboratories under UL Subject 1724, “Outline of Investigation for Fire Tests for Electrical Circuit Protective Systems.” Additional commentary on practical issues that arise during design and installation is included in the next section.

728.5. Installations. A careful examination of the eight subsections supports the above assertion. The fire testing is very robust, and also considers likely firefighting activity by incorporating hose stream testing after the full fire exposure testing is completed. To make certain the installation in the field performs as tested in the laboratory, the installation instructions are exacting and require extraordinary attention to detail. By way of example, consider Type MI cable, which is the basis for one widely used design. The **NEC** support distance for MI cable (332.30) is a 6 ft maximum spacing. However, when used for this purpose, the maximum spacing drops to 1 m (39 in.), and the cable must be routed along a concrete or masonry wall. In addition, the supports must use steel clamps of a prescribed configuration, and be secured to the wall with a steel concrete screw of a stipulated length and diameter. In addition, the testing applies only to continuous cable runs; if splicing is required, it must occur not less than 12 in. into a protected space on the cold side of a rated partition.

Other designs use conductors with ceramifiable insulation installed in tubular steel raceways, with some recognizing EMT and others not. These systems use special conductors, such as RHH but with

nonstandard diameters, so the manufacturer's information needs to be consulted for wire fill. The raceway fill tables in Annex C have an end note warning not to use their values for these applications for this reason. This insulation, upon exposure to extreme heat, breaks down but the residue is akin to colored glass, not capable of significant movement but capable of maintaining the integrity of the circuit for a rated period of time. The designs have interesting additional requirements for running the circuits.

For example, "The raceway should be connected together using the coupling type referenced in the system, such as steel set-screw type for EMT or threaded types of couplings for IMC and RMC. No other coupling should be used unless noted in the specific system." This is because under the hose stream testing compression couplings usually fail, and even set-screw couplings must have their screws driven very hard with a significant dimple or the raceway will pull apart and fail the test.

These designs also address equipment grounding conductors installed in the same raceway, and the special requirements are anything but intuitive. "The bare or insulated ground wire may be of special manufacture to be compatible with the system. The system will specify the manufacturer of an allowable ground wire. If not specified, the ground should be the same as the fire-rated wire described in the system." This is because a separate equipment grounding conductor of random insulation type, under fire conditions, may be incompatible with the tested cables it is in intimate contact with; unless tested, this cannot be predicted. This is the reason that some designs have disallowed the use of a THHN equipment grounding conductor, because its outgassing products from heating proved incompatible with its RHH companions. Wire pulling compounds, if used, must also be included in the design for the same reasons.

728.60. Grounding. For systems using raceways and separate equipment grounding conductors, the separate grounding conductor must be recognized in the system design so as to assure that an insulation breakdown during a fire does not react with the special insulation required for the ungrounded conductors. The system must specify the conductor to be used, and any alternative must be marked with the system number. See also the discussion at 250.120(A).

728.120. Marking. In addition to standard markings, cables and conductors used for these systems must be surface marked with fire rating expressed as hours, a suffix "FRR" (for fire-resistive rating) and the system identification number.

ARTICLE 750. ENERGY MANAGEMENT SYSTEMS

750.1. Scope. This article, new in the 2014 NEC, covers these systems, which have a very expansive definition. The simple fact of a monitor creates a system based on the literal text of the definition. Management systems presumably do more than watch; they also control, as effectively defined as turning power off or on or varying its magnitude.

750.20. Alternate Power Systems. This section places the availability of alternate power sources for five designated loads as off limits for energy management interference.

750.30. Load Management. Article 700 allows for emergency generators to support nonemergency loads; however, when the emergency loads call for generator support, nonemergency loads must be shed automatically to the extent necessary to allow for full support of the emergency loads. 750.30(A)(2) prohibits the management system from interfering in that function, as well as comparable actions for three other areas.

750.50. Field Markings. If a management system is capable of controlling remote loads, a

directory must be posted that displays the controlled circuits or devices on the “enclosure of the controller, disconnect, or branch-circuit overcurrent device.” The use of the conjunction “or” suggests that any of the locations is acceptable. Note that if a receptacle is to be controlled, it must display the special mark required by 406.3(E).

ARTICLE 760. FIRE ALARM SYSTEMS

760.1. Scope. As indicated by informational note No. 1, the various elements associated with the fire alarm system are now all covered in a single **NFPA** Standard: **NFPA 72**. The overall article here has been revised to consolidate the various requirements to facilitate comprehension as well as to correlate with changes made in Art. 725. This article covers fire alarm systems, including the initiating and notification appliances and the fire alarm control panel. It does not cover a run of reciprocally alarming smoke detectors connected to a conventional branch circuit in a residential occupancy.

Most of the provisions in this article line up with equivalent provisions in Art. 725, with Non-Power-Limited Fire Alarm Circuits corresponding to Class 1 signaling circuits, and Power-Limited Fire Alarm Circuits corresponding to Class 3 signaling circuits. The commentary that follows highlights the differences, so for any section not commented on here, the comments on the identical section number in Art. 725 apply.

760.2. Definitions. A fire alarm circuit is the wiring system between the power supply or overcurrent device and the farthest connected equipment that is part of that system.

760.3. Other Articles. Parts (A) and (B) incorporate the usual limitations on usage in ducts and plenum cavities, including correlation with the new 300.22(B) Exception. There is no reference to cable tray, motor control, or instrumentation tray cable as at 725.3(E, F, and G), which is appropriate. On the other hand, this section does reference Art. 770 because optical fiber cables are used in fire alarm systems, as is Art. 725 in the context of building controls that frequently must respond following a fire alarm activation. In addition, 300.8 is now specifically referenced in order to keep foreign systems out of fire alarm raceways.

Part (H) incorporates the rules in 300.7(A) for sealing raceway interiors that are subject to convective air migration, particularly where condensation is a likely result.

Part (I) brings in the vertical support rules for cables run in raceway, but only for the circuit-integrity (CI) cables. This makes sense because in a fire condition, these cables become extremely brittle and vertical supports can easily make a significant difference in how long they survive. These cables must be used in close agreement with the directions that come with them from their manufacturer in terms of installation methods, and these may be more restrictive than the limits in 300.19.

Part (J) incorporates the general prohibition against overfilling raceways in 300.17, without making an explicit mention of raceway fill limitations in [Chap. 9](#). Note that although 300.17 is mentioned in 760.51 on non-power-limited (NPLFA) systems, it does not appear for the power-limited ones (PLFA).

Part (K) requires a bushing in accordance with 300.15(C) where cables emerge from being sleeved in a raceway riser for physical protection. Note that the actual 300.15(C) rule requires a fitting to protect the cable from abrasion, which could be some sort of change-over fitting, and does not mention a bushing.

760.24. Mechanical Execution of Work. In addition to the usual content of this section, the 2014 **NEC** has added part (B) to address the support of circuit integrity (CI) cables. They must be supported every 24 in. and every 18 in. in places where they run within 7 ft of the floor, using steel supports. The wording is supposed to put some of the requirements for the fire-resistive system into the **NEC**, but the total requirements are always far more complicated. Refer to the commentary at 728.5 on this point. In addition, the original proposal included wording referring to running on a surface, but the final wording left that out and the result does not correlate with the actual fire-resistance specification.

760.32. Fire Alarm Circuits Extending Beyond One Building. This treatment differs from its counterparts at 725.52 and 725.141 in that the Part I location makes it apply to all power levels with only a single entry. Power-limited fire alarm circuits running outdoors are either installed as communications circuits or as conventional circuits according to the rules of Part I of Art. 300. Non-power-limited fire alarm circuits must meet those requirements and also the applicable provision in Part I of Art. 225.

To correlate with developments in **NFPA 72**, this section now has a new (2014 **NEC**) informational note pointing to UL 497B, Protectors for Data Communications. The intent is not obviously based simply on the information presented on the printed page; however, the UL standard points in turn to the Guide Card category QVGQ. This covers the category “Isolated Loop Circuit Protectors for Communications Circuits.” This category includes the following general description:

The purpose of the isolated loop circuit protector is to suppress abnormal voltages caused by hazards such as lightning and other EMI transients. An isolated loop circuit protector is intended for use on data or communication lines that are not exposed to accidental contact with electric light or power conductors operating at over 300 V to ground.

Although there is no direct requirement here, the intent is to mandate that transient surge protection based not on the usual Art. 285 approach, but instead on the protectors used for communications circuits that are to be provided. In particular the protection should be one of these devices, particularly because these are not line-voltage systems. The QVGQ category is one of five in a broader category of protectors that specifically include those protectors covered in Part II of Art. 800, which closes the loop because 760.32 does make that reference.

760.41. NPLFA Circuit Power Source Requirements. Part (A) lines up with 725.41(B), with unlimited power and voltage not to exceed 600 V. It includes express permission to secure a fire alarm circuit disconnect in the closed position. Part (B) forbids the use of either arc-fault circuit interrupter or ground-fault circuit interrupter protective devices for its branch circuit, which must be an individual branch circuit. It also includes other requirements not previously mandated by the **NEC**. The location of the branch-circuit overcurrent device supplying a fire alarm control panel shall be marked on the control panel. The circuit disconnecting means must be marked “FIRE ALARM CIRCUIT” and must be accessible only to qualified personnel, which raises obvious questions in many occupancies. It must be marked in red, but not so as to damage or obscure any manufacturer’s markings.

760.48. Conductors of Different Circuits in Same Cable, Enclosure, or Raceway. Part (A) of this is functionally the same as 725.48; however, part (B) is much more limiting. A non-power-limited fire alarm circuit conductor can run in the same raceway as a power supply conductor only if they are connected to the same equipment.

760.49. NPLFA Circuit Conductors. Part (A) differs from 725.49 only in that it does not recognize flexible cord. Part (B) is essentially the same except Type FFH-2 is not recognized, and Types PAF and PTF are only recognized for high-temperature operation. Part (C) simply requires copper conductors; the old “special stranding” rules that required solid or bunch-tinned copper up to 7-strand 16 and 18 AWG, and up to 19-strand 14 AWG, were deleted in the 1996 NEC.

760.53. Multiconductor NPLFA Cables. This section has no counterpart in Art. 725. Part (A) covers the wiring methods for these cables. They can be fished through concealed spaces and run on exposed building surfaces. All cable terminations must be in listed equipment, including fire alarm devices, boxes, or utilization equipment. Where exposed, the cable layout must be such that the wiring is protected as much as possible, such as by routing next to door framing. If less than 2.1 m (7 ft) from the floor, the cable must be secured at 450-mm (18-in.) intervals or less. A kick pipe must be installed where passing through a floor such that the cable is protected to the 2.1-m (7-ft) height using a metal raceway or Type PVC or RTRC conduit. Only RMC, PVC, RTRC, IMC LFNC, or EMT are permitted in hoistways, but the cables can also enter elevator raceways as included in 620.21.

Part (B) creates the same type of cable hierarchy for these cables as in Art. 725, with a plenum grade on top (NPLFP), a riser grade (NPLFR), and a general-purpose grade (NPLF) at the bottom. Given the limited need, there is no limited grade (“X” suffix) in this category. Note that the riser grade now applies to cabling extending vertically through “one or more” instead of the wording “more than one” floor, thereby increasing the demand for riser-rated cabling.

760.121. Power Sources for PLFA Circuits. The permitted power sources here are much simpler than in Art. 725. In addition, as with 760.41, AFCI and GFCI are off-limits for protecting the fire alarm control panel. This part also includes other requirements not previously mandated by the NEC. The location of the branch-circuit overcurrent device supplying a fire alarm control panel shall be marked on the control panel. The circuit disconnecting means must be marked “FIRE ALARM CIRCUIT” and must be accessible only to qualified personnel, which raises obvious questions in many occupancies. It must be marked in red, but not so as to damage or obscure any manufacturer’s markings.

760.130. Wiring Methods and Materials on Load Side of the PLFA Power

Source. This wiring can use NPLFA wiring methods and materials, including the ones covered in 760.49 and 760.53, with no mutual conductor heating derating penalties applied. As with their Class 2 and Class 3 counterparts, if the PLFA markings per 760.124 are removed, a PLFA circuit can be reclassified as an NPLFA circuit.

Part (B) requires devices to be installed in accordance with their directions, and also 300.11(A) with respect to staying off the designed supports of a suspended ceiling, and in addition 300.15, which effectively requires a box at termination points. The cabling rules are identical to the ones for NPLFA runs as covered in 760.53(A).

760.135. Installation of PLFA Cables in Buildings. This article uses the same hierarchy of cable insulation covered at length at 725.135. As in that case, this section is a new method of presenting this information, with the various classifications of installation circumstance listed in lettered subsections, roughly in order of decreasing levels of resistance to flame and smoke. So this list begins with actual ductwork (no suffix, only special rules) and then plenum installations (suffix “P”), then riser installations (suffix “R”), then a catch-all of intermediate industrial/commercial installations, and then general building installations (no suffix). The section ends with coverage of

nonconcealed spaces and portable fire alarm systems. Item (I) does not line up with 725.135(L&M) because instead of an “X” category, there is an allowance for any cable that meets the copper content and 26 AWG size minimum (18 AWG if single conductor cable) requirements to be run for exposed uses in these areas up to 3 m (10 ft) in length. Item (J) recognizes portable fire alarm systems for a stage or set protection, wired per 530.12.

760.136. Separation from Electric Light, Power, Class 1, NPLFA, and Medium-Power Network-Powered Broadband Communications Circuit

Conductors. These rules line up almost exactly with 725.136 except that manholes and cable trays are not covered.

760.139. Installation of Conductors of Different PLFA Circuits, Class 2, Class 3, and Communications Circuits in the Same Cable, Enclosure, Cable Tray, Raceway, or Cable Routing Assembly.

PLFA circuits are treated in the same category as Class 3 circuits in Art. 725, and most of the requirements in this section follow logically from that principle. Part (A) allows two or more PLFA circuits in the same location, together with Class 3 circuits and communications circuits. Part (B) lines up exactly with 725.139(C) on Class 2 and Class 3 circuits in common locations for the same reason. Part (C) covers intermingled network-powered broadband circuits (low-power type) and permits the PLFA wiring in those locations. Part (D) lines up with 725.139(F) and forbids installing PLFA wiring with audio amplifier output wiring as covered in 640.9(C).

760.142. Conductor Size. This section recognizes conductors as small as 26 AWG if part of a multiconductor cable. The equipment terminations must be listed as suitable for such terminations, or the 26 AWG must be joined to a larger conductor using a step-up splice listed as suitable for the conversion. These cables are increasingly used with multiplexed, addressable fire alarm systems.

760.145. Current-Carrying Continuous Line-Type Fire Detectors. These include listed, continuous line-type copper pneumatic tubing that also carries signaling circuits. They can be used with PLFA circuiting.

760.154. Applications of Listed PLFA Cables. Almost all the narrative subsection material that was located here has been relocated to Sec. 760.135 in the 2014 NEC, where it has been reformatted as a series of lists. What remained behind is a table of applications of questionable utility. One important subsection did not make the trip, however. Part (A) and its associated table presents visually the cable hierarchy discussed at length in the commentary on 725.135. This part authorizes a substitution table that covers that discussion. Communications cabling has a comparable voltage capability to FPL cabling, and therefore can be used in lieu of FPL where otherwise ranked on an equal level; for example, CMR can be used in an FPLR application, but CMR cannot substitute for FPLP. Circuit integrity cables are also recognized in all three levels (FPLP-CI, FPLR-CI, and FPL-CI).

Figure 760.154(A) is the customary cable substitution hierarchy presented in graphic form, with communications cables shown as the next level up.

760.176. Listing and Marking of NPLFA Cables. This section covers the listing requirements for the cables used in Part II of the article, as follows:

Part (A) covers the requirement for 18 AWG and larger copper wire, solid or stranded.

Part (B) covers the insulation levels required, that is, 600 V.

Part (C) covers Type NPLFP for plenum cavity applications.

Part (D) covers Type NPLFR for riser applications.

Part (E) covers Type NPLF for general-purpose applications.

Part (F) covers cables additionally rated for circuit integrity (CI). This part is now split in order to make a useful distinction between CI cable itself and CI cable as a component of an electrical circuit protective system. Any given CI cable that relies on a raceway to protect it must be specifically listed and marked as part of such a system. The best approach is to follow Art. 728 and the listing specifications exactly. Refer to the commentary in that article for more information on this point.

Part (G) covers voltage markings on NPLFA cables, that being for a maximum of 150 V, with CI cables listed for circuit integrity required to show this with a “CI” designation. Temperature ratings and markings for these cables follow those in 760.179(I); refer to that location for more details.

760.179. Listing and Marking of PLFA Cables and Insulated Continuous Line-Type Fire Detectors. In addition to the specific requirements below, cable used in a wet location, including underground, must be listed for use in such locations or use a moisture-impervious metal sheath.

Part (A) covers the requirement for copper conductors, solid or stranded.

Part (B) covers the requirement for 18 AWG and larger wire for single conductors, and 26 AWG or larger for multiconductor cable.

Part (C) covers the required voltage rating of 300 V.

Part (D) covers Type FPLP for plenum cavity applications.

Part (E) covers Type FPLR for riser applications.

Part (F) covers Type FPL for general-purpose applications.

Part (G) covers cables additionally rated for circuit integrity (CI). This category is split in the same way and for the same reasons as the comparable part of 760.176.

Part (H) covers coaxial cables, which will have the customary hierarchy listing. The rule also recognizes that the center conductor can be permitted to use 30 percent conductivity copper covered steel.

Part (I) has the indicated cable types in a table of required markings, along with the CI designation if appropriate, and the rule that voltage ratings not be marked together with the same exception as in 725.179(L) for cables with multiple ratings, some of which may require a voltage marking as part of a listing. PLFA cables, if rated higher than 60°C, must have the temperature marked on the cable, but the conductor size must always be marked.

Part (J) covers insulated continuous line-type fire detectors equipped with 300-V insulation per 760.179(C), which must be highly resistant to abrasion. The insulation must also be resistant to the spread of fire and smoke, as covered in 760.179(D, E, or F as applicable).

ARTICLE 770. OPTICAL FIBER CABLES AND RACEWAYS

770.1. Scope. This article is interesting in that it covers “wiring” that in some cases does not bring with it even a single conductive element, although the cabling will always be used in

conjunction with electrical circuits. Figure 770-1 shows operation of a fiber-optic (FO) link in the transmission of a telephone signal.

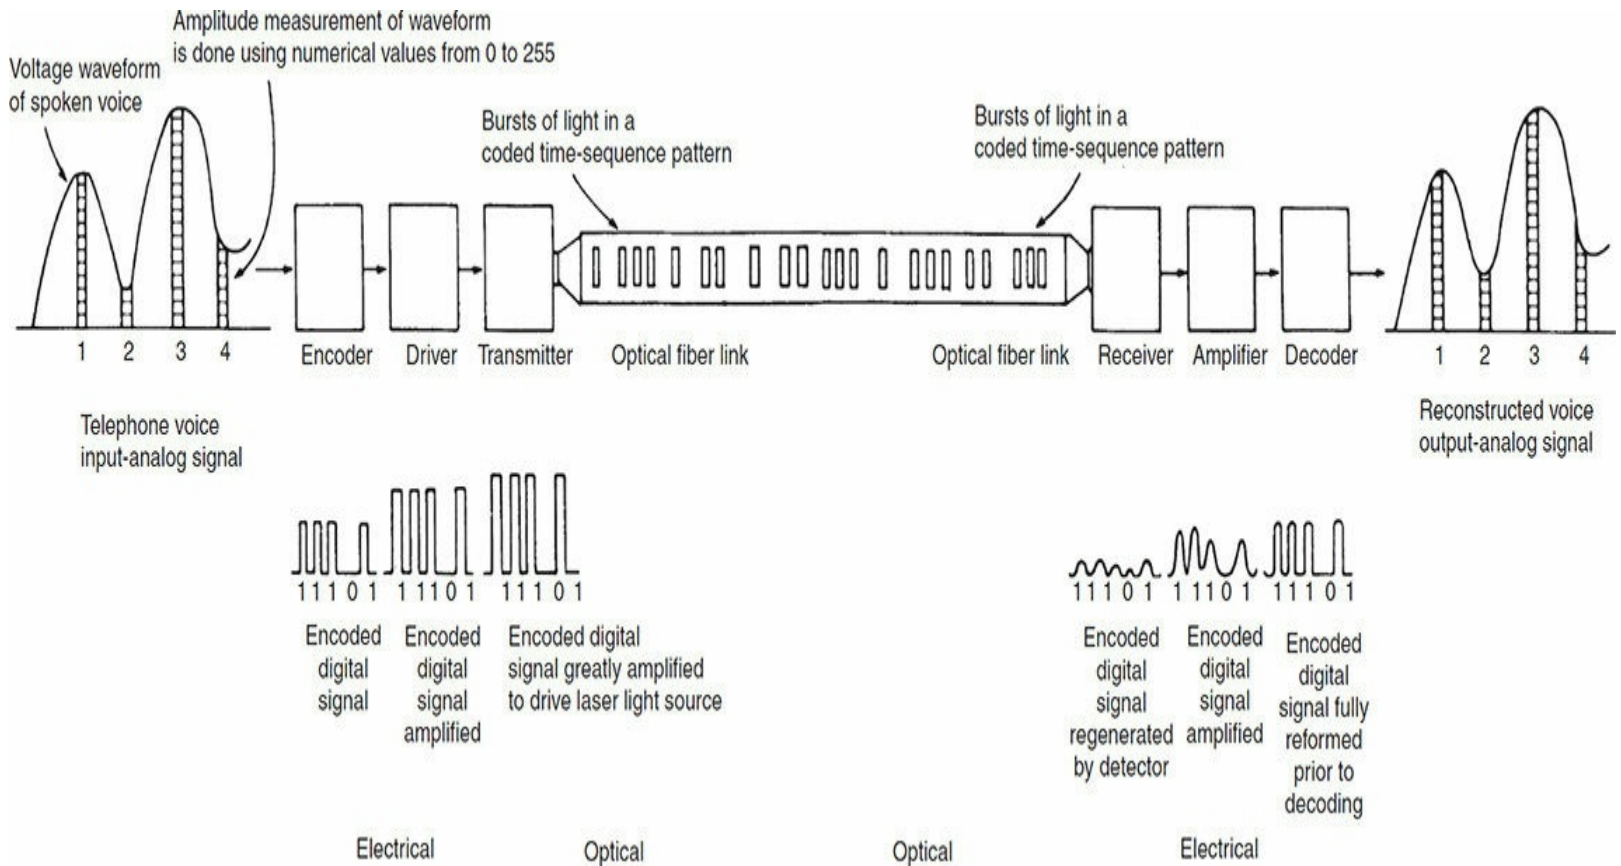

Fig. 770-1. The transmission of a signal (left to right) along an optical fiber link (a cable) at center. At the left, an electrical signal is converted to light pulses that are sent through the fiber cable by a laser diode (a light signal generator), and then, at the right, the light pulses are received and reconstructed into the original electrical signal from the left. (Sec. 770.2.)

770.2. Definitions. There are several that need to be kept in mind:

Abandoned Optical Fiber Cable is not terminated at any equipment other than a connector, and is not identified for future use with a tag.

Cable Routing Assembly is a single channel or connected multiple channels that form a structural system to support high densities of optical fiber cables and other limited energy cables including Class 2 and Class 3 cables within the scope of Art. 725 and often associated with information technology and communications equipment. This definition has been moved to Art. 100 because it applies to multiple articles.

Composite Optical Fiber Cable contains optical fibers together with current-carrying electrical conductors.

Conductive Optical Fiber Cable contains metallic strength members, or a metallic vapor barrier, or a metallic sheath or armor, or any combination of these conductive elements. Figure 770-2 shows an example.

Fig. 770-2. This fiber-optic cable, which is used in a mile-long telephone communication line, is classified as a *conductive* type of optical fiber cable because of the steel wires used to provide an outer mechanical sheath over the fiber assembly. (Sec. 770.5.)

Exposed (to Accidental Contact) applies to a conductive optical fiber cable that is in such a position that it would be likely to become energized in the event that a support or insulation or both failed.

Nonconductive Optical Fiber Cable contains no electrically conductive members in any form.

Optical Fiber Cable. A factory or field assembly of one or more optical fibers having an overall covering. This definition has been changed in the 2014 **NEC** and now includes the concept of a field-assembled cable for which the jacket is installed first, and then the optical fibers are drawn in.

Point of Entrance is the point within a building at which cable emerges from an external wall, or a floor slab, or from RMC or IMC. In such cases the use of heavy-wall steel conduit artificially extends the point of entrance into a building, doing for this wiring what 230.6 does for service entrance conductors. This is an important concept, and it holds here and for all of [Chap. 8](#). See also Sec. 770.49, which now contains the bonding requirement for the conduit.

770.12. Innerduct for Optical Fiber Cables. Optical fiber cables are sensitive to pulling tension, and communications raceways, which are a corrugated nonmetallic product closely related to electrical nonmetallic tubing, are frequently pulled into large ducts, particularly on underground applications where there may be debris in the duct. This provides a uniform pulling environment with a very low coefficient of friction.

770.21. Access to Electrical Equipment Behind Panels Designed to Allow Access. It is contrary to the **NEC** to drape endless quantities of these cables across suspended ceiling panels in a way that limits the intended access to the ceiling cavity above them.

770.24. Mechanical Execution of Work. In addition to the usual neat and workmanlike manner requirement, this section also requires exposed cabling (which includes the area above a suspended ceiling) to be supported to structure such that normal building operations will not damage the cable. In addition, if the wiring is run parallel to framing, it must meet the 32-mm (1¼-in.) spacing requirement from the leading edge of the framing. Finally, the wiring must stay off the tie wires designed to support a suspended ceiling, in accordance with 300.11. Where cable ties and other nonmetallic components are used in 300.22(C) spaces, they must be listed for that environment.

770.25. Abandoned Cables. This has the effect of requiring that any “abandoned” optical fiber cables—as defined in 770.2 as not being terminated or identified for future use with a tag—must be removed. It is no longer permissible to leave abandoned optical fiber cables in place when they are no longer in use, unless they have been “identified” for future use.

770.26. Spread of Fire or Products of Combustion. This is a restatement of 300.21, as applied to this article.

770.44. Overhead (Aerial) Optical Fiber Cables. This addresses a construction that contains a metallic noncurrent-carrying strength member and is designed for overhead work. It corresponds to 800.44, where this book provides more installation details.

770.47. Underground Optical Fiber Cables Entering Buildings. This section title should add the word “Conductive” ahead of “Optical Fiber” because the requirements only address conductive cables and exactly parallel other comparable provisions such as 820.47. Where such cables enter a building from a manhole or other enclosure they must be separated from non-power-limited circuits and power circuits, and the enclosures must be partitioned. For direct burial applications they must observe a 1-ft separation unless the power wiring (divided into two exceptions, one for services and one for everything else but the requirements are essentially the same) is in a raceway or using a cable method that includes metal cable armor.

770.48. Unlisted Cables and Raceways Entering Buildings. Part (A) allows unlisted outside plant cables, either conductive or nonconductive, to enter a building and move through general-purpose spaces (not risers or plenums) up to 15 m (50 ft) from the point of entrance. This allows a transition length along which a convenient point can be provided for a transition to the listed cables required for most interior work. If such a point is unavailable, the point of entrance can be artificially extended through the use of grounded heavy-wall steel conduit.

Part (B) allows unlisted nonconductive outside plant cables to enter buildings and continue without any length restriction, if they are run within IMC, RMC, PVC, or EMT. Note that for risers and plenum cavities EMT and PVC are excluded.

770.49. Metallic Entrance Conduit Grounding. Heavy-wall metal conduit containing optical fiber entrance cables must be bonded to a grounding electrode as covered in 770.100(B). This, in combination with the point of entrance definition, creates the remote entry point for this work that is the parallel to 230.6 for power service work. In fact, it used to be part of the definition, but was separated because definitions cannot contain requirements. Similar sections occur throughout [Chap. 8](#).

770.93. Grounding or Interruption of Noncurrent-Carrying Metallic Members of Optical Fiber Cables. This rule is split into a termination outside or inside a building, but the action to be taken is the same in either event. Make a grounding connection as covered in 770.100, or place an insulating joint as near as practicable to the point of entry.

770.100. Entrance Cable Bonding and Grounding. If grounded (and not merely interrupted as permitted in 770.93) the grounding must comply with the rules of this section.

Part (A) requires the grounding conductor to be insulated, made of copper (or other corrosion-resistant material), and stranded or solid. The size must be no smaller than 14 AWG (or larger if needed to equal the current-carrying capacity of the grounded elements in the cable assembly) and having an ampacity roughly equal (or larger) than the conductive elements of the cable assembly, but it need not be larger than 6 AWG. It must run in as straight a line as practical, and be guarded from physical damage. If run in a metal raceway, both ends must be bonded even though 250.64(E) imposes that requirement only on ferrous raceways.

Bonding conductors must be as short as practicable, and in one- or two-family dwellings they must not exceed 20 ft in length. If that distance is too short, then a separate electrode must be provided

within that distance in accordance with 770.100(B)(3)(2), with that electrode then bonded to the local power system electrode as per 770.100(D). An informational note advises that other buildings will benefit from observing this length limitation, but there is no mandatory rule.

Part **(B)** covers electrode terminations. If there is an intersystem bonding termination, then the termination is to that point. If the intersystem bonding point is lacking but there is one or more grounding electrodes, the connection must be made to that grounding system through one of the optional methods listed. If the premises served have no intersystem bonding termination and no grounding electrode system, then the bonding connection is to the nearest traditional building electrode (water pipe, building steel, concrete-encased electrode, ground ring), and if all those are missing then to a 1.5-m (5-ft) ground rod, driven into permanently damp soil to the extent practicable, using connections that comply with 250.70.

Part **(D)** requires that this electrode, although required to be at least 1.8 m (6 ft) distant from other electrodes, must be bonded to the power system grounding electrode system with a conductor no smaller than 6 AWG copper. Steam and hot water pipes are off limits for grounding conductors, as are lightning protection conductors. The power system bonding requirement is presumably waived at mobile homes for which the connection would be impractical. This is the apparent result of the wording of an exception that, in violation of the Style Manual, is not in the form of a complete sentence and therefore unclear as to effect. Refer to the discussion at 770.106 for more information.

770.106. Grounding and Bonding of Entrance Cables at Mobile Homes. This is very difficult to follow, because there is no straightforward explanation of what happens when the mobile home has an electrical supply that complies with the **NEC**. Specifically, mobile homes are supposed to have a bonding terminal on their chassis at an accessible location, as required in 550.16(C)(1). They are also supposed to have either service equipment or a feeder disconnect located within 9.0 m (30 ft), per 550.32(A). If they have actual service equipment at that location, or if they have a feeder disconnect with a regrounded neutral at that point, there will be a grounding electrode system connected at that disconnect. In fact, even if the disconnect does not include a regrounded neutral, 250.32(A) still requires a grounding electrode connection at this point. Assuming the optical fiber entry comes from this location, a bonding connection between the conductive elements in the optical fiber cable and the grounding system at the disconnect will meet all requirements and no further action needs to be taken at the mobile home. If, and only if, the disconnect is located at an excessive distance or grounded incorrectly does the necessity of creating a local electrode at the mobile home kick in.

This brings up the separate question of bonding. If the mobile home is permanently connected to a Code-compliant disconnect, then the permanent equipment grounding system connecting the mobile home and the disconnect is sufficient for these purposes. However, if the mobile home is cord-and-plug-connected, removing the plug would disrupt this continuity. In this case there is a conundrum because this wording was brought over from 800.106. Article 800 (telephone) systems have primary protectors that will not exist on these systems. That leaves only one option, a grounding electrode, and therefore, through this back door, a local grounding electrode becomes required in the event of a cord-and-plug connection. The grounding electrode must be connected to the conductive elements of the optical fiber cable, and also to the mobile home bonding terminal as previously mentioned.

This requirement was copied to here from Art. 800. The reason it is difficult to follow is that the essential context was not brought with it, and should have been. See 800.90(B) second paragraph for this information, substituting “grounding electrode” for “primary protector.”

770.110. Raceways and Cable Routing Assemblies for Optical Fiber

Cables. Raceways can be [Chap. 3](#) methods, as shown in [Fig. 770-3](#), or communications raceways as covered later. Communications raceways, as mentioned in the discussion about 770.12, are very close to ENT in construction and this section even mandates the use of the installation provisions in Art. 362 having to do with bends, supports, joints, and perhaps most intriguingly, 362.56 which invokes the box-at-termination rules in 300.15. In addition, if current-carrying conductors are in a raceway with optical fiber cables, the wire fill rules apply to the combination. On the other hand, if the raceway only contains optical fiber cables, the fill limitations do not apply. [Figure 770-4](#) shows a termination enclosure for optical fiber cables.

Fig. 770-3. A pullbox in a metric designator 38 (trade size 1½) EMT run carrying the 10-conductor cables, with a bright orange tag identifying the FO conduit (inset shows FO cable). (Sec. 770.5.)

Fig. 770-4. A NEMA 3R splice box in the telecommunications room of one of the buildings, with two 10-conductor cables entering at top (arrow) and the individual FO conductors terminated in special connectors (bottom arrow). FO conductors are used as data communication links between five different buildings in which a banking firm has branch locations in a large city. The overall circuiting includes the runs within the buildings (connecting to computers, video equipment, telephones, and telecommunications equipment) and over 5 mi of underground 30-conductor FO cable with a metal armor sheath run under the city in ducts.

Note that as of the 2014 **NEC**, the term of art for these raceways is “communications raceway” because the product employed is common throughout this article and [Chap. 8](#). The definition has been relocated to Art. 100 because it does now apply across numerous articles.

Part **(B)** covers raceway fill, and limits **NEC** fill limitations to applications where nonconductive optical fiber cables are run in the same raceway as “electric light or power conductors.” This appears to be a sort of shorthand notation for distinctions made in 770.133. Specifically, fill limits should apparently be applied to applications covered by 770.133(A) and they need not be applied to applications covered by 770.133(B) and 770.133(C).

Part **(C)**, new as of the 2014 **NEC**, covers cable routing assemblies. These are usually open on top and serve as continuous support for cables. They are customized by application, as in general-purpose, riser, or plenum, with a comparable substitution hierarchy. The default support intervals are 3 ft for horizontal runs and 4 ft for vertical runs, with an allowance for longer spans if part of the listing, but never over 10 ft.

770.113. Installation of Optical Fiber Cables and Raceways, and Cable Routing Assemblies. This section totaled four lines in the 2008 edition, and in subsequent editions runs to almost two full pages. There are some general principles at work that make this less complicated than it appears. The entire two pages boils down to the following:

1. The hierarchy of cable compositional categories, and by logical extension the hierarchy of compositional categories for the nonmetallic raceways and supporting assemblies that contain those cables, continues without change. Refer to the discussion at 725.135 regarding the history and applications of these categories, which have not changed since the advent of this work in the 1987 **NEC**. Specifically, there are plenum exposures, which require the most severe testing for both smoke generation and vertical flammability, and result in a “P” suffix on cable assemblies. There are riser exposures that are the next most severely tested, focusing on vertical flammability, and result in a “R” suffix on cable assemblies. Then there are general-purpose applications that receive general fire load testing and result in either a “G” suffix or no suffix. This is a hierarchy, so riser suitability implies general purpose suitability as well, and the plenum grade can be used in all locations. At this time there are no low-grade residential optical fiber cables (suffix “X”) recognized.
2. If a cable is pulled into a [Chap. 3](#) raceway, its suitability follows that of the enclosing [Chap. 3](#) raceway, just as surely as the THHN or RHW or XHHW-2 that could otherwise be pulled into the same raceway without a separate evaluation of the fire resistance of its insulation.
3. Fireproof shafts with firestopping at every floor cancel the need for special riser ratings, and one- and two-family dwelling exposures, even vertical ones, do not merit a riser rating either.

770.114. Grounding. Conductive optical fiber cables must have their conductive members grounded, either to a grounded equipment rack, or as specified in 770.100(B)(2). The reason for a reference that only applies to a building with a grounding means, according to the proposal substantiation, is that this section is only supposed to apply to cables within buildings, and cables outside of buildings use 770.100. That substantiation is both true and beside the point; however, the section says what it says.

770.133. Installation of Optical Fibers and Electrical Conductors. There are three types of optical cables, each with their own system separation rules, as follows:

- a. *Composite optical fiber cables* containing non-power-limited control or power circuits are

only permitted to be used where the optical fiber and the non-power-limited components are functionally associated. However, once a composite cable qualifies for use under this criterion, it may be used in the same raceway or cable tray as non-power-limited wiring conductor, and these cables may enter other wiring enclosures for termination or other purposes. In industrial occupancies only, with qualified maintenance and supervision, composite cables are even permitted with the power conductor operating at medium voltage (over 600 V).

- b. *Conductive optical fiber cables* are not permitted in the same raceway or cable tray as non-power-limited wiring of any kind.
- c. *Nonconductive optical fiber cables* are permitted within a common raceway or the same cable tray as non-power-limited wiring of any kind operating at 600 V or less. If the nonconductive fiber cables are functionally associated with the non-power-limited wiring, the cables are permitted in non-power-limited wiring enclosures. Nonconductive optical fiber cables are also permitted in common wiring enclosures where installed in a factory- or field-assembled control center. In industrial occupancies only, with qualified maintenance and supervision, nonconductive optical fiber cables are also permitted with the power conductors operating at medium voltage (over 600 V).
- d. *With power-limited circuits* optical fiber cables are permitted without limitation as to being either conductive or nonconductive, and are permitted to be part of a composite cable with, and to run in the same wiring raceways, cable trays, and other enclosures with copper wiring that is part of a power-limited system. Specifically, optical fiber cabling is permitted with a Class 2 or Class 3 system per Art. 725, or a power-limited fire alarm system per Art. 760, or a communications system as covered in Art. 800, or a CATV system covered in Art. 820, or a network-powered broadband communications system having a low-power source as defined by the applicable parameters in Table 830.15.

Where these requirements specify a separation between optical fiber cabling of any type and electrical power or control circuits of any type, those separation requirements can be met by providing a permanent or listed barrier between the systems. This can be accomplished in cable tray or surface raceway systems by using barriers compatible with the tray or surface raceway, and in an enclosure by either arranging a fixed and grounded permanent barrier or by enclosing the optical fiber cables in a grounded raceway as required. For example, flexible metal conduit is often used within a non-power-limited enclosure to extend either the non-power-limited source wiring or the power-limited or optical fiber cabling from the entry point to a point where system separation need no longer be maintained. Refer to 800.133(B) for detailed coverage of how 770.133(B) should be applied.

Part (D) echoes 300.11(B) and disallows the use of a electrical raceways as a support for optical fiber cables tied to its outside. However, there is an exception for optical fibers to run up a mast on its outside, if “intended for the attachment and support of such cables.” This can never include a service mast, for which 230.28 absolutely disallows any connections thereto except the service drop conductors, and 225.17 places the same limits for other power circuits.

770.154. Application of Listed Optical Fiber Cables and Raceways. The installation requirements for these cables now reside at 770.110 and 770.113, and the applications have been converted to a full-page table that summarizes the results.

770.179. Optical Fiber Cables. This section covers the listing requirements for the cables used in the applications just covered. It also, as of the 2014 **NEC**, contains essential requirements

for field-assembled optical fiber cables. The overall covering must be marked on the surface to indicate the specific “optical fiber conductors” with which it is listed, and the “optical fiber conductors” must bring with them a marking tape that indicates the outer cover with which they are listed. In that way the inspector can verify that the proper components are used with each other. The provision goes on to require that overall covering of a field-assembled optical fiber cable meets the listing requirements for “optical fiber raceways.” Of course, this raises several questions, such as how an optical fiber can be a “conductor” and why an “optical fiber raceway” is not actually a “communications raceway” when the former term was supposedly obsolete. The following subsections address the listing requirements for the possible applications:

Part (A) covers Types OFNP and OFCP for plenum cavity applications.

Part (B) covers Type OFNR and OFCR for riser applications.

Part (C) covers Type OFNG and OFCG for general-purpose applications.

Part (D) covers Type OFN and OFC for general-purpose applications. The presence or absence of a “G” suffix depends on the test protocol used. A “no suffix” cable may not have been tested to a certain Canadian standard and could be restricted in certain applications within the Canadian market.

Part (E) covers optical fiber circuit integrity (CI) cables, which will retain their communications function for a rated time period during a fire exposure through a self-sacrificing ceramifiable outer jacket. This classification follows others throughout the limited energy cabling articles. Technically, CI cables must be installed in free air to retain the validity of that designation. A separate paragraph (2) covers fire-resistive cables. They will have the protective system number on them or on the smallest unit container (note, however, that 728.100 requires the marking on the cable). In either case they must be installed under all the terms of the listing. Refer to the commentary on the new Art. 728 for more information.

Part (F) provides specific marking and listing information for field-assembled optical fiber cables that fully address the general information presented in the parent language of the section. Note that in this case the reference is not to optical fiber raceways, but to communications raceways instead.

770.180. Grounding Devices. Equipment employed to bond metallic components of cable assemblies covered in Art. 770 to grounding and bonding conductors must be listed, or be part of a larger component that is listed.

Chapter Eight

ARTICLE 800. COMMUNICATIONS CIRCUITS

800.1. Scope. This article covers communications circuits and equipment. The definition of a “communications circuit” (discussed below) is essential to understanding this scope statement.

Considerable attention has been paid to modernizing the usage of grounding and bonding terms in the communications article to correctly line up with usage now in effect throughout the rest of the NEC and within Art. 250. New informational drawings explain the usage to those who were accustomed to old practice.

The paragraph titled “Code Arrangement” of the “Introduction to the Code” (90.3) states that [Chap. 8](#), which includes Art. 800, “Communication Circuits,” is independent of the preceding chapters except as they are specifically referred to.

800.2. Definitions. A *communications circuit* extends voice, audio, video, data, interactive services, telegraph (except radio), outside wiring for fire alarm and burglar alarm from the communications utility to the customer’s communications equipment up to and including terminal equipment such as a telephone or facsimile machine.

The connection to the facilities of a serving utility is an essential component of this definition. Ethernet connections between computers or between computers and a router are not communications circuits and are covered as signaling circuits in Art. 725.

A *communications raceway* is an enclosed nonmetallic channel for communications cabling.

Exposed (to Accidental Contact) applies to a communications cable that is in such a position that it would be likely to become energized in the event that a support or insulation or both failed.

800.3. Other Articles. This section correlates with Art. 770 to bring in its provisions if optical fiber is used as part of the communications circuit, along with the terminology “cable routing assembly” as defined in Art. 100, together with its installation rules. It also brings in the rules of 300.22 because due to this [Chap. 8](#) location, only Code rules from [Chaps. 1](#) through [7](#) specifically referenced apply to this work.

800.12. Innerduct. Listed communications raceways can be used by right where pulled into larger [Chap. 3](#) raceways; such applications are now formally defined as innerduct. The number pulled in to the larger raceway is not specified, which is appropriate because any applicable wire/cable fill will be calculated in reference to the specific innerduct being used. The specific style must agree with the application (plenum, riser, etc.).

800.18. Installation of Equipment. With the exception of test equipment used temporarily, all equipment electrically connected to a telecommunications network must be listed as suitable for that purpose.

800.21. Access to Electrical Equipment Behind Panels Designed to Allow

Access. It is contrary to the **NEC** to drape endless quantities of these cables across suspended ceiling panels in a way that limits the intended access to the ceiling cavity above them.

800.24. Mechanical Execution of Work. In addition to the usual neat and workmanlike manner requirement, this section also requires exposed cabling (which includes the area above a suspended ceiling) to be supported to structure such that normal building operations will not damage the cable. In addition, if the wiring is run parallel to framing, it must meet the 32-mm (1¼-in.) spacing requirement from the leading edge of the framing. Finally, the wiring must stay off the tie wires designed to support a suspended ceiling, in accordance with 300.11. Where cable ties and other nonmetallic components are used in 300.22(C) spaces, they must be listed for that environment. An informational note (2) provides a cross-reference to the controlling rule in **NFPA 90A**.

800.25. Abandoned Cables. This has the effect of requiring that the accessible portions of any “abandoned” conductors—as defined in 800.2 as not being terminated or identified for future use with a tag—must be removed. It is no longer permissible to leave abandoned communications cables in place when they are no longer in use, unless they have been “identified” for future use.

800.26. Spread of Fire or Products of Combustion. This is a restatement of 300.21, as applied to this article.

800.44. Overhead Communications Wires and Cables. This section divides the topic into pole wiring and over rooftops. Part (A) covers pole work and requires communications wires to run below power wiring on the same pole if practicable, and never attached to the same cross arm. The climbing space is to be as required in 225.14(D), and there must be a minimum of a 300-mm (12-in.) separation from power wiring at any point in a span, including at their point of attachment at the load end. This reduced spacing only applies if the spacing at the pole meets the required 1-m (40-in.) spacing on the pole. Part (B) covers rooftops, and the default clearance is 2.5 m (8 ft), with exceptions for auxiliary buildings such as garages, and also for mast applications and steep roof applications that exactly duplicate the comparable exceptions for service drops operating at not over 300 V.

800.47. Underground Circuits Entering Buildings. Where in manholes with power circuits, barriers must be arranged to create a separate section for the communications circuits. Note that although 800.110 requires installers to run **Chap. 3** raceways in accordance with the applicable **Chap. 3** rules, which include rules for wet locations, that requirement was never intended to extend to mandating a wet-location criterion for the enclosed cabling. UL 444, the applicable product standard, does not recognize such a rating. This rule specifically waives the normal wet-location rule in **Chap. 3**. Although this is not required because **Chap. 8** stands alone, the cabling manufacturers requested an explicit reference due to repeated misapplications by the inspection community. Note, however, that gel-filled cable constructions (“flooded” cables, so-called) for this work have been around for generations, and have a well-proven track record of endurance in wet and underground applications.

800.48. Unlisted Cables and Raceways Entering Buildings. Unlisted outside plant cables may enter a building and move through general-purpose spaces (not risers or plenums) up to 15 m (50 ft) from the point of entrance. This allows a transition length along which a convenient point can be provided for a transition to the listed cables required for most interior work. If such a point is unavailable, the point of entrance can be artificially extended through the use of grounded heavy-wall steel conduit. The last sentence addresses the artificial extension into a building of a point of

entrance, much as 230.6 does for service entrance conductors with concrete encasement, etc. For communications circuits, this is done with heavy-wall conduit. This is an important concept, and it holds for all of [Chap. 8](#). See also the next section, which contains the bonding requirement for the conduit.

800.49. Metallic Entrance Conduit Grounding. Heavy-wall metal conduit containing optical fiber entrance cables must be bonded to a grounding electrode as covered in 800.100(B). This, in combination with the point of entrance definition, creates the remote entry point for this work that is parallel to 230.6 for power service work. In fact, it used to be part of the definition, but was separated because definitions cannot contain requirements. Similar sections occur throughout [Chap. 8](#).

800.50. Circuits Requiring Primary Protectors. The requirement that creates the need for this section is 800.90, discussed below. Part (A) covers the drop wire from the last outdoor support to the protector and it must be listed for this purpose, as covered in 800.173. Part (B) covers the required 100-mm (4-in.) system separation from open power wiring (not in raceways or cable assemblies) on the outside of buildings. Note that communications wiring outdoors that is exposed (see definition above) to contact with power wiring over 300 V to ground, as on most utility poles, must be separated from building woodwork by wiring on porcelain knobs, etc., unless fuseless protectors are used or where the exposed wiring has a grounded metallic sheath.

Part (C) covers circuits entering a building ahead of the primary protector. The building must be protected from the unprotected wiring through a bushing or metal raceway, unless the entry is through masonry, or uses metal sheathed cable, or qualifies for a fuseless primary protector (see 800.173 for a cable assembly that inherently meets this requirement) or is listed drop cable extending from circuits running with a metallic sheath. Raceways must slope up in the out-to-in direction or else drip loops must be provided outside. Raceways must also have a service head, and if ahead of the protector, must be grounded.

800.90. Protective Devices. Part (A) covers where primary protectors are required, which can be summarized with respect to the entering circuits as wherever there is a lightning exposure or exposure to contact by power wiring over 300 V to ground. The second note provides good information as to where a lightning exposure might be disregarded, such as in high-rise construction areas where lightning will be intercepted, or for short interbuilding cable runs not over 42 m (140 ft) apart and running as direct burial or in underground conduit with either a metallic cable shield or the conduit being metallic. Areas on the west coast and in other locations with five or fewer thunderstorm days a year are also candidates to avoid this requirement. (A)(1) gives five instances where a fuseless protector is permitted; (A)(2) covers the fused protectors that are required in the event that local conditions do not permit qualification under one of those five allowances.

Part (B) covers the location of primary protectors, which is in, on, or immediately adjacent to the building served, as near as practicable to the point of entrance. And note the definition of that term; it is possible to extend that point through the use of grounded heavy-wall conduit. The second paragraph covers mobile homes, and accepts a protector at the remote disconnecting means as long as the distance is within NEC requirements in 550.32(A).

800.93. Grounding or Interruption of Metallic Sheath Members of Communications Cables. This rule is split into a termination outside or inside a building, but the action to be taken is the same in either event: Make a grounding connection as covered in 800.100, or place an insulating joint as near as practicable to the point of entry. Here again that point of entry

can be extended through the use of conduit.

800.100. Cable and Primary Protector Bonding and Grounding. Both the protector and any metallic members of a cable sheath must be grounded in accordance with the rules of this section.

Part (A) requires the grounding conductor to be listed and insulated, made of copper (or other corrosion-resistant material), and stranded or solid. The size must be no smaller than 14 AWG, or larger if needed to equal the current carrying capacity of the grounded metallic elements of the sheath, or of the protected conductors in the cable. It must run in as straight a line as practical, and be guarded from physical damage. If run in a metal raceway, both ends must be bonded even though 250.64(E) only imposes that requirement on ferrous raceways. It must be as short as practicable, and not over 6 m (20 ft) in one- and two-family dwellings. If the 6-m (20-ft) limitation can't be met, place an additional electrode as covered in 800.100 and then bond this electrode to the power system electrode with a 6 AWG or larger copper wire.

Part (B) covers electrode terminations. If there is an intersystem bonding termination, then the termination is to that point. If the intersystem bonding point is lacking but there is one or more grounding electrodes, the connection must be made to that grounding system through one of the optional methods listed. If the premises served have no intersystem bonding termination and no grounding electrode system, then the bonding connection is to the nearest traditional building electrode (water pipe, building steel, concrete-encased electrode, ground ring), and if all those are missing then to a 1.5-m (5-ft) ground rod, driven into permanently damp soil to the extent practicable, using connections that comply with 250.70.

Part (D) requires that this electrode, although required to be at least 1.8 m (6 ft) distant from other electrodes, must be bonded to the power system grounding electrode system with a conductor no smaller than 6 AWG copper. The power system bonding requirement is presumably waived at mobile homes for which the connection would be impractical. This is the apparent result of the wording of an exception that, in violation of the Style Manual, is not in the form of a complete sentence and therefore unclear as to effect. Refer to the discussion at 800.106 for more information.

800.106. Grounding of Entrance Cables at Mobile Homes. This is very difficult to follow, because there is no straightforward explanation of what happens when the mobile home has an electrical supply that complies with the NEC. Specifically, mobile homes are supposed to have a bonding terminal on their chassis at an accessible location, as required in 550.16(C)(1). They are also supposed to have either service equipment or a feeder disconnect located within 9.0 m (30 ft), per 550.32(A). If they have actual service equipment at that location, or if they have a feeder disconnect with a regrounded neutral at that point, there will be a grounding electrode system connected at that disconnect. In fact, even if the disconnect does not include a regrounded neutral, 250.32(A) still requires a grounding electrode connection at this point. Assuming the communications entry comes from this location, a bonding connection between the conductive elements in the communications cable jacket and the grounding system at the disconnect will meet all requirements and no further action needs to be taken at the mobile home. If, and only if, the disconnect is located at an excessive distance or grounded incorrectly does the necessity of creating a local electrode at the mobile home kick in. The context for this rule is at 800.90(B), second paragraph.

This brings up the separate question of bonding. If the mobile home is permanently connected to a Code-compliant disconnect, then the permanent equipment grounding system connecting the mobile home and the disconnect is sufficient for these purposes. However, if the mobile home is cord-and-

plug-connected, removing the plug would disrupt this continuity. Article 800 systems have primary protectors that will not exist on most other systems. That leaves only one option, a grounding electrode, and therefore, through this back door, a local grounding electrode becomes required in the event of a cord-and-plug connection. The grounding electrode must be connected to the conductive elements of the communications cable, and also to the mobile home bonding terminal as previously mentioned.

800.110. Raceways for Communications Wires and Cables. Raceways can be [Chap. 3](#) methods or communications raceways as covered later. These raceways are very close to ENT in construction and this section even mandates the use of the installation provisions in Art. 362 having to do with bends, supports, joints, and perhaps most intriguingly, 362.56 which invokes the box-termination rules in 300.15. However, no raceway fill limitations apply.

Part (C), new as of the 2014 **NEC**, covers cable routing assemblies. These are usually open on top and serve as continuous support for cables. They are customized by application, as in general-purpose, riser, or plenum, with a comparable substitution hierarchy. The default support intervals are 3 ft for horizontal runs and 4 ft for vertical runs, with an allowance for longer spans if part of the listing, but never over 10 ft.

800.113. Installation of Communications Wires, Cables and Raceways. There are some general principles at work that make this less complicated than it appears. The entire two pages boils down to the following:

1. The hierarchy of cable compositional categories, and by logical extension the hierarchy of compositional categories for the nonmetallic raceways and supporting assemblies that contain those cables, continue without change. Refer to the discussion at 725.135 regarding the history and applications of these categories, which have not changed since the advent of this work in the 1987 **NEC**. Specifically, there are plenum exposures, which require the most severe testing for both smoke generation and vertical flammability, and result in a “P” suffix on cable assemblies. There are riser exposures that are the next most severely tested, focusing on vertical flammability, and resulting in an “R” suffix on cable assemblies. Then there are general-purpose applications that receive general fire load testing and result in no suffix. Residential grades (suffix “X”) apply to one- and two-family dwellings less than 6 mm (¼ in.) in diameter, and for multifamily dwellings in nonconcealed spaces. This is a hierarchy, so general-purpose acceptability includes residential, riser suitability implies general-purpose suitability as well, and the plenum grade can be used in all locations. Under carpet cable (suffix “UC”) is suitable for general-purpose applications as described.
2. If a cable is pulled into a [Chap. 3](#) raceway, its suitability follows that of the enclosing [Chap. 3](#) raceway, just as surely as the THHN or RHW or XHHW-2 that could otherwise be pulled into the same raceway without a separate evaluation of the fire resistance of its insulation.
3. Fireproof shafts with firestopping at every floor cancel the need for special riser ratings, and one- and two-family dwelling exposures, even vertical ones, do not merit a riser rating either.

800.133. Installation of Communications Wires, Cables, and Equipment. Part (A) sets forth the system separation rules, which are comparable to Art. 725 provisions. Part (A)(1) covers raceways, cable trays, boxes, and cable assemblies, in three headings, the first being uses with “other circuits.” This raises the editorial problem of beginning a discussion of three alternatives with “other,” as in other than what? So, this analysis begins with the last item (c) covering non-power

limited circuits. The rule is no common locations allowed, but there are three exceptions. The first recognizes a permanent barrier or listed divider. The second exception allows a common enclosure where the power-limited and non-power-limited wiring must terminate on the same equipment, as in the case of some powered equipment with a communications interface. In this case there is a general solution and a limited alternative. The general solution is to restrain the wiring with duct, tie-downs, or other methods such that a 6-mm (1/4-in.) air separation is maintained between systems. Note that this provision is for dead-end wiring only, not daisy chains (“solely for power supply to” does not mean to connect and then to feed another piece of equipment). The third exception correlates with 620.36 with respect to the traveling cable.

The second, “non-other” item is (b), covering communications circuits sharing a cable assembly with Class 2 and Class 3 circuits. In such cases the combination is allowed but the entire assembly becomes reclassified as a communications cable; and the Class 2 or Class 3 circuit is now an Art. 800 circuit and must meet the listing requirements of this article. On the other hand, there are composite cables comprised of jacketed signaling cables alongside of jacketed communications cables, all within a common overall jacket, and in this case the signaling circuit is permitted, but not required, to be reclassified as a communications circuit. Note that even though this rule does not expressly cover the topic, Type NMS cable relies on this concept, and UL has listed this sort of hybrid cable for many years, as expressly covered in 334.116(C). Such cable assemblies do not depend on conductor insulation alone to establish the required system separation, squarely in accordance with the spirit of these rules; however, the literal text of this wording is in direct conflict with the [Chap. 3](#) permission.

What remains therefore, in (a), is that which is therefore “other.” And this would cover the use of communications cables (as distinguished from conductors sharing a cable assembly) with other power-limited circuits in raceways and enclosures. The context for these rules is that communications circuits have a voltage exposure that is comparable to power-limited fire alarm or Class 3 signaling circuits. Therefore, the following systems can share an enclosure with communications cables: (1) Class 2 and Class 3 cabling—Art. 725 (or in Art. 645); (2) Power-limited fire alarm wiring—Art. 760; (3) Optical fiber cabling both conductive and nonconductive—Art. 770; (4) CATV systems—Art. 820; and (5) Low-power network-powered broadband communications—Art. 830.

Part (A)(2) requires a 50-mm (2-in.) separation from open power wiring and other open, non-power-limited circuit conductors. Two exceptions apply, the first where a raceway on either system provides separation, or where the non-power-limited wiring uses [Chap. 3](#) cabled wiring methods. The second applies where fixed barriers such as porcelain tubes or flexible tubing are installed.

Part (B) covers conductor support and states that cables must not be tie-wrapped to or otherwise supported by electrical raceways, as also disallowed in 300.11(B). However, there is an exception for communications cables to run up a mast on its outside if it is “intended for the attachment and support of such cables.” This can never include a service mast, for which 230.28 absolutely disallows any connections thereto except the service drop conductors. Part (C) brings in the prohibition against ductwork locations subject to loose stock and vapor removal in 300.22(A). This may seem odd and commonsensical, unworthy of mention here, but [Chap. 8](#) articles carry no baggage from the first seven chapters, except only that which they go back to get. So, this is necessary.

800.154. Applications of Listed Communications Wires and Cables and Communications Raceways and Listed Cable Routing Assemblies. The installation requirements for these cables now reside at 800.110 and 800.113, and the applications have been

converted to several tables that summarize the result, beginning with Table 154a covering the wires and cables, and then Table 154b covering communications raceways, and then Table 154c covering cable routing assemblies. The cable substitution hierarchy table and its associated figure remain here, as Table 800.154d (literally appearing in Fig. 800.154).

800.156. Dwelling Unit Communications Outlet. In new construction, at least one communications outlet must be provided within all dwelling units and cabled to the service demarcation point of the communications utility. This is true regardless of plans to rely on cellular phone service.

800.170. Equipment. Reiterating 800.18, all communications equipment, even a lowly RJ-11 jack that will be field installed, must be listed as suitable for connection to a telecommunications network. As of the 2014 NEC, cable ties used in plenum cavities must be listed for that application as well.

800.173. Drop Wire and Cable. Communications wires without a metallic shield that run from the last outdoor support to the primary protector must be listed as being suitable for the purpose, and shall have the current-carrying capacity as covered in 800.90(A)(1)(b) or (c). The last condition means that they will “safely fuse on all currents greater than the current-carrying capacity of the primary protector” and thereby qualify the installation as not requiring a fused protector.

800.179. Communications Wires and Cables. This section includes general rating provisions that apply to all iterations of this cabling. Communications wires and the cables (other than the outer shield on coaxial cable) must be insulated for 300 volts, but the actual voltage rating must not be marked on the cable, unless required by other listings. The concern is the likelihood unqualified persons may interpret such a marking as indicative as suitable for power applications. This wiring must be suitable for 60°C or higher, and if higher than that default value, the temperature rating must be marked accordingly. The listing requirements for these cables follow:

Part (A) covers Types CMP for plenum cavity applications.

Part (B) covers Type CMR for riser applications.

Part (C) covers Type CMG for general-purpose applications.

Part (D) covers Type CM for general-purpose applications. The presence or absence of a “G” suffix depends on the test protocol used. A “no suffix” cable may not have been tested to a certain Canadian standard and could be restricted in certain applications within the Canadian market.

Part (E) covers Type CMX for limited use in residential applications.

Part (F) covers Type CMUC undercarpet wires and cables.

Part (G) covers communications circuit integrity (CI) cables. These are additionally marked with the designation “CI.” This part is now split in order to make a useful distinction between CI cable itself and CI cable as a component of an electrical circuit protective system. Any given CI cable that relies on a raceway to protect it must be specifically listed and marked as part of such a system. The best approach is to follow Art. 728 and the listing specifications exactly. Refer to the commentary in that article for more information on this point.

Part (H) covers communications wires, as opposed to cables, as used in cross-connect arrays and distributing frames.

Part (I) covers hybrid power and communications wire, typically cross-listed as a composite of both Type NM and Type CM.

800.180. Grounding Devices. Equipment employed to bond metallic components of cable assemblies covered in Art. 800 to grounding and bonding conductors must be listed, or be part of a larger component that is listed.

800.182. Communications Raceways and Cable Routing Assemblies. Parts (A), (B), and (C) cover communications raceways, one for each basic level of the hierarchy. As previously noted, the use of one of these raceways does not relieve the installer of the responsibility to pull in communications cables with equivalent fire resistance into the raceway. For example, a plenum communications raceway in an air-handling plenum cavity per 300.22(C) must have CMP cabling pulled into it. This section also applies to cable routing assemblies.

ARTICLE 810. RADIO AND TELEVISION EQUIPMENT

810.1. Scope. This article covers antenna systems for radio and television reception, and amateur radio transmission, as well as citizen band equipment. The article does not cover equipment that couples signaling impulses to power line conductors. The 2014 **NEC** has clarified that parabolic and flat antennas are included in the scope of this article.

810.4. Community Television Antenna. The antenna of such a system is covered here. Any coaxial distribution is covered under Art. 820.

810.5. Radio Noise Suppressors. This equipment must be listed and in a protected location.

810.6. Antenna Lead-In Protectors. This section, new as of the 2014 **NEC**, provides the listing requirements for these devices, along with the field grounding requirement to install per 810.21(F).

810.7. Grounding Devices. Equipment employed to bond metallic components of cable assemblies, or metal parts of equipment or antennas to grounding and bonding conductors must be listed, or be part of a larger component that is listed.

810.11. Material. Except as used for a short lead-in (under 11 m or 35 ft), antenna and lead-in conductors must be hard drawn copper or other high-strength, corrosion-resistant material.

810.12. Supports. Outdoor antennas must be securely supported and not attached to a service mast, or any pole or similar structure carrying power circuits over 250 V line-to-line. Insulators must be strong enough to secure the antenna and the lead-in must be securely attached to the antenna.

810.13. Avoidance of Contacts with Conductors of Other Systems. For service drops and conductors on the exteriors of buildings, the requirements for insulating covering and methods of installation depend on the likelihood of crosses occurring between signal conductors and light or power conductors. Antenna wiring must be kept where it will not come into contact with power wiring, and a 600-mm (2-ft) minimum spacing is required.

810.14. Splices. The antenna may unavoidably be so located that in case of a break in the wire, it may come in contact with electric light or power wires. For this reason, the wire should be of sufficient size to have considerable mechanical strength. Splices must be made so the conductors are not appreciably weakened.

810.15. Grounding. Masts and metal structures supporting antennas must be grounded as covered in 810.21. This includes antennas for satellite TV reception.

The 2017 **NEC**, for the first time, is incorporating a specific lightning protection concept from

NFPA 780, *Standard for the Installation of Lightning Protection Systems* into a mandatory provision. In this case a satellite television provider successfully argued for relief from the necessity to ground all antennas.

Specifically, an antenna within the scope of Art. 810 need not be grounded if it is within a zone of protection extending from an adjacent structure. The concept, known as the rolling sphere, is that a lightning discharge occurs after a downward leader from a cloud, moving in jagged steps based on the voltage, contacts an upward leader from an object on the ground. The downward progression is not smooth, advancing in a series of jumps in varying directions. These jumps typically don't exceed 150 ft. Therefore, if you roll a sphere of that radius around adjacent objects, and your (in this case) antenna never pierces the underside of the sphere as it rolls by, then any downward leader will first intercept the adjacent structure. To some extent the protection is a function of probability. A leader with enormous charge behind it will move with longer branching jumps, suggesting the radius of the sphere be decreased to decrease the probability of being struck. However, the radius chosen in **NFPA 780** (based on a charge that will result in a 10 kA peak discharge) will intercept 91 percent of all lightning events.

810.16. Size of Wire-Strung Antenna—Receiving Stations. For wire-strung antennas, Table 810.16(A) gives the minimum AWG sizes based on span. Part (B) covers self-supporting antennas, including the ones for satellite TV reception. Here again they must be located away from overhead power drops.

810.17. Size of Lead-In—Receiving Station. The tensile strength of a lead-in must at least equal that of the antenna in 810.16.

810.18. Clearances—Receiving Station. Lead-ins must not swing closer than 600 mm (2 ft) to power circuits up to 250 V wire-to-wire, and not within 3 m (10 ft) of higher voltage wiring. If the wiring is tied down on insulators or otherwise secured and not over 150 V between conductors, the spacing can come down to 100 mm (4 in.). A lead-in must never be closer than 1.8 m (6 ft) to a lightning down conductor. Underground lead-ins must be at least 300 mm (12 in.) from power, lighting, or Class 1 circuits, unless either the power side or the lead-in side is run in a raceway or metal cable armor.

Part (B) covers the lead-ins where they run indoors. In this case the separation is 50 mm (2 in.), also allowed closer if the systems are permanently separated through the use of fixed nonconductors or the power side is using metal raceways or cable armor. The wiring can enter the same box as long as a permanently installed barrier keeps the systems apart.

810.19. Electrical Supply Circuits Used in Lieu of Antenna—Receiving Stations. The coupling device between the supply circuit wiring and the antenna leads must be listed.

810.20. Antenna Discharge Units—Receiving Stations. Every lead-in conductor from an outdoor antenna must be provided with a listed antenna discharge unit, unless it is enclosed in a continuous metallic shield that is grounded per 810.21, or protected with its own antenna discharge unit. Antenna discharge units must be located as near as practicable to the point of entrance into the building they protect, and ahead of any radio set. They must be grounded in accordance with 810.21.

810.21. Bonding Conductors and Grounding Electrode Conductors—Receiving Stations. Grounding conductors must comply with (A) through (K).

The **NEC** requires the grounding conductor to be made of copper (or other corrosion-resistant

material), and stranded or solid. Insulation is not required and it can run inside or outside the building. The size must be no smaller than 10 AWG (or 8 AWG aluminum, or 17 AWG bronze or copper-clad steel). It must run in as straight a line as practical, securely fastened in place, and be guarded from physical damage. If run in a metal raceway, both ends must be bonded even though 250.64(E) only imposes that requirement on ferrous raceways. A grounding electrode conductor or bonding conductor can also be used for operational purposes at a ground station.

Part (F) covers electrode terminations. If there is an intersystem bonding termination, then the termination is to that point. If the intersystem bonding point is lacking but there are one or more grounding electrodes, the connection must be made to that grounding system through one of the optional methods listed. If the premises served have no intersystem bonding termination and no grounding electrode system, then the bonding connection is to the nearest traditional building electrode (water pipe, building steel, concrete-encased electrode, ground ring), and if all those are missing then to a 1.5 m (5 ft) ground rod, driven into permanently damp soil to the extent practicable, using connections that comply with 250.70.

810.52. Size of Antenna. The minimum size of antenna conductors for citizen band and for ham radio transmission/reception operations is given in Table 810.52, which is also the size of the lead-in as specified in 810.53.

810.54. Clearance on Building. Antenna conductors must be firmly mounted at least 75 mm (3 in.) clear of the surface wired over, and the lead-in conductors must observe the same clearance. If, however, coaxial cable (“continuous metal shield”) is used for the lead-in, the clearance rule disappears provided the coaxial cable shield is grounded to the station grounding conductor as covered in 810.58.

810.55. Entrance to Building. If a coaxial cable with a 810.58 grounding connection is not used for the lead-in wire, the lead-in conductor must enter through an insulating nonabsorbent tube or bushing, or through an opening arranged so the entrance wires can be firmly secured with a 50-mm (2-in.) clearance, or through a drilled hole in a pane of glass.

810.56. Protection Against Accidental Contact. Antenna lead-ins must be positioned so inadvertent contact with them would be difficult.

810.57. Antenna Discharge Units—Transmitting Stations. Every lead-in must have an antenna discharge unit, or other suitable method to drain off static charge. This could be as simple as a connection to the station ground when the station is not operating.

810.58. Bonding Conductors and Grounding Electrode Conductors—Amateur and Citizen Band Transmitting and Receiving Stations. The grounding conductors must comply with the minimum provisions of 810.21, with the size no smaller than as in 810.21(H), but also no smaller than the lead-in. The operating grounding conductor must not be smaller than 14 AWG.

810.70. Clearance from Other Conductors. All station conductor wires must be at least 100 mm (4 in.) from power or signaling wiring, unless separated from them with a securely fastened insulator such as a porcelain tube or loom. This section also has an exception, not in the form of a complete sentence and therefore of uncertain meaning, pointing to Art. 640. This exception is probably obsolete. It was in the NEC over 50 years ago when Art. 640 was firmly rooted in the vacuum tube era, and it is unlikely to have any meaning with today’s technology.

810.71. General. Transmitters must be enclosed in a grounded metal enclosure, and any external controls must have their operating handles connected to an equipment grounding conductor as well, if the controls are accessible to operating personnel, assuming the transmitter is powered from the premises wiring system, or grounded using the 810.21 system if otherwise. The transmitter enclosure doors must have interlocks that will shut down any voltages above 350 between conductors when any access door opens.

ARTICLE 820. COMMUNITY ANTENNA TELEVISION AND RADIO DISTRIBUTION SYSTEMS

820.2. Definitions. A *coaxial cable* is a cylindrical assembly comprising a central signaling conductor surrounded by a dielectric and then set within a metallic tube or shield, and usually covered by an insulating jacket.

Exposed (to Accidental Contact) applies to a CATV cable that is in such a position that it would be likely to become energized in the event that a support or insulation or both failed.

820.3. Other Articles. This section correlates with Art. 770 to bring in the terminology “cable routing assembly” as defined in 770.2, together with its installation rules. It also brings in the rules of 300.22 because due to this [Chap. 8](#) location, only Code rules from [Chaps. 1](#) through [7](#) specifically referenced apply to this work.

820.15. Power Limitations. Coaxial cable on systems within the scope of this article is permitted to provide up to 60 V in the process of providing limited power to some equipment directly associated with the system.

820.21. Access to Electrical Equipment Behind Panels Designed to Allow

Access. It is contrary to the NEC to drape endless quantities of these cables across suspended ceiling panels in a way that limits the intended access to the ceiling cavity above them.

820.24. Mechanical Execution of Work. In addition to the usual neat and workmanlike manner requirement, this section also requires exposed cabling (which includes the area above a suspended ceiling) to be supported to structure such that normal building operations will not damage the cable. In addition, if the wiring is run parallel to framing, it must meet the 32-mm (1¼-in.) spacing requirement from the leading edge of the framing. Finally, the wiring must stay off the tie wires designed to support a suspended ceiling, in accordance with 300.11. Where cable ties and other nonmetallic components are used in 300.22(C) spaces, they must be listed for that environment. An informational note (2) provides a cross-reference to the controlling rule in **NFPA 90A**.

820.25. Abandoned Cables. This has the effect of requiring that any “abandoned” conductors—as defined in 820.2 as not being terminated or identified for future use with a tag—must be removed. It is no longer permissible to leave abandoned CATV cables in place when they are no longer in use, unless they have been “identified” for future use.

820.26. Spread of Fire or Products of Combustion. This is a restatement of 300.21, as applied to this article.

820.44. Overhead (Aerial) Coaxial Cables. Part (A) covers pole and drop work and requires CATV wires to run below power wiring on the same pole if practicable, and never attached to the same cross arm. The climbing space is to be as required in 225.14(D), and there must be a

minimum of 300 mm (12 in.) separation from power wiring at any point in a span, including at their point of attachment at the load end. This reduced spacing only applies if the spacing at the pole meets the required 1 m (40 in.) spacing on the pole.

Part **(B)** covers roof clearances, and the default clearance is 2.5 m (8 ft), with exceptions for auxiliary buildings such as garages, and also for mast applications and steep roof applications that exactly duplicate the comparable exceptions for service drops operating at not over 300 V.

Part **(C)** covers coaxial cables to run up a mast on its outside if it is “intended for the attachment and support of such cables.” This can never include a service mast, for which 230.28 absolutely disallows any connections thereto except the service drop conductors. This prohibition is accurately conveyed in the statement of the rule.

Part **(D)** covers interbuilding runs, and requires secure supports at the points of attachment. The cable must be identified for this purpose, which has been clarified in the equivalent passage in Art. 830 [830.44(F)] as being “suitable for outdoor aerial applications.” The exception following provides for a messenger in the event the span is too much for the CATV on its own.

Part **(E)** covers wiring on the outside of buildings. The CATV cabling must be not less than 100 mm (4 in.) from non-power-limited circuits, or else separated with some fixed nonconductive barrier. In addition, the CATV wiring must be routed to avoid interference with adjacent communications wiring. Finally, cables on buildings must avoid separations of less than 1.8 m (6 ft) from lightning protection system conductors wherever practicable.

820.47. Underground Circuits Entering Buildings. Where in manholes with power circuits, barriers must be arranged to create a separate section for the communications circuits. Direct-buried cables must be separated not less than 300 mm (12 in.) from direct-buried non-power-limited circuits, such as service laterals run as single-conductor Type USE. If the power circuits are in a recognized wiring method, either raceway or recognized cable assembly including multiconductor Type USE or jacketed Type MC listed for direct burial, then the spacing rule does not apply.

820.48. Unlisted Cables and Raceways Entering Buildings. Unlisted outside plant cables may enter a building and move through general-purpose spaces (not risers or plenums) up to 15 m (50 ft) from the point of entrance. This allows a transition length along which a convenient point can be provided for a transition to the listed cables required for most interior work. If such a point is unavailable, the point of entrance can be artificially extended through the use of grounded heavy-wall steel conduit. The last sentence addresses the artificial extension into a building of a point of entrance, much as 230.6 does for service entrance conductors with concrete encasement, etc. For communications circuits, this is done with heavy-wall conduit. This is an important concept, and it holds for all of [Chap. 8](#). See also the next section, which contains the bonding requirement for the conduit.

820.49. Metallic Entrance Conduit Grounding. Heavy-wall metal conduit containing optical fiber entrance cables must be bonded to a grounding electrode as covered in 820.100(B). This, in combination with the point of entrance definition, creates the remote entry point for this work that is parallel to 230.6 for power service work. In fact, it used to be part of the definition, but was separated because definitions cannot contain requirements. Similar sections occur throughout [Chap 8](#).

820.93. Grounding of the Outer Conductive Shield of Coaxial Cables. This rule is split into a termination outside or inside a building, but the action to be taken is the same in either

event: Make a grounding connection as covered in 820.100 as near as practicable to the point of entry. Here again that point of entry can be extended through the use of conduit. Part (C) covers a primary protector, should one be installed (not required as of this Code). If used, it must be listed and applied at the point of entrance. And, per (D), it must not be located in a hazardous (classified) location.

820.100. Cable Bonding and Grounding. Both the protector and any metallic members of a cable sheath must be grounded in accordance with the rules of this section. A new exception effectively correlates this grounding requirement with allowances in 840.101(A). Refer to the discussion at that point. The grounding procedures that follow address coaxial cables that originate off-site and that are subject to lightning exposures. This exception has been extended as of the 2017 **NEC** through the incorporation of a concept taken from **NFPA** 780. Refer to a more detailed discussion in 810.15.

Part (A) requires the grounding conductor to be listed and insulated, made of copper (or other corrosion-resistant material), and stranded or solid. The size must be no smaller than 14 AWG. It must run in as straight a line as practical, and be guarded from physical damage. If run in a metal raceway, both ends must be bonded even though 250.64(E) only imposes that requirement on ferrous raceways. It must be as short as practicable and not over 6 m (20 ft) in one- and two-family dwellings. If the 6-m (20-ft) limitation can't be met, place an additional electrode as covered in 820.100 and then bond this electrode to the power system electrode with a 6 AWG or larger copper wire.

Part (B) covers electrode terminations. If there is an intersystem bonding termination, then the termination is to that point. If the intersystem bonding point is lacking but there is one or more grounding electrodes, the connection must be made to that grounding system through one of the optional methods listed. If the premises served have no intersystem bonding termination and no grounding electrode system, then the bonding connection is to the nearest traditional building electrode (water pipe, building steel, concrete-encased electrode, ground ring), and if all those are missing then to a 1.5-m (5-ft) ground rod, driven into permanently damp soil to the extent practicable, using connections that comply with 250.70.

New language added in the 2014 **NEC** clarifies that steam or hot water piping, or down conductors from air terminals on a lightning protection system, must never be employed for the required bonding and grounding functions. This latter provision correlates with 250.60 for conventional grounding systems. Note, however, that 250.106 does require the lightning protection grounding system terminals to be bonded to the grounding electrode system in the building. And the system set up in this section will either use that system as well or be bonded to it.

Part (D) requires that this electrode, although required to be at least 1.8 m (6 ft) distant from other electrodes, must be bonded to the power system grounding electrode system with a conductor no smaller than 6 AWG copper. The power system bonding requirement is presumably waived at mobile homes for which the connection would be impractical. This is the apparent result of the wording of an exception that, in violation of the Style Manual, is not in the form of a complete sentence and therefore unclear as to effect. Refer to the discussion at 820.106 for more information.

Part (E) correlates with 820.93(C) and opens the door to protective devices that are being developed to shunt excessive shield currents so the shields do not incinerate in response to current imposed by a failure in a power system neutral with the coaxial shield running in parallel and fully accessible through the electrode bonding rules. These devices divert 60 Hz current while blocking

high-frequency current, thereby keeping the principal function of the cable shielding in operation.

820.103. Equipment Grounding. This section specifically recognizes that the coaxial shield is an equipment grounding conductor when connected to the equipment being supplied by it.

820.106. Grounding of Entrance Cables at Mobile Homes. This is very difficult to follow, unless you factor in the wording in the first paragraph of 820.93. Specifically, mobile homes are supposed to have a bonding terminal on their chassis at an accessible location, as required in 550.16(C)(1). They are also supposed to have either service equipment or a feeder disconnect located within 9.0 m (30 ft), per 550.32(A). If they have actual service equipment at that location, or if they have a feeder disconnect with a regrounded neutral at that point, there will be a grounding electrode system connected at that disconnect. In fact, even if the disconnect does not include a regrounded neutral, 250.32(A) still requires a grounding electrode connection at this point. Assuming the communications cable entry comes from this location, a bonding connection between the conductive elements in the communications cable and the grounding system at the disconnect will meet all requirements and no further action needs to be taken at the mobile home. If, and only if, the disconnect is located at an excessive distance or grounded incorrectly does the necessity of creating a local electrode at the mobile home kick in. The philosophical context for this rule is at 800.90(B), second paragraph.

This brings up the separate question of bonding. If the mobile home is permanently connected to a Code-compliant disconnect, then the permanent equipment grounding system connecting the mobile home and the disconnect is sufficient for these purposes. However, if the mobile home is cord-and-plug-connected, removing the plug would disrupt this continuity. In this case there is a conundrum because this wording was brought over from 800.106. Article 800 (telephone) systems have primary protectors that will not exist on these systems. That leaves only one option, a grounding electrode, and therefore, through this back door, a local grounding electrode becomes required in the event of a cord-and-plug connection. The grounding electrode must be connected to the conductive elements of the CATV cable, and also to the mobile home bonding terminal as previously mentioned.

820.110. Raceways and Cable Routing Assemblies for Coaxial Cables. Raceways can be [Chap. 3](#) methods or CATV raceways as covered later. These raceways are very close to ENT in construction and this section even mandates the use of the installation provisions in Art. 362 having to do with bends, supports, joints, and perhaps most intriguingly, 362.56 which invokes the box-at-termination rules in 300.15. On the other hand, conduit fill limitations do not apply. Innerducts are also suitable for routing these cables.

Part (C), new as of the 2014 **NEC**, covers cable routing assemblies. These are usually open on top and serve as continuous support for cables. They are customized by application, as in general-purpose, riser, or plenum, with a comparable substitution hierarchy. The default support intervals are 3 ft for horizontal runs and 4 ft for vertical runs, with an allowance for longer spans if part of the listing, but never over 10 ft.

820.113. Installation of Coaxial Cables. There are some general principles at work that make this less complicated than it appears. The entire two pages of Code text boils down to the following:

1. The hierarchy of cable compositional categories, and by logical extension the hierarchy of compositional categories for the nonmetallic raceways and supporting assemblies that contain those cables, continues without change. Refer to the discussion at 725.135 regarding the

history and applications of these categories, which have not changed since the advent of this work in the 1987 **NEC**. Specifically, there are plenum exposures, which require the most severe testing for both smoke generation and vertical flammability, and result in a “P” suffix on cable assemblies. There are riser exposures that are the next most severely tested, focusing on vertical flammability, and result in a “R” suffix on cable assemblies. Then there are general-purpose applications that receive general fire load testing and result in either a “G” suffix or no suffix. Residential grades (suffix “X”) apply to cables less than 10 mm ($\frac{3}{8}$ in.) in diameter, and for general usage up 3 m (10 ft) in nonconcealed spaces. This is a hierarchy, so general-purpose acceptability includes residential, riser suitability implies general-purpose suitability as well, and the plenum grade can be used in all locations.

2. If a cable is pulled into a **Chap. 3** raceway, its suitability follows that of the enclosing **Chap. 3** raceway, just as surely as the THHN or RHW or XHHW-2 that could otherwise be pulled into the same raceway without a separate evaluation of the fire resistance of its insulation.
3. Fireproof shafts with firestopping at every floor cancel the need for special riser ratings, and one- and two-family dwelling exposures, even vertical ones, do not merit a riser rating either.

820.133. Installation of Communications Wires, Cables, and Equipment. Part (A) sets forth the system separation rules, which are comparable to Art. 725 provisions. Part (A)(1) covers raceways, cable trays, boxes, and cable assemblies, in three headings, the first being uses with “other circuits.” This raises the editorial problem of beginning a discussion of two alternatives with “other,” as in other than what? So, this analysis begins with the last item (b) covering non-power-limited circuits. The rule is no common locations allowed, but there are two exceptions. The first recognizes a permanent barrier or listed divider. The second exception allows a common enclosure where the power-limited and non-power-limited wiring must terminate on the same equipment, as in the case of some powered equipment with a coaxial cable interface. In this case the solution is to restrain the wiring with duct, tie-downs, or other methods such that a 6-mm ($\frac{1}{4}$ -in.) air separation is maintained between systems. Note that this provision is for dead-end wiring only, not daisy chains (“solely for power supply to” does not mean to connect and then to feed another piece of equipment).

What remains therefore, in (a), is that which is therefore “other.” And this would cover the use of coaxial cables with other power-limited circuits in raceways and enclosures. The context for these rules is that communications circuits have a voltage exposure that is comparable to power-limited fire alarm or Class 3 signaling circuits. Therefore, the following systems can share an enclosure with communications cables: (1) Class 2 and Class 3 cabling—Art. 725 (or in Art. 645); (2) Power-limited fire alarm wiring—Art. 760; (3) Optical fiber cabling both conductive and nonconductive—Art. 770; (4) communications systems—Art. 800; and (5) Low-power network-powered broadband communications—Art. 830.

Part (A)(2) requires a 50-mm (2-in.) separation from open power wiring and other open, non-power-limited circuit conductors. Two exceptions apply, the first where a raceway on either system provides separation, or where the non-power-limited wiring uses **Chap. 3** cabled wiring methods. The second applies where fixed barriers such as porcelain tubes or flexible tubing are installed.

Note that even though this rule does not expressly cover the topic, Type NMS cable relies on this concept, and UL has listed this sort of hybrid cable for many years, as expressly covered in 334.116(C). Such cable assemblies do not depend on conductor insulation alone to establish the required system separation, squarely in accordance with the spirit of these rules; however, the literal text of this wording is in direct conflict with the **Chap. 3** permission.

Part (B) covers conductor support and states that cables must not be tie-wrapped to or otherwise supported by electrical raceways, as also disallowed in 300.11(B). However, there is an exception for coaxial cables to run up a mast on its outside if it is “intended for the attachment and support of such cables.” This can never include a service mast, for which 230.28 absolutely disallows any connections thereto except the service drop conductors. The correct statement of this rule is found at 820.44(C).

820.154. Applications of Listed CATV Cables. The installation requirements for these cables now reside at 820.113, and the applications have been converted to a full-page table that summarizes the results. The cable substitution hierarchy table and its associated figure remain here.

820.179. Coaxial Cables. This section includes general rating provisions that apply to all iterations of this cabling. The voltage rating must not be marked on the cable, unless required by other listings. The concern is the likelihood unqualified persons may interpret such a marking as indicative as suitable for power applications. This wiring must be suitable for 60°C or higher, and if higher than that default value, the temperature rating must be marked accordingly. The listing requirements for these cables follow:

Part (A) covers Types CATVP for plenum cavity applications.

Part (B) covers Type CATVR for riser applications.

Part (C) covers Type CATV for general-purpose applications.

Part (D) covers Type CATVX for limited use in residential applications.

820.180. Grounding Devices. Equipment employed to bond metallic components of cable assemblies covered in Art. 800 to grounding and bonding conductors must be listed, or be part of a larger component that is listed.

ARTICLE 830. NETWORK-POWERED BROADBAND COMMUNICATIONS SYSTEMS

830.1. Scope. These systems are being designed and implemented to provide a combination of voice, audio, video, data, and interactive services. Powering, grounding, bonding, and electrical protection issues for these new systems had not been adequately addressed in the **NEC** articles that heretofore covered communications systems. As explained in the informational note, the systems typically involve a cable that supplies some power from the network as well as signal to a network interface unit, which converts the broadband signal to their components, such as voice, data, and video. The second informational note calls attention to the exclusions in 90.2(B)(4) that apply to some facilities of communications utilities.

830.2. Definitions

Exposed to Accidental Contact with Electrical Light or Power Conductors. This is a similar definition to that in Art. 800, but there are differences. The defined term is much more specific than the general term “Exposed” in Art. 830, and the possibility of contact could occur through a failure of a support or of insulation; Art. 830 requires both elements to fail.

Fault Protection Device. This is an electronic device intended for personnel protection. It is used with low power network-powered broadband communications circuits, and in the event of a

fault such as a cable short or open condition, it limits the current and/or voltage and provides acceptable protection from shock.

Network Interface Unit (NIU). This is the device that breaks the broadband signal into its component parts, such as voice, data, and video. It also isolates the network power from the premises signal circuits. It may, but does not necessarily, contain primary and secondary protectors. See [Fig. 830-1](#) for application.

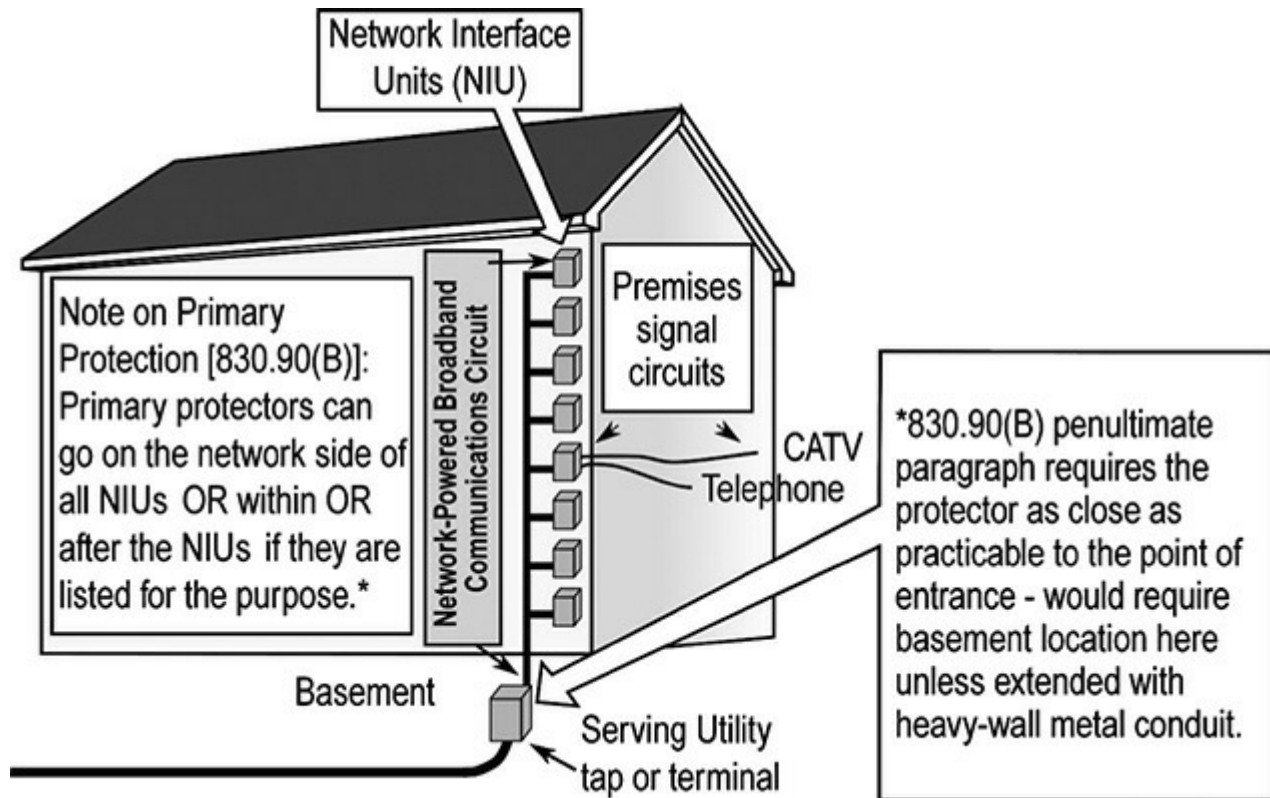

Fig. 830-1. Network Interface Units are where the component signals are separated. (Sec. 830.2.)

Network-Powered Broadband Communications Circuit. The circuit extending from the communications utility's serving terminal or tap up to and including the NIU. A power system analogy might be a service drop or lateral, plus the associated service entrance conductors and ending at the service disconnect. There are important differences, however, in terms of how far and under what conditions the respective circuits can enter a building, based on the relative degree of risk posed by the different systems. A note describes how a typical single-family circuit would fit into the requirements.

Point of Entrance is the point within a building at which cable emerges from an external wall, or a floor slab, or from RMC or IMC. In such cases the use of heavy-wall steel conduit artificially extends the point of entrance into a building, doing for this wiring what 230.6 does for service entrance conductors. This is an important concept, and it holds for all of [Chap. 8](#). See also Sec. 830.49, which now contains the bonding requirement for the conduit.

830.3. Other Articles. This section covers the application of other articles, and incorporates a generic hazardous (classified) location reference, Sec. 300.22, and specific references to other material as appropriate for specific circuits derived from the NIU. The two items in [Chap. 8](#) include Art. 800 for communications, and Art. 820 for CATV and for radio distributions, unless protection has been arranged in accordance with Sec. 830.90(B)(3) in the output side of the NIU. Three items

apply in [Chap. 7](#), including Art. 770 for optical fiber cables, Art. 760 for power-limited fire alarm circuits, and Art. 725 for Class 2 and Class 3 signaling circuits. The requirements to properly apply listing requirements [110.3(B)] and to protect against cable damage (300.4) are included as well.

830.15. Power Limitations. This sets the allowable power limitations for low and medium power circuits. Both systems share a 100 VA maximum power rating, but the medium power source can be up to 150 V, as opposed to the 100 V limitation on the low power source. In addition to the table, a dc source as high as 200 V is permitted within the medium power classification, provided its maximum current to ground is 10 mA.

The table limitations for this circuit are identical to those for a Class 3 “Not Inherently Limited” circuit except there isn’t any maximum current nameplate rating specified for the power source, due to the potential drop that normally occurs along a service transmission line. To accommodate this variation in potential, the Network Interface Units (NIUs), amplifiers, and other utility equipment are designed to operate over a wide range of supply voltages. The supply current to the equipment varies inversely as the voltage.

For example, an NIU connected at a point on the transmission line where the potential is 50 V would require twice the current of an NIU connected at a point where the potential is 100 V, but the input volt ampere rating of both would be the same and is not to exceed 100 VA. In addition to the 100 VA rating, the required $100 \div V$ overcurrent protection (or equivalent) limits the current to $100 \div V$.

The low power source is figured as the likely source for a single-family dwelling, perhaps for an existing CATV subscriber, and the medium power source for similar occupancies with greater functionality or for multiple NIUs or for greater distances from the transmission lines. As proposed, there was originally a high power source option with a 150-V limit (same as medium power) but a 2250-VA power limit. High power cable is a coaxial construction with a grounded shield and 600-V insulation on the center conductor, which provide a high level of mechanical protection and electrical isolation of the center conductor. During the comment period there were serious technical issues raised regarding some of the details and the panel elected to proceed with the new article (1999 NEC) but only after stripping out the high power provisions.

830.21. Access to Electrical Equipment Behind Panels Designed to Allow

Access. It is contrary to the NEC to drape endless quantities of these cables across suspended ceiling panels in a way that limits the intended access to the ceiling cavity above them.

830.24. Mechanical Execution of Work. In addition to the usual neat and workmanlike manner requirement, this section also requires exposed cabling (which includes the area above a suspended ceiling) to be supported to structure such that normal building operations will not damage the cable. In addition, if the wiring is run parallel to framing, it must meet the 32-mm (1¼-in.) spacing requirement from the leading edge of the framing. Finally, the wiring must stay off the tie wires designed to support a suspended ceiling, in accordance with 300.11. Where cable ties and other nonmetallic components are used in 300.22(C) spaces, they must be listed for that environment. An informational note (2) provides a cross-reference to the controlling rule in NFPA 90A.

830.25. Abandoned Cables. This has the effect of requiring that any “abandoned” conductors—as defined in 830.2 as not being terminated or identified for future use with a tag—must be removed. It is no longer permissible to leave abandoned network-powered broadband communications cables in place when they are no longer in use, unless they have been “identified” for

future use.

830.26. Spread of Fire or Products of Combustion. This is a restatement of 300.21, as applied to this article.

830.40. Entrance Cables. Both the equipment and the cables used on these systems need to be listed for the purpose, although there is the usual cable substitution table (Table 830.154) that allows a better cable to substitute for a lesser one. The first exception, however, grandfathers all CATV system coaxial cables installed per Art. 820 before Jan. 1, 2000, for low power usage.

Although the subsections following essentially cover the usual four-tier hierarchy for this type of cabling (-P, -R, - , -X), there are some interesting gaps. There isn't a BMP cable, for example, so medium-power cabling installed in plenum cavities would go back to Sec. 300-22(c) wiring methods. In addition, there isn't a BLR cable, so running low power systems in a riser would require the better grade BMR cable normally identified with medium power applications.

830.44. Overhead (Aerial) Cables. Part (A) covers running cable on and from poles and the wording follows 820.44(A). Where practicable, these cables should run below any non-power-limited circuits, and they are forbidden to run on a common crossarm.

Part (B) rule and its exception correspond to 820.44(B).

Part (C) provides a set of grade clearances based on NESC dimensions. Neither Art. 800 nor Art. 820 have any required clearances from grade. They run somewhat lower than similar dimensions in 225.18, which is appropriate because they are supposed to run below power conductors where practicable.

Part (D) points to Table 680.9(A) for its pool clearances.

Part (E) covers the final span requirement, which came directly from the 1996 version of 230.9. It needs to be correlated with important changes to that section subsequently that added what is now 230.9(B).

Part (F) covers runs between buildings; the wording comes partially from 820.44(D).

Part (G) covers cabling routed on buildings. The first three paragraphs come directly from 820.44(E), and the fourth paragraph was added. It requires protecting network-powered broadband communications cables from damage, to a height of 8 ft from grade, as shown in [Fig. 830-2](#). The exception (another incomplete sentence) recognizes that the use of a listed fault protection device to the circuit provides an acceptable level of protection from electric shock. With this level of protection on a low power network-powered broadband communications circuit, the mechanical protection requirements can be relaxed without sacrificing safety.

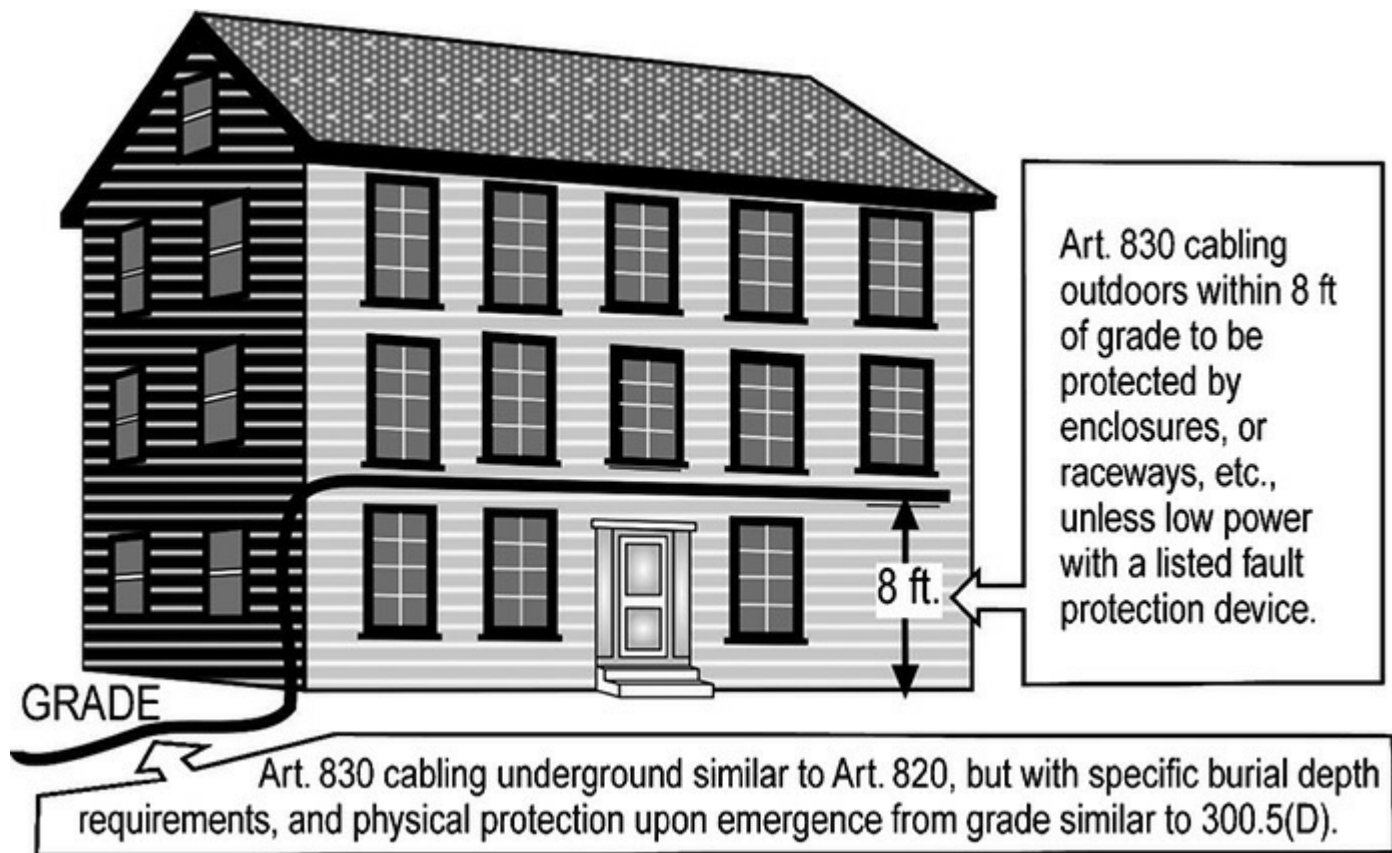

Fig. 830-2. Higher power levels lead to enhanced protection rules [Sec. 830.44(I)(4); 830.47].

830.47. Underground Network-Powered Broadband Communications Cables Entering Buildings.

Due to somewhat greater power levels on these systems, this section includes an additional set of requirements based on the 1996 **NEC** version (uncorrelated with 1999 and subsequent changes) of 300.5 for physical protection of underground power circuits, including a requirement to protect direct-buried cables that make a transition to above grade by using raceway or equal to the point of entrance (or at least to a height of 8 ft).

The section comes with a burial depth table similar to Table 300.5 but greatly simplified and with many burial depths reduced. There is an exception here, like the one in 830.44(G)(4), that waives the mechanical protection requirements if there is a fault protection device on a low-power circuit. The last subsection, part **(D)**, picks up what is now the second sentence of 680.11 for underground clearances to swimming pools. Because the rule points to the entire section in Art. 680, the entire rule in 680.11 applies, including the 2008 modification requiring the raceway system to be complete and not just a sleeve.

830.49. Metallic Entrance Conduit Grounding. Heavy-wall metal conduit containing optical fiber entrance cables must be bonded to a grounding electrode as covered in 820.100(B). This, in combination with the point of entrance definition, creates the remote entry point for this work that is parallel to 230.6 for power service work. In fact, it used to be part of the definition, but was separated because definitions cannot contain requirements. Similar sections occur throughout [Chap. 8](#).

830.90. Primary Electrical Protection. Part **(A)** includes the requirements for installing primary protectors for broadband circuits run as unprotected aerial circuits. This is a simplified version of 800.90(A), although without the requirement for protection at each end of an interbuilding circuit with a lightning exposure. This presumably reflects an expectation that these circuits principally involve utility-to-customer connections under the control of utilities, given the “network

powered” nature of these systems, and not premises-wired PBX equivalents. However, the section does go on to capture both informational notes (unenforceable, of course) from 800.90(A), the second of which is appropriately modified by deleting the provision covering the likelihood of interbuilding exposures.

Part (B) is based on 800.90(B). The text has been revised to reflect the presence of the NIU and the options for providing primary protection, on the network side of the NIU, incorporated within the NIU, or on the derived circuits (output side of the NIU). The options help to resolve technical problems, such as signal attenuation by a protector placed on the network-side broadband cable, while providing identical electrical protection and safety. Mobile homes are protected just as they are in Sec. 800.90(B).

Part (C) works within the context of hazardous (classified) locations and limits the placement of either a primary protector or other equipment serving that function, in the same way as 800.90(C).

830.93. Grounding or Interruption of Metallic Members of Network-Powered Broadband Communications Cables. This is based on 820.93. The text has been revised to accommodate additional metallic cable members “not used for communications or powering.” These members must be either grounded or interrupted by an insulating joint or equivalent device. A coaxial cable shield is part of the signal path and cannot be interrupted. Therefore, the rule requires grounding for coaxial cable shields, and permits all other noncommunications or nonpower conductors to be either grounded or interrupted. This approach is also applied in 800.93. A paragraph addresses mobile homes to clarify the treatment of metallic members in those locations.

830.100. Cable, Network Interface Unit, and Primary Protector Bonding and Grounding. These grounding rules were directly modeled on the equivalent language in what is now Sec. 800.100 and Sec. 800.106.

The only difference is that instead of just referring to primary protectors, the text also refers to NIUs with protectors and NIUs with metallic enclosures as requiring grounding according to the rules in this part. In addition, 830.100(A)(3), in addition to setting 14 AWG as the minimum size (also true in Art. 800), additionally requires that the size be such that its current-carrying capacity be approximately equal to that of the grounded metallic member(s) and protected conductor(s) of the cable, but it need not be larger than 6 AWG. Correlating language now applies in both Art. 800 and Art. 820.

830.106. Grounding and Bonding at Mobile Homes. This is very difficult to follow, unless you factor in the wording in the second paragraph of 830.93. Specifically, mobile homes are supposed to have a bonding terminal on their chassis at an accessible location, as required in 550.16(C)(1). They are also supposed to have either service equipment or a feeder disconnect located within 9.0 m (30 ft), per 550.32(A). If they have actual service equipment at that location, or if they have a feeder disconnect with a regrounded neutral at that point, there will be a grounding electrode system connected at that disconnect. In fact, even if the disconnect does not include a regrounded neutral, 250.32(A) still requires a grounding electrode connection at this point. Assuming the network-powered broadband communications cable entry comes from this location, a bonding connection between the conductive elements in the cable and the grounding system at the disconnect will meet all requirements and no further action needs to be taken at the mobile home. If, and only if, the disconnect is located at an excessive distance or grounded incorrectly does the necessity of creating a local electrode at the mobile home kick in. The context for this rule is at 830.90(B), second

full paragraph just above (C).

This brings up the separate question of bonding. If the mobile home is permanently connected to a Code-compliant disconnect, then the permanent equipment grounding system connecting the mobile home and the disconnect is sufficient for these purposes. However, if the mobile home is cord-and-plug-connected, removing the plug would disrupt this continuity. In this case there is a conundrum because this wording was brought over from 820.106. Article 800 (telephone) systems have primary protectors that will not exist on these systems. That leaves only one option, a grounding electrode, and therefore, through this back door, a local grounding electrode becomes required in the event of a cord-and-plug connection. The grounding electrode must be connected to the conductive elements of the network-powered broadband communications cable, and also to the mobile home bonding terminal as previously mentioned.

830.110. Raceways and Cable Routing Assemblies for Network-Powered

Broadband Communications Cables. Low-power network-powered broadband communications cables can run in [Chap. 3](#) raceways installed in accordance with the applicable article, but fill restrictions will not apply. Medium-power network-powered broadband cables in a raceway must use a [Chap. 3](#) type, installed according to its requirements in [Chap. 3](#), and conduit fill limitations will apply to these cables.

Part (C), new as of the 2014 **NEC**, covers cable routing assemblies. These are usually open on top and serve as continuous support for cables. They are customized by application, as in general-purpose, riser, or plenum, with a comparable substitution hierarchy. The default support intervals are 3 ft for horizontal runs and 4 ft for vertical runs, with an allowance for longer spans if part of the listing, but never over 10 ft.

830.113. Installation of Network-Powered Broadband Communications

Cables. There are some general principles at work that make this less complicated than it appears. The entire two pages of Code text boils down to the following:

1. The hierarchy of cable compositional categories, and by logical extension the hierarchy of compositional categories for the nonmetallic raceways and supporting assemblies that contain those cables, continues without change. Refer to the discussion at 725.135 regarding the history and applications of these categories, which have not changed since the advent of this work in the 1987 **NEC**. Specifically, there are plenum exposures, which require the most severe testing for both smoke generation and vertical flammability, and result in a “P” suffix on cable assemblies. There are riser exposures that are the next most severely tested, focusing on vertical flammability, and result in an “R” suffix on cable assemblies. Then there are general-purpose applications that receive general fire load testing and result in no suffix. Residential grades (suffix “X”) apply to cables less than 10 mm ($\frac{3}{8}$ in.) in diameter. This is a hierarchy, so general-purpose acceptability includes residential, riser suitability implies general-purpose suitability as well, and the plenum grade can be used in all locations. These cables also come in an underground configuration, with a “U” suffix.
2. If a cable is pulled into a [Chap. 3](#) raceway, its suitability follows that of the enclosing [Chap. 3](#) raceway, just as surely as the THHN or RHW or XHHW-2 that could otherwise be pulled into the same raceway without a separate evaluation of the fire resistance of its insulation.
3. Fireproof shafts with firestopping at every floor cancel the need for special riser ratings, and one- and two-family dwelling exposures, even vertical ones, do not merit a riser rating either.

830.133. Installation of Network-Powered Broadband Communications Cables and Equipment. Part (A)(1) includes the rules regarding separation of broadband cables from other wiring, as illustrated in Fig. 830-3.

Fig. 830-3. System separation rules are always important. [Sec. 830.133(A)(1).]

Low power network-powered broadband communications circuits are essentially Class 3 circuits. Medium-power network-powered broadband communications circuits are not Class 3 circuits (similar in some ways but not the same; Class 3 status was denied), but they do have a 600-V jacket. With those principles in mind, the following separation rules make sense:

First, low and medium power cables (not circuit wires) are permitted in the same raceway.

Second, low power cables are permitted in raceways with power-limited fire alarm, CATV, Class 2 and 3, Art. 800 communications, and both conductive and nonconductive optical fiber.

Third, [this paragraph combines (c) and (d) of Code text] medium power circuits cannot be installed in a common raceway or enclosure with any of those same systems, with the only exception being nonconductive optical fiber.

Fourth, both low power and medium power broadband circuits have to be divorced from non-power-limited wiring entirely, but with the customary exceptions for barriered separations and for entry into an enclosure housing equipment connected to both systems, with a maintained 6-mm ($\frac{1}{4}$ -in.) air separation.

Part (A)(2) on system separation for other applications follows the same rules as for similar CATV applications in 820.133(A)(2), with a normal 2-in. separation and allowances for routing the other circuits in independent Chap. 3 wiring methods or raceways, or for the use of raceways or for porcelain or flexible tubing in addition to the insulation on the broadband cabling.

Part (B) is the wording to keep broadband conductors off interior raceways. This wording is based on similar wording used in 820.133(B).

830.154. Applications of Network-Powered Broadband Communications System Cables. The installation requirements for these cables now reside at 820.113, and the applications have been converted to a full-page table that summarizes the results. The cable substitution hierarchy table remains here.

830.160. Bends. This section, a first in the communications articles, requires that any bends in the cable be made so as not to damage it. This is in Part V, so it only applies indoors.

830.179. Network-Powered Broadband Communications Equipment and Cables. Cables outside and entering buildings must be listed accordingly. Low power circuits get the usual permitted substitutions (see Fig. 830-4) plus the grandfathering in 830.179 Exception No. 1.

	Medium Power	Low Power
Plenum Cavities	NONE-use 300.22(C) wiring methods	BLP
Riser	BMR	BLR
General purpose	BM	BL
Dwelling Unit	NONE-use BM	BLX
Outdoor underground	BMU	BLU

Note: 830.179 Exception No. 1 grandfathers all Art. 820 cabling installed prior to 1/1/2000 per Art. 820 for low-power uses.

Fig. 830-4. Cable substitutions are incomplete for the medium power level. (Sec. 830.179.)

There are just two listing sequences in this section, and they leave gaps on the medium power side. The medium power varieties include BMR for risers, BM for general-purpose applications and BMU for underground use, leaving the limited residential use and the plenum cavity use without a cable type. On the other hand, the low-power list is fully populated, from the plenum cavity BLP, to the

riser BLR, to general-purpose BL, to residential limited application BLX, and the underground BLU.

830.180. Grounding Devices. Equipment employed to bond metallic components of cable assemblies covered in Art. 800 to grounding and bonding conductors must be listed, or be part of a larger component that is listed.

ARTICLE 840. PREMISES-POWERED BROADBAND COMMUNICATIONS SYSTEMS

840.1. Scope. As explained in an informational note that follows, these systems extend from an unpowered optical fiber cable, either conductive or nonconductive, that carries a broadband signal through to an optical network terminal that has a battery backup and is powered from the premises wiring system. The network terminal divides the incoming signal into conventional telephone, high-speed internet, video, and interactive services.

840.2. Definitions. In addition to other applicable definitions from Arts. 100, 770, 800, and 820, there are three definitions unique to Art. 840:

Network Terminal is a device that converts network-provided signals (optical, electrical, or wireless) into component communications elements, and is considered a network device on the premises that is connected to a communications service provider and is powered at the premises.

Premises Communications Circuit is a circuit that extends communication functions from the network terminal to premises communications equipment such as telephones, facsimile machines, and answering machines, and also extends outside wiring if present, as for burglar and fire alarm systems.

Premises Community Antenna Television (CATV) Circuit is the circuit that extends CATV signals for audio, video, data, and interactive systems to on-premises equipment and appliances as necessary.

840.3. Other Articles. Part (E) incorporates Arts. 725, 760, 770, 800, and 820 as they would be expected to apply to premises wiring supplied from an Art. 840 system. Part (F) brings in other [Chap. 8](#) articles, and part (G) requires reclassification of limited power conductors running with communication wires as such.

840.44. Overhead Optical Fiber Cables. This section is identical to 800.44; refer to the coverage in this book for those applications. Note that, for some reason, this section applies to aerial conductive optical cables, but is silent regarding nonconductive cables, although its provisions, such as climbing space, would seemingly apply generally. The likely explanation is that a metallic strength member is considered essential to any optical fiber cable run overhead. The next two sections (840.45 and 840.46) bring in by reference the appropriate requirements for other cables run overhead.

840.47. Underground Optical Fiber Cables Entering Buildings. Part (A) requires a barrier between the conductive versions of these cables and non-power-limited wiring in manholes, handholes, and raceways. Part (B) covers direct burial applications. Conductive cable styles require a 300 mm (12 in.) separation from non-power-limited wiring unless that wiring is in a raceway or is cabled with a metallic armor. No separation is required from Type UF cable, or Type USE cables provided they are not part of service wiring. Part (C) requires underground entrances to have at least 150 mm (6 in.) of cover. Parts (B) and (C) bring in by reference the appropriate requirements for communications and coaxial cables run underground, including completing the process of establishing

a remote entry point for a cable entrance, comparable to what 230.6 accomplishes for service entrance work.

840.48. Unlisted Wires and Cables Entering Buildings. This section incorporates the appropriate requirements for communications, coaxial, and optical fiber cables entering buildings.

840.49. Metallic Entrance Conduit Grounding. By the cross references made, the customary bonding requirements are applied.

840.90. Protective Devices. This incorporates the panoply of protective devices for communications circuits generally into this article.

840.93. Grounding or Interruption. This section simply incorporates the requirements of 770.93, 800.93, and 820.93 as they would apply to the cable at hand.

840.101. Premises Circuits Not Leaving the Building. These provisions apply where the supply optical cable is nonconductive or conductive and the conductive member has been interrupted by an insulating joint or equivalent, and where all building circuits that are supplied by the network terminal do not leave the building. Part (A) covers within-building runs of CATV cable (Art. 820), and its shield must be grounded using one of the procedures covered in 820.100 (or 820.106 for mobile homes), or a “fixed” connection to an equipment grounding conductor covered in 250.118 (apparently, any EGC that is convenient), or a grounding terminal on the network terminal, provided the network terminal is itself grounded using an 820.100 (or 820.106 for a mobile home) method. If this is done, the network terminal grounding connection must be made to an equipment grounding conductor (here again, apparently, any EGC that is convenient), using a “listed grounding device” that maintains continuity even if the network terminal is unplugged. Communications (Art. 800) circuits need not be grounded, and the network terminal need not be grounded unless otherwise required by its listing. Assuming the coaxial cable in use has its shield grounded in a manner that does not depend on the network terminal, a cord-and-plug connection is permitted for the network.

840.106. Grounding and Bonding at Mobile Homes. This section shares the problem in 770.106 regarding requirements for mobile homes with supply connections that do comply with current **NEC** provisions. The cross-references to 800.106(A)(1), 820.106(A)(1), 800.106(A)(2), and 820.106(A)(2) share this problem as well. Refer to the discussion at 770.106 and 800.106 for more information.

840.113. Installation on the Customer Premises Side of the Network

Terminal. The usual installation procedures in 800.113 and 800.133, and 820.113 and 820.133 for premises communications wiring and premises CATV wiring, respectively, apply.

840.160. Powering Circuits. Communications cables are authorized to provide up to 60 watts of power for powering communications equipment. In the event that a higher power capability is entertained, the limits designed in 725.144 for power over Ethernet are permitted to be used.

840.179. Equipment and Cables. The network terminal must be listed for applications covered by this article. The associated cables must be listed in accordance with 770.179, 800.179, and 820.170 as applicable.

840.180. Grounding Devices. Equipment employed to bond metallic components of cable assemblies covered in Art. 800 to grounding and bonding conductors must be listed, or be part of a larger component that is listed.

Chapter Nine

TABLES

The basic requirements governing the maximum permitted fill for raceways and tubing recognized by the **NEC** are covered in Table 1 of [Chap. 9](#). That table shows 53 percent as the maximum cross-sectional area of a raceway or tube that may be occupied by a conductor, where a single conductor is run within a raceway or tube. Where there are two conductors within the raceway or tube, then the maximum permitted *fill*—the area occupied by the conductors—is reduced to no more than 31 percent of the raceway or tube’s cross-sectional area, which is shown in the applicable part of Table 4. And the most commonly encountered installation—three or more conductors in the raceway or tube—permits a maximum fill of no more than 40 percent of the cross-sectional area of the conduit.

Table 1 does not apply where conduit sleeves are used to protect various types of cables from physical damage. As indicated in Note 2, it applies only to “complete systems.” And Note 1 directs the reader to the new Annex C for conduit fill where all conductors are the same size and insulation type.

While Note 3 mentions bare (as well as insulated) equipment grounding or bonding conductors, Note 8 to Code Table 1 applies to all forms of *bare* conductors (equipment grounding conductors and neutral or grounded conductors). Where any bare conductors are used in conduit or tubing, the dimensions given in Table 8 may be used. Because *all* wires utilize space in raceways, they must be counted in calculating raceway sizes whether the conductors are insulated or bare.

In regard to Note 5, there are conductors (particularly high-voltage types) that do not have dimensions listed in [Chap. 9](#), and this note also applies to optical fiber cables. Conduit sizes for such conductors may be determined by computing the cross-sectional area of each conductor as follows:

$$D^2 \times 0.7854 = \text{cross-sectional area}$$

where D = outside diameter of conductor, including insulation. Then the proper conduit size can be determined by applying Tables 1 and 4 for the appropriate number of conductors.

example: Three single-conductor, 5-kV cables are to be installed in conduit. The outside diameter D of each conductor is 0.750 in. Then $0.750^2 \times 0.7854 \times 3 = 1.3253 \text{ in}^2$. From Tables 1 and 4 (40 percent fill) a metric designator 53 (trade size 2) rigid metal conduit would be permitted. Code Tables in Annex C are based on Table 1 allowable percentage fills, and have been provided for the sake of convenience. Although revisions have been made to eliminate conflict, in any calculation, Table 1 is the table to be used where any conflict may occur.

Table 1 is also used for computing conduit sizes where various sizes of conductors or conductor types are to be used in the same conduit. It is also used, and has been retitled accordingly, to calculate allowable fill where cable assemblies are drawn into raceway systems that are complete. To this end, Note 9 now expressly includes optical fiber cables as a potential application.

An example of Note 7 would be to determine how many 14 AWG Type TW conductors would be permitted in a ½-in. rigid metal conduit. For three or more such conductors, Table 1 permits a 40 percent fill. From Table 4, 40 percent of the internal cross-sectional area of a ½-in. rigid metal conduit is 0.125 sq in. From Table 5, the cross-sectional area of a 14 AWG Type TW conductor is 0.0139 sq in. Thus, $0.125/0.0139 = 8.9$, or 9 such conductors would be permitted in a ½-in. conduit. Where the decimal is less than 0.8 (such as 0.7), the decimal would be dropped and the whole number would be the maximum number of equally sized conductors permitted; for example, 8.7 would be 8 conductors (see Note 7). This same procedure can apply to a single conductor evaluated for a raceway fill calculation.

The following is an example for computing a conduit size for various conductor sizes:

Number	Wire Size and Type	Table 5 Cross-sectional Area (ea.) (in ²)	Subtotal Cross-sectional Area (in ²)
3	10 AWG TW	0.0243	0.0729
3	12 AWG TW	0.0181	0.0543
3	6 AWG TW	0.0726	0.2178
Total cross-sectional area			0.345

Table 1 permits a 40 percent fill for three or more conductors. Following the 40 percent column in Table 4, 1-in. rigid metal conduit would be required for these nine conductors, which have a combined cross-sectional area of 0.345 sq in.

Table 5A gives the maximum number of compact conductors permitted in trade sizes of conduit or tubing. Conductors with “compact-strand” construction have the cross-section areas of their strands shaped as trapezoids to provide tight “nesting” of the strands when they are twisted together. Such construction eliminates the air voids that occur when individual strands of circular cross section are twisted together and results in a smaller overall diameter of the total bundle of strands. Thus, a 600-kcmil compact-strand assembly has an overall cross-sectional area of a conventional 500 kcmil with circular strands.

Note 6 of Table 1 in Chap. 9 recognizes the fact that compact-strand conductors have increased conduit fill because of their overall smaller area. Compact-strand conductors are covered by Table 5A in Chap. 9 of the NEC.

Note 9, intended to address fill issues of multiconductor cables, added a new sentence in the 2017 NEC, as follows:

“Assemblies of single insulated conductors without an overall covering shall not be considered a cable when determining conduit or tubing fill area. The conduit or tubing fill for the assemblies shall be calculated based upon the individual conductors.” This revision clarifies that assembled conductors should not be considered to be a cable, but instead treated as individual conductors for wire fill calculation.

The new sentence in the NEC completely invalidates the assertion regarding raceway fill in the advertisement. The correct fill limit is (and was) the customary 40 percent. Figure 9-1 shows the incorrect advertising assertion.

Fig. 9-1. This photo combination showed up as an advertisement from several leading trade publications. It included the following announcement: “Pulls Like a Single Cable—With 53 percent conduit fill (per **NEC Chap. 9**).”

Note 10, new in the 2014 **NEC**, clarifies a frequent topic of interest, namely, are the wire dimensions in Table 5 for the smaller sizes based on stranded wire or solid wire? It turns out that they are worst-case sizes based on stranded configurations. In coordination with the insertion of the words “actual dimensions or” into Note 6, it is now clear that if solid data from the manufacturer are available relative to the actual wiring being installed, that data can be used.

As indicated in the previous example, **Table 4** in **Chap. 9** provides a variety of dimensional data for the various Code-recognized raceways and tubing. As of the 2014 **NEC**, this table is now arranged with the 40 percent fill column closest to the raceway size, significantly improving user-friendliness. It correlates the metric dimensions (millimeters) with imperial system units (inches) and gives specific values for various fills. These values represent the maximum useable area for the percent fill indicated at the top of the table. The total cross-sectional area of the contained conductors or fixture wires must not exceed the value indicated for the percent fill permitted by Table 1, **Chap. 9**.

Table 5 in **Chap. 9** provides dimensional data—diameter and cross-sectional area—for all Code-recognized conductor and fixture wire sizes and insulation types. Simply locate the size and insulation type of the conductors in question and use the value shown for the specific conductor size and insulation type to determine the total cross-sectional area of the conductors. And this table has been rearranged for user-friendliness as well, with the cross-sectional area columns closest to the wire size columns. Then, Table 4 can be used to determine the minimum permitted size of raceway or tubing that is needed to satisfy the Code-prescribed fill limitations given in Table 1 and its accompanying notes.

Table 2 contains the Code-prescribed minimum bending radii for all conduits and tubings recognized in **Chap. 3** of this Code. These data, which were located in 344.24 of the 2002 **NEC**, indicate the minimum radius permitted, as measured to the centerline of the raceway. Notice that the one-shot and full shoe benders are permitted to provide a smaller radius than “other bends” typically made with a hickey in the smaller sizes.

Table 9, which is not directly referred to in any **NEC** location and therefore has no mandatory application, is nevertheless an invaluable reference source for determining accurate voltage drop on ac circuits. It was compiled for the 1987 **NEC** using Neher-McGrath calculations, as also underlie

the Annex B tables and the 310.15(C) formula. The effective impedances that read directly out of the table use an 85 percent power factor, which is very good for most industrial work, particularly where conductors are loaded near 75°C, which is the usual upper limit for terminations. For conductors operating at room temperature, frequently more realistic, the numbers need to be adjusted. The example and analysis that follows is complicated because it does not use standard values. If you carefully digest this analysis, you should always be able to work any calculations that come your way, especially those that allow for direct applications of the table under simpler conditions.

For this example, suppose a 480V 3-phase feeder comprised of a double run of 250 kcmil copper in steel raceway to a motor control center is loaded to 370 A, and the wires are operating at 25°C. If the motors are lightly loaded such that a 75 percent power factor is measured, determine the voltage drop for a 200 ft (60 m) run. Note that the impedance for the double run is the same as that for a single run with the total current halved, so this analysis can proceed on the basis of 185 A flowing over a set of 250 kcmil conductors.

To adjust the resistance values in Table 9, use the footnote to Table 8. In this example, to reflect the 50°C lower operating temperature the formula works like this:

$$R_2 = 0.054[1 + 0.00323(25 - 75)] = 0.054(0.8385) = 0.045 \text{ ohms/kFT}$$

The next step is to read out the reactance, which is 0.052 ohms/kFT. The power factor angle of the circuit must be determined next. To do this, take the power factor as a decimal (0.75) into a table of cosines, or use a scientific calculator (including the ones built into most computer operating systems; just enter the decimal, set the “INV” check box, and click on the cosine button) to get this angle, which is about 41.4 degrees. This is also the arccosine of the power factor. Now use the formula at the bottom of Note 2 to determine the effective impedance for the circuit in ohms/kFT to neutral under the revised conditions (Z_c), as follows:

$$Z_c = (R \times 0.75) + [X_L \times \sin(41.4^\circ)] = 0.054 \times 0.75 + 0.052 \times 0.66 = 0.068$$

Using Ohm’s Law ($E = IZ$), find the line-to neutral voltage drop under the specified loading:

$$E_D = 185 \text{ A} \times 0.068 = 12.6 \text{ volts/kFT} = 0.0126 \text{ volts/FT}$$

Because the circuit is 200 ft long, the drop (to neutral) is $200 \text{ FT} \times 0.0126 \text{ volts/FT} = 2.5 \text{ V}$. The final step is to convert the line-to-neutral drop to more useful line-to-line values in a 3-phase circuit. To do this, simply apply the usual $\div 3$ multiplier:

$$E_{D \text{ (line to line)}} = \sqrt{3} E_{D \text{ (line to neutral)}} = 1.73 \times 2.5 = 4.3 \text{ volts}$$

Referring to 215.2(A) informational note No. 2, this number, which is less than 1 percent of the 480-V circuit voltage, is certainly acceptable.

Table 10 on conductor stranding gives the standard stranding configurations for Class B and Class C copper stranding, along with Class B aluminum stranding. With reference to the fine-stranded conductor termination limitations in 110.14 (second paragraph), any conductors more finely stranded than the configurations presented in this table are required to use terminations identified for the class of stranding employed by the conductor at hand.

Tables 11(A) and (B). These tables are not for general field use. Refer to the discussion at 725.121 for more information.

INFORMATIVE ANNEX A. PRODUCT SAFETY STANDARDS

This annex provides a listing of the various standards that are used to test products by third-party testing facilities, such as Underwriters Laboratories. These tests are designed to establish the suitability of a particular manufacturer's product for use in a specific installation or application covered by the **NEC**. A certain amount of information regarding proper use and installation can be gleaned from the actual testing and the pass/fail criteria given in these publications, which will serve to enhance one's knowledge and prevent misapplication or misuse, as required by 110.3(B).

INFORMATIVE ANNEX B. APPLICATION INFORMATION FOR AMPACITY CALCULATION

The data given here are for use where conductor ampacity is calculated "under engineering supervision," as covered by 310.15(C). It should be noted that many jurisdictions do not recognize the use of 310.15(C)—especially if the conductor ampacity determined by that method is greater than the ampacity that would be permitted by the more familiar procedure given in part **(B)** of 310.15. Always check with the local authority having jurisdiction before determining conductor ampacity in accordance with 310.15(C). And, where such calculation is permitted, it must be conducted under "engineering supervision," which would preclude application by a good percentage of the electrical design and installation community.

Table B.310.15(B)(3)(11). Adjustment Factors for More Than Three Current-Carrying Conductors in a Raceway or Cable with Load Diversity.

[Adapted with permission from the *Engineers's Edition, Illustrated Changes in the 1999 National Electrical Code*, © 1998, Penton Business Media. All rights reserved.]

The current edition of the **NEC** generally makes it prohibitive to install more than nine conductors in a raceway due to the prohibitive derating factors for mutual conductor heating [see coverage of Example D3(a) later in this chapter] that take effect at that point. For example, just 10 current-carrying conductors invoke a 50 percent derating factor, and the derating penalties get worse from there. However, there is an alternative, at this location. As just noted, access to Annex B is through engineering supervision, but if that is achievable, the old ampacity derating factors are revivable.

This table is almost the same table as the one the industry used under the old Note 8 for about 30 years, from the late 1950s to the late 1980s. Originally, this table was based on an assumption that when 10 or more conductors were in a raceway, half of them were control circuits energized in the 1 to 2 A range. If all the conductors were, however, energized and supplying power loads, then the allowable currents had to be further decreased. To that effect, the 1987 **NEC** added a cautionary asterisk note stating that table factors were based on 50 percent diversity. Eventually the table was exiled to Annex B where it resides today, and Table 310.15(B)(3)(a) (in the main body of the Code) reflects the worst possible case of zero diversity on any of the wires. As a practical matter, that is not a realistic assumption.

The table differs from the one in Art. 310 in its three break points over the nine-conductor fill

level. Specifically, the next cut point is 10 to 24 conductors and the derating factor is 70 percent, followed by 25 to 42 conductors taken at 60 percent, and 43 to 85 conductors taken at 50 percent. These three levels are qualified by a note that indicates that they assume a “load diversity” of 50 percent. The purpose of this analysis is to make that statement usable so the table itself can be used easily.

Verification of table validity The table comes with an informational note that includes a formula that underlies the table and that can be used to deal with more complicated “real-world” diversity questions, such as all the conductors being energized, but carrying varying loads.

$$A_2 = \sqrt{\frac{0.5N}{E}} \times (A_1) \text{ or } A_1, \text{ or } A_1, \text{ whichever is less}$$

where:

A_1 = ampacity from Table 310.15(B)(16), etc., multiplied by the appropriate factor from Table B.310.15(B)(3)(11)

N = total number of conductors used to obtain the multiplying factor from Table B.310.15(B)(3)(11)

E = desired number of conductors in the raceway or cable

A_2 = ampacity limit for the current-carrying conductors in the raceway or cable

For example, if twenty 12 AWG THHN conductors are involved having an ampacity (from Table 310-16) of 30 A, a diversity of 50 percent could mean only 10 are carrying current at a particular time. From Table B.310.15(B)(3)(11), the derating factor (under engineering supervision) to be applied is 70 percent.

Allowable ampacity = 30 A times 0.70 = 21 A

Figuring the heating effect of the 10 conductors fully loaded to 21 A produces the following:

$I^2R = 10 \text{ times } 21^2 \text{ times } R = 4410 R$ (R being the resistance per unit length of 12 AWG copper, which will be taken as a constant for these calculations).

Expressed in English, the formula says that the desired ampacity (A_2) is the square root of one half the ratio of the total number of current-carrying conductors (N) to the number of energized conductors (E), all times the “old-fashioned” ampacity as calculated from App. B.310.15(B)(3)(11) (A_1).

Therefore, working from this formula, first calculate the “old-fashioned” ampacity [Table 310.15(B)(16) ampacity times B.310.15(B)(3)(11) factor]. In this case, that would be 30 A times 0.7 = 21 A. This is the number that goes into the formula as “ A_1 .”

Then, the final ampacity is:

$$A_2 = \sqrt{[0.5N\sqrt{E}]} \text{ times } A_1$$

$$A_2 = \sqrt{[0.5 \text{ times } (20\sqrt{20})]} \text{ times } 21 \text{ A}$$

$$= 0.71 \text{ times } 21 \text{ A} \approx 15 \text{ A}$$

The ratio between the developed ampacity here (15 A) and the Table 310.15(B)(16) ampacity (30 A) is 50 percent, which is identical to that shown in Table 310.15(B)(3)(a) for a similar conductor fill, and the heating effect is:

$$I^2R = 20 \times 15^2 \times R = 4500 R$$

The close agreement between the two results (4410 R vs. 4500 R) validates this approach and holds on other numbers of conductors in a raceway. This is no accident, because both Sec. 310.15(B)(3)(a) and the formula in Annex B are based on the same laws of physics. The principle can be broadened to allow a qualified engineer to develop corrected ampacities under many other load conditions and numbers of conductors in a raceway or cable, as covered in the next section.

Applying the formula to general cases. The table footnote actually refers to a “load diversity” of 50 percent. This is not a defined term in the Code, and can refer to circuit configurations other than half fully on/half off. The overall approach is to first figure the limiting amount of heat $W = N(I^2R)$ that the conductors in the raceway to be evaluated will generate assuming a 50 percent diversity and using the adjustment factor in Table B.310.15(B)(3)(11). This sets the limit on the amount of heat that is allowable. If there are different size conductors involved, then begin with the 50 percent that will give the largest I^2R heating when loaded as allowed in the table.

The next step is to work backward and calculate the ampacity of the conductors under the actual conditions. If all the conductors are the same size, plug the amount of heat just calculated (“ W ”) into the rearranged formula $I = \sqrt{(W \div NR)}$; this gives the equivalent allowable heating with “ N ” conductors equally loaded. Calculations involving combinations of conductor sizes are more complicated but the principle is the same. Remember to factor in the resistances as ratios (based on [NEC Chap. 9 Table 8](#)) to the conductor resistance used in the initial determination of allowable heating. This way the resistance per unit length (“ R ”) is a constant and need not be actually calculated. [Figure 9-2](#) shows a worked-out example of 12 and 14 AWG conductors mixed in the same raceway, along with other loading versus heating examples of interest.

As shown in [Fig. 9-2](#), many different combinations of numbers of conductors energized versus reduced loads can amount to “a load diversity of 50 percent.” As currents fall away from their theoretical maximums, the heating falls by the square of those decreases. This is the reason that under actual loading conditions there was very little documentation of any problems with the traditional approach. The example also shows how a possible design load at zero diversity (all 24 wires carrying 16 A each) could overheat the conductors. This is why Table 310.15(B)(3)(a) was changed a few cycles back.

(Does not consider allowable overcurrent protective devices)

INFORMATIVE ANNEX C. CONDUIT AND TUBING FILL TABLES FOR CONDUCTORS AND FIXTURE WIRES OF THE SAME SIZE

The tables given in this annex are based on the rule of Table 1, Chap. 9; the dimensions given for raceways and tubing in Table 4, Chap. 9; and the dimensional data provided for conductors and fixture wires in Table 5, Chap. 9. Where conductors of the same size and insulation type are run in a common raceway or tube, the maximum number permitted within any sized raceway or tube can be readily determined by consulting the table that covers the type of raceway or tubing that is to be used. Because all types of liquidtight flexible nonmetallic conduit are allowed without a 6-ft limitation, LFMC-C values were added to this annex as to the 2017 **NEC**.

As of the 2005 **NEC**, notes were added to most of the tables calling attention to the fact that 2-h fire rated RHH conductors have much larger cross-sectional areas than conventional RHH conductors, and that the cable manufacturer's published data must be consulted to determine allowable raceway fill. This cable has ceramifiable insulation that turns to a brittle, glass-like consistency after a fire exposure, avoiding a failure for a limited period of time in order to facilitate a building evacuation or other necessary functions during the time period specified in its fire rating.

INFORMATIVE ANNEX D. EXAMPLES

Example D3(a) Industrial Feeders in a Common Raceway

Perhaps the most vital task confronting electrical personnel on the design side is correctly choosing the size of a wire to use in any particular application. Unfortunately, that is also one of the most complex tasks as well, because so many different factors influence the result, from termination limits to insulation style to continuous loading issues. There have always been two parts to this puzzle, beginning with knowing how to calculate the load that the wire would have to serve, and then selecting the wire. The majority of examples in this annex are quite good, but aimed at the first half of the problem, determining loads. Now there is an example that tackles the other side of the problem. Example D3(a) essentially stipulates the load at the outset, and goes through figuring out which conductor to install. The text that follows uses the exact approach given in Example D3(a), and expands on every step in the process, so you can really see how it is done. In general, Example D3(a) keeps the load data in the form of volt-amperes until the end, whereas this analysis converts to amperes sooner because those numbers are more intuitively familiar to users. In addition, a result in amperes is immediately recognizable in terms of whether a change in wire size is required. However, the procedures are identical. It is not simple, but there are a few key concepts that will keep you headed in the right direction.

The 2011 **NEC** inadvertently added another level of difficulty because of changes to a handful of ampacity ratings in Table 310.15(B)(16), one of which (1 AWG @ 90°C, 150A reduced to 145 A) changes a number of calculations within the scope of Example D3(a). The loads that make up Example D3(a) were carefully selected for their value as instructional material. Specifically, any procedural misstep would result in an actual change of wire size and not simply a difference of volt-amperes. The **NEC** example was still correct as written, but it no longer had the same instructional value because its load profile no longer generated wire size changes at certain critical points. The solution, implemented in the 2014 **NEC**, reduced the noncontinuous load group by 4 A, which restored those wire size break points at intermediate stages of the calculations. Looking at the load profile in D3(a), this was done by lowering the air compressor size from 7.5 hp to 5 hp. This lowered the current from 11 A to 7.6 A (from Table 430.250), and since this is still the largest motor, the 25 percent adder line (from 430.24) decreased as well, providing the necessary 4 A reduction. Example D3(a) (as volt-amperes and not amperes) now uses 68 A continuous and 47 A noncontinuous in its feeder calculations for ungrounded conductors. All feeder calculations and procedures presented here line up exactly with Example D3(a).

NEC rules for the ends of a wire differ from those for the middle (Adapted from *Practical Electrical Wiring*, 22nd edition, © Park Publishing, 2014, all rights reserved). The key to applying these rules, and the new **NEC** Example D3(a) in Informative Annex D on this topic is to remember that the end of a wire is different from its middle. Special rules apply to calculating wire sizes based on how the terminations are expected to function. Entirely different rules aim at ensuring that wires, over their length, don't overheat under prevailing loading and conditions of use. These two sets of rules have nothing to do with each other—they are based on entirely different thermodynamic considerations. Some of the calculations use, purely by coincidence, identical multiplying factors. Sometimes it is the termination requirements that produce the largest wire, and sometimes it is the requirements to prevent conductor overheating. You can't tell until you complete all the calculations and then make a comparison. Until you are accustomed to doing these

calculations, do them on separate pieces of paper.

Current is always related to heat Every conductor has some resistance and as you increase the current, you increase the amount of heat, all other things being equal. In fact, you increase the heat by the square of the current. The ampacity tables in the **NEC** reflect heating in another way. As you can see in **NEC** Table 310.15(B)(16), the tables tell you how much current you can safely (meaning without overheating the insulation) *and continuously* draw through a conductor under the prevailing conditions—which is essentially the definition of ampacity in **NEC** Art. 100: *The maximum current, in amperes that a conductor can carry continuously under the conditions of use without exceeding its temperature rating.*

Ampacity tables show how conductors respond to heat The ampacity tables do much more than what is described in the previous paragraph. *They show, by implication, a current value below which a wire will run at or below a certain temperature limit.* Remember, conductor heating comes from current flowing through metal arranged in a specified geometry (generally, a long flexible cylinder of specified diameter and metallic content). In other words, for the purposes of thinking about how hot a wire is going to be running, you can ignore the different insulation styles. As a learning tool, let's make this into a “rule” and then see how the **NEC** makes use of it:

A conductor, regardless of its insulation type, runs at or below the temperature limit indicated in an ampacity column when, after adjustment for the conditions of use, it is carrying equal or less current than the ampacity limit in that column.

For example, a 90°C THHN 10 AWG conductor has an ampacity of 40 A. Our “rule” tells us that when 10 AWG copper conductors carry 40 A under normal-use conditions, they will reach a worst-case, steady-state temperature of 90°C just below the insulation. Meanwhile, the ampacity definition tells us that no matter how long this temperature continues, it won't damage the wire. That's often not true of the device, however. If a wire on a wiring device gets too hot for too long, it could lead to loss of temper of the metal parts inside, cause instability of nonmetallic parts, and result in unreliable performance of overcurrent devices due to calibration shift.

Termination restrictions protect devices Because of the risk to devices from overheating, manufacturers set temperature limits for the conductors you put on their terminals. Consider that a metal-to-metal connection that is sound in the electrical sense probably conducts heat as efficiently as it conducts current. If you terminate a 90°C conductor on a circuit breaker, and the conductor reaches 90°C (almost the boiling point of water), the inside of the breaker won't be much below that temperature. Expecting that breaker to perform reliably with even a 75°C heat source bolted to it is expecting a lot.

Testing laboratories take into account the vulnerability of devices to overheating, and there have been listing restrictions for many, many years to prevent use of wires that would cause device overheating. These restrictions now appear as 110.14(C) in the **NEC**. Smaller devices (generally 100 A and lower, or with termination provisions for 1 AWG or smaller wire) historically weren't assumed to operate with wires rated over 60°C such as TW. Higher-rated equipment assumed 75°C conductors but generally no higher for 600-V equipment and below. This is still true for the larger equipment. (Note that medium-voltage equipment, over 600 V, has larger internal spacings and the usual allowance is for 90°C per 110.40, but that equipment will not be further considered at this point.) Smaller equipment increasingly has a “60/75°C” rating, which means it will function properly even where the conductors are sized based on the 75°C column of Table 310.15(B)(16).

Figure 9-3 shows a “60/75°C” marking on a 20-A circuit breaker, which means it can be used with 75°C conductors, or with 90°C conductors used under the 75°C ampacity column. In the case of a circuit breaker, using the allowance for 75°C terminations requires that both the CB as well as its enclosing panelboard carry this designation. Always remember, though, that wires have two ends. Successfully using the smaller (higher ampacity) wires requires equivalent markings on both the circuit breaker and panelboard (or fused switch) and the device at the other end. Refer to Fig. 9-4 for an example of this principle at work.

Fig. 9-3. A 20-A circuit breaker marked as acceptable for 75°C terminations. (Chap. 9.)

Every wire has two ends. This wire must be sized as if it had 60°C insulation because ...

Fig. 9-4. Always consider both ends of a wire when making termination temperature evaluations. (Chap. 9.)

Splices as terminations Not all terminations occur on electrical devices or utilization equipment. Some terminations occur in the middle of a run where one conductor is joined to another. The same issue arises when we make a field connection to a busbar that runs between equipment. Busbars, usually rectangular in cross section, are often used to substitute for conventional wire in applications involving very heavy current demands. When you make a connection to one of these busbars (as distinct from a busbar within a panel), or from one wire to another, you only have to be concerned about the temperature rating of the compression connectors or other splicing means involved. Watch for a mark such as “AL9CU” on the lug. This one means you can use it on either aluminum or copper conductors, at up to 90°C, but only where the lug is “separately installed” (**NEC** text).

Lug temperature markings usually mean less than they appear to mean. Many contactors, panelboards, etc., have termination lugs marked to indicate a 90°C acceptance. Ignore those markings because the lugs aren’t “separately installed.” Apply the normal termination rules for this kind of equipment. What’s happening here is that the equipment manufacturer is buying lugs from another manufacturer who doesn’t want to run two production lines for the same product. The lug you field install on a busbar, and use safely at 90°C, also works when furnished by your contactor’s OEM. But on a contactor you don’t want the lug running that hot. The lug won’t be damaged at 90°C, but the equipment it is bolted to won’t work properly.

Protecting devices under continuous loads The **NEC** defines a continuous load as one that continues for 3 h or longer. Most residential loads aren’t continuous, but many commercial

and industrial loads are. Consider, for example, the banks of fluorescent lighting in a store. Not many stores always stay open less than 3 h at a time. Although continuous loading doesn't affect the ampacity of a wire (defined, as we've seen, as a continuous current-carrying capacity), it has a major impact on electrical devices. Just as a device will be affected mechanically by a heat source bolted to it, it also is affected mechanically when current near its load rating passes through it continuously. To prevent unremitting thermal stress on a device from affecting its operating characteristics, the **NEC** restricts the connected load to not more than 80 percent of the circuit rating. The reciprocal of 80 percent is 125 percent, and you'll see the restriction stated both ways. Restricting the continuous portion of a load to 80 percent of the device rating means the same thing as saying the device has to be rated 125 percent of the continuous portion of the load. If you have both continuous and noncontinuous load on the same circuit, take the continuous portion at 125 percent, and then add the noncontinuous portion. The result must not exceed the circuit rating.

example Suppose, for example, a load consists of 47 A of noncontinuous load and 68 A of continuous load (115 A total) as shown in [Fig. 9-5](#). Calculate the minimum capacity we need to allow for our connected equipment as follows:

- Step 1: $47 \text{ A} \times 1.00 = 47 \text{ A}$
- Step 2: $68 \text{ A} \times 1.25 = 85 \text{ A}$
- Step 3: Minimum = 132 A

Minimum wire size at terminals:
 $47A + (1.25)68A$
 $= 132A$
(1/0 AWG @ 75°C)

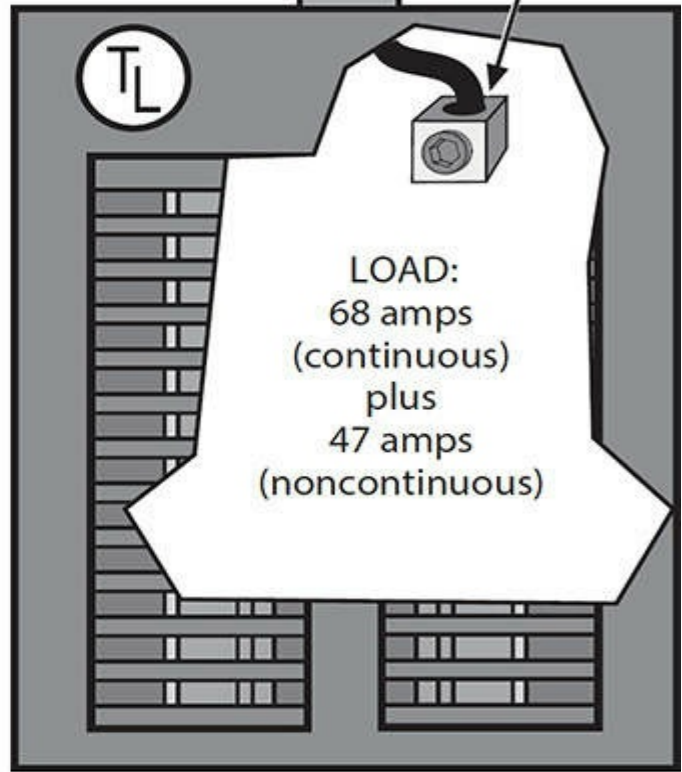

Fig. 9-5. Continuous loads require increased wire sizes, so terminating devices will not overheat. This is true even if the size based on the ampacity required over the run seemingly allows a smaller wire.

A device such as a circuit breaker that will carry this load profile must be rated no less than 132 A, even though only 115 A actually passes through the device. In the case of overcurrent protective devices, the next higher standard size would be 150 A. In general, for overcurrent protective devices not over 800 A, the **NEC** allows you to round upward to the next higher standard overcurrent device size. In this case, suppose a standard wire size had a 90°C ampacity of 140 A (there doesn't happen to be one, but this is only for discussion). The **NEC** normally allows a 150-A fuse or circuit breaker to protect such a conductor.

Having gone this far, it's easy to make two mistakes at this point. First, although you can round up in terms of the overcurrent device rating, you can't round up in terms of conductor loading, not even 1 A. Number 1 AWG conductors in the 75°C column can carry 130 A. If your actual load runs at 131 A, you have to use a larger wire. Second, when continuous loads are a factor, you have to build in additional headroom on the conductor sizes to ensure that the connected devices perform properly. This last point continually results in confusion because it may seem to contradict what was said about conductor ampacity tending to be the factor that determines minimum wire size.

In our work we handle conductors, and we worry about conductors getting overheated. Device manufacturers don't worry about conductors in this sense; they worry about their devices getting overheated and not performing properly. Continuous loads pose real challenges in terms of heat dissipation from the inside of mechanical equipment. Remember that when you bolt a conductor to a device, the two become one in the mechanical as well as the electrical sense. Device manufacturers rely on those conductors as a heat sink, particularly under continuous loading. The **NEC** allows for this by requiring conductors carrying continuous loads to be oversized at those terminations according to the same formula that applies to the device, namely an additional 25 percent of the continuous portion of the load.

example Our 10 AWG THHN conductor, for example, will carry 40 A for a month at a time without damage to itself. But under those conditions the conductor would represent a continuous 90°C heat source. Now watch what happens when we (1) size the conductor *for termination purposes* at 125 percent of the continuous portion of the load, and (2) use the 75°C column for the analysis. This calculation assumes the termination is rated for 75°C instead of the default value of 60°C:

Step 1: $1.25 \times 40 \text{ A} = 50 \text{ A}$

Step 2: Table 310.15(B)(16) at 75°C = 8 AWG

We go from a 10 AWG conductor to an 8 AWG conductor (6 AWG if the equipment doesn't have the allowance for 75°C terminations). That is just one customary wire size, but look at it from the device manufacturer's perspective. Number 10 AWG carrying 40 A continuously is a continuous 90°C heating load. What about the 8 AWG? Use the ampacity table in reverse, according to our "rule." Forty amperes happens to be the ampacity of an 8 AWG, 60°C conductor. Therefore, any 8 AWG wire (THHN or otherwise) won't exceed 60°C when its load doesn't exceed 40 A. By going up just one wire size, the termination temperature dropped from 90°C to 60°C. The **NEC** allows manufacturers to count on this headroom.

To recap, if you have a 40-amp continuous load, the circuit breaker must be sized at least at 125

percent of this value, or 50 A. In addition, the conductor must be sized to carry this same value of current *based on the 75°C ampacity column (or 60°C if not evaluated for 75°C)*. The manufacturer and testing laboratory count on a relatively cool conductor to function as a heat sink for heat generated within the device under these continuous operating conditions.

In the feeder example, including the 125 percent on the continuous portion of the load brings us to a 132-A conductor, and the next larger one in the 75°C column is a 1/0. Remember to use the 75°C column here because the 150-A device exceeds the 100-A threshold (below which the rating is assumed to be 60°C). Remember, only 115 A (68 A + 47 A) of current actually flows through these devices. The extra 17 A (the difference between 115 A and 132 A) is phantom load. You include it only so your final conductor selection is certain to run cool enough to allow it to operate in accordance with the assumptions made in the various device product standards.

There are devices manufactured and listed to carry 100 percent of their rating continuously, and the **NEC** recognizes their use in exceptions. Typically these applications involve very large circuit breaker frame sizes in the 600-A range (although the trip units can be smaller). Additional restrictions accompany these products, such as on the number that can be used in a single enclosure and on the minimum temperature rating requirements for conductors connected to them. Learn how to install conventional devices first, and then apply these 100 percent-rated devices if you run across them, making sure to apply all installation restrictions covered in the directions that come with this equipment. The warning about wires having two ends applies here with special urgency; be aware that one of these devices at one end of a circuit doesn't imply anything about the suitability of equipment at the other end. Review the discussion in [Chap. 2](#), at 215.2 under the heading "A Comparison: 100 Percent-Rated versus Non-100 Percent-Rated OC Devices" for an extensive analysis of where these devices may prove advantageous.

Grounded conductors have a special allowance The **NEC** includes an exception for feeder grounded conductors [215.2(A)(1) Exception No. 2] that allows them to be excluded from the upsizing requirement for continuously loaded wiring, provided they do not terminate on an overcurrent device. This is appropriate for feeder conductors that run from busbar to busbar and have no relevance as a heat sink for a connected device.

The middle of a wire—preventing conductors from overheating None of the preceding discussion has anything to do with preventing a conductor from overheating. That's right. All we've done is to be sure the device works as the manufacturer and the test lab anticipate in terms of the terminations. Now we have to be sure the conductor doesn't overheat. Again, ampacity is by definition a continuous capability. *The heating characteristics of a device at the end of the run don't have any bearing on what happens in the middle of a raceway or cable assembly.*

To reiterate, you have to compartmentalize your thinking at this point. We just covered the end of the wire; now we'll get to the middle of the wire. Remember being asked to do these on separate pieces of paper? Lock the first one up, and forget everything you just calculated. It has absolutely no bearing on what comes next. Only after you've made the next series of calculations should you retrieve the first sheet of paper. And only then should you go back and see which result represents the worst case and therefore governs your conductor choice.

If you have trouble making this distinction, and many do, apply an imaginary pull box at each end of the run ([Fig. 9-6](#)). Actually, with the cost of copper near historic highs, the imaginary pull boxes are becoming real. One large contractor, faced with installing a 300-ft triple run of Type MC cable for a 1200 A feeder, installed three sets of 500 kcmil cable made up with 90°C THHN (ampacity =

1290 A) between pull boxes at each end. From each pull box he extended 600-kcmil conductors into the device terminations (75°C ampacity = 1260 A). The savings in copper more than paid for the labor and materials expense of providing the pull boxes. The **NEC** now plainly permits this procedure to take place by right, with a new Exception No. 2 in 215.2(A)(1)(a). In [Fig. 9-6](#), make the pull boxes real. A set of feeder conductors run between the boxes can be sized for the conditions that truly affect ampacity, in this case mutual conductor heating and ambient temperature. Larger wires, based on the termination rules, land on the line and load side equipment terminals, and exit the terminating enclosures (this is both appropriate and mandatory under the terms of the exception), arriving in the pull boxes. The conductors are then spliced with connectors rated purely in terms of allowable temperature encountered, as covered in 110.14(C)(2). Another very convenient option would be to use power distribution blocks, as covered in 314.28(e). And there are many other examples that use this procedure. Cablebus operates safely using free-air ampacity numbers (see 370.80) that allow for much smaller wires than would ever be considered for terminations, and this allows for an orderly transition to the equipment. A similar procedure applies to MI cable terminations where necessary (see the discussion at 332.80).

Fig. 9-6. These imaginary pull boxes at each end of the run illustrate how to separate raceway/cable heating calculations from termination calculations. The **NEC** now allows the pull boxes to become real. Because the allowance is in Art. 215, it only applies to feeders and not branch circuits. ([Chap. 9.](#))

To begin this part of the analysis, review the ampacity definition. Conductor ampacity is its current-carrying capacity *under the conditions of use*. For **NEC** purposes, two field conditions

routinely affect ampacity, and they are mutual heating and ambient temperature. Either or both may apply to any electrical installation. Both of these factors reduce ampacities from the table numbers.

Mutual conductor heating A conductor under load dissipates its heat through its surface into the surrounding air; if something slows or prevents the rate of heat dissipation, the temperature of the wire increases, possibly to the point of damage. The more conductors there are in the same raceway or cable assembly, the lower the efficiency with which they can dissipate their heat. To cover this mutual heating effect, the **NEC** imposes derating penalties on table ampacity values. Penalties increase with the number of conductors in a raceway or cable assembly. **NEC** Table 310.15(B)(3)(a) limits the permissible load by giving adjustment factors that apply to table ampacities. For example, if the number of wires exceeds 3 but is fewer than 7, the ampacity is only 80 percent of the table value; if the number exceeds 6 but is fewer than 10, 70 percent; more than 9 but fewer than 21, 50 percent, and so on. However, if the raceway is not over 24 in. long (classified as a nipple), the **NEC** assumes heat will escape from the ends of the raceway and the enclosed conductors need not have their ampacity derated.

Apply the footnote to Table 310.15(B)(3)(a) and count only conductors that are connected to electrical equipment and that will actually carry current at one time, plus any spares left in the raceway. Conductors that will be subject to noncoincident energization are not counted. For example, only count one of the two travelers in a three-way switch loop. Another example would be a variable speed drive used to control two identical motors through interlocking contactors, such that only one of the two motors could operate at once, but all six wires are running in the same raceway; only count three of the six wires.

Grounding conductors are never counted. A neutral wire that carries only the unbalanced current of a circuit (such as the neutral wire of a three-wire, single-phase circuit, or of a four-wire, three-phase circuit) is not counted for derating purposes in some cases. But remember: Grounded wires are not always neutrals. Suffice it to say for now that in most modern systems one conductor is deliberately connected to ground, and neutrals are almost always grounded. The grounded (“white”) wire of a two-wire circuit carries the same current as the hot wire and, although a neutral under the **NEC** definition if it connects to a neutral point, is not a neutral in the sense of carrying only unbalanced current. If you install two such two-wire circuits in a conduit, they must be counted as four wires.

The grounded (“white”) wire of a three-wire corner-grounded delta power circuit is a phase conductor carrying the same current as the two ungrounded phase conductors and is *not* a neutral. It must be counted for derating purposes.

How (and when) to count neutrals Although neutral conductors are counted for derating purposes only if they are actually current-carrying, it is increasingly common in commercial distribution systems derived from three-phase, four-wire, wye-connected transformers to find very heavily loaded neutrals. If the circuit supplies mostly electric-discharge lighting (fluorescent, mercury, and similar types), you must always count the neutral. In such circuits, the neutral carries a “third harmonic” or 180-Hz current produced by such luminaires. Be aware that the neutrals of such circuits or feeders must be counted because those harmonic currents add together in the neutral instead of canceling out, and therefore require derating. The remainder of the feeder examples in this analysis of Example D3(a) (see [Figs. 9-6](#), [9-7](#), and [9-9](#)) generally assume (due to typical industrial load profiles) that the neutrals must be counted on the same basis as the ungrounded conductors.

if neutrals not counted ...

Minimum wire size in raceway

if 35°C

Minimum wire size in raceway
 $(47A+68A)/0.7/0.96$
 $= 171A$
(2/0 AWG @ 90°C)

Fig. 9-8. The two feeders in Fig. 9-7 as they would be affected by adding an elevated ambient temperature.

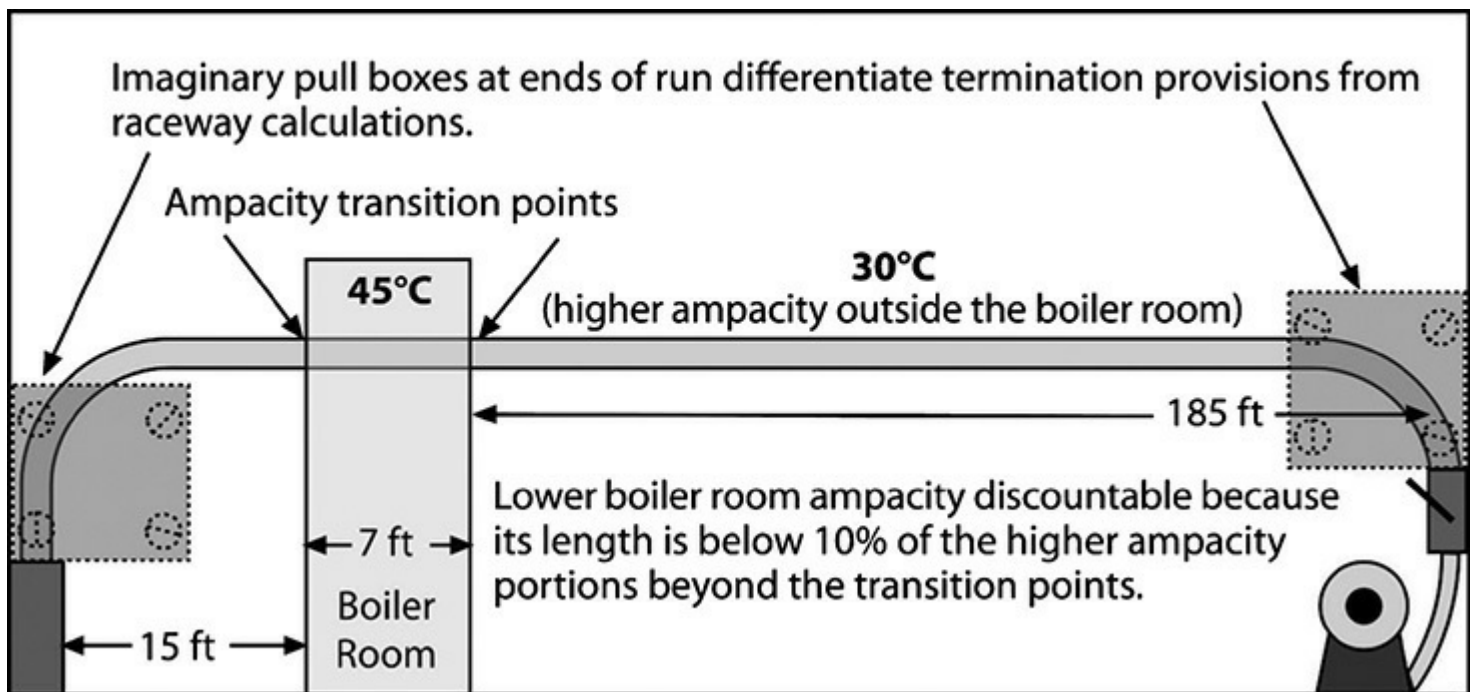

Fig. 9-9. There is a limited exception to the weak link in the chain principle. [310.15(A)(2) Exception.]

In addition, harmonic currents from other nonlinear loads often add instead of canceling in three-phase, four-wire, wye-connected neutrals as well. In fact, there are conditions where such loads cause the neutral to carry *more load* than the ungrounded conductors. There are now Type MC cable assemblies manufactured with oversized neutral conductors to address this problem. Finally, any time you run just two of the three-phase conductors of a three-phase, four-wire system together with the system neutral, that neutral always carries approximately the same load as the ungrounded conductors and must always be counted. This arrangement is very common on large apartment buildings where the feeder to each apartment consists of two-phase wires along with a neutral, but the overall service is three-phase, four-wire.

However, the neutral of a true single-phase, three-wire system need not be counted, because harmonic currents fully cancel in these systems. The overwhelming majority of single-family and small multifamily dwellings and most smaller farms have these distributions.

How (and when) to count control wires Many types of control wires, such as motor control wires and similar wires that carry only intermittent or insignificant amounts of current need not be counted, provided the continuous control current does not exceed 10 percent of the conductor ampacity, as covered in 725.51(B). For example, a motor starter with a 120-V coil might require 100 VA to operate, or less than 1 A, and even less to hold in. Since that is an intermittent load, and in any event it is less than 10 percent of the ampacity of 14 AWG, you could use 14 AWG wires for this control circuit and run them in the same raceway as the power wires without counting them for derating purposes. Because derating applies to every wire in the conduit unless it is a qualified neutral or grounding conductor, for a typical three-wire control circuit this special allowance has a major impact on the ampacity of those power wires. For a normal three-phase motor circuit running in the same conduit, it allows the power wires to be counted at 100 percent of their table value instead

of 80 percent.

Conductor ampacity adjustment Now that you know how to count the number of wires in a conduit for derating purposes, it's time to learn how to apply **NEC** rules to the result. Using the **NEC** directly means going from the ampacity table to the adjustment factor (by which you multiply), and comparing the result to the load. That's great for the inspector who checks your work, but it doesn't help you pick the right conductor in the first place. You want to go the other way: Knowing the load, you want to select the proper conductor. Consider the Example D3(a) intermediate results as previously mentioned, using a feeder with 47 A of noncontinuous load and 68 A of continuous load. [Figure 9-6](#) shows the impact of whether or not neutrals are counted for adjustment purposes.

Refer to [Fig. 9-7](#). Suppose you have two of those feeders supplying identical load profiles and run in the same conduit. That would be (as previously noted we are counting the neutrals) eight countable conductors in the raceway. *For this part of the analysis, ignore continuous loading and termination problems.* Remember, you should be using a fresh sheet of paper for this calculation.

Start with 115 A of actual load (47 A + 68 A), and *divide* (you're going the other direction, so you use the opposite of multiplication) by 0.7 [the factor in **NEC** Table 310.15(B)(3)(a)], to get 164 A in this case. In other words, any conductor with a table ampacity that equals or exceeds 164 A will mathematically be guaranteed to carry the 115-A load safely. A 1/0 AWG THHN conductor, with an ampacity of 170 A, will carry this load safely under the conditions of use, and it might appear to work. Whether it represents your final choice depends on the outcome of the analysis explained in the later topic on choosing a conductor.

Ambient temperature problems High ambient temperatures hinder the dissipation of conductor heat just as in the case of mutual heating. To prevent overheating, the **NEC** provides ambient temperature correction factors for Table 310.15(B)(16), the ampacity table that applies to these calculations, in Table 310.15(B)(2)(a). In addition, the **NEC** has a Table [310.15(B)(3)(c)] of mandatory temperature adders for rooftop wiring (with a specific and glaring exception for XHHW-2 insulation). Getting back to the feeder example, suppose the circuit conductors go through a 35°C ambient. Their ampacity goes down (for 90°C conductors) to 96 percent of the base number in the ampacity table. Here again, start with 115 A, and *divide* by 0.96 to get 120 A. Any 90°C conductor with an ampacity equal to or higher than 120 A would carry this load safely. What happens if, as shown in [Fig. 9-8](#), you have *both* a high ambient temperature *and* mutual heating? Divide twice, once by each factor. In this case:

$$115 \text{ A} \div 0.7 \div 0.96 = 171 \text{ A}$$

A 2/0 AWG THHN conductor (ampacity = 195 A) would carry this load without damaging itself. Again, this would be true whether or not the load was continuous, and whether or not the devices were allowed for use with 90°C terminations. Don't cheat; the termination calculations are still supposed to be locked up in another drawer.

When diminished ampacity applies to only a small part of the run You will run into installations where most of a circuit conforms to **NEC** Table 310.15(B)(16) but a small portion requires very significant derating. For example as illustrated in [Fig. 9-9](#), your circuit may be 207 ft long, with 200 ft in normal environments and 7 ft of it passing through a corner of a boiler room with a very high ambient temperature. The **NEC** generally observes the weak-link-in-the-chain principle

and requires the lowest ampacity anywhere over a run to be the allowed ampacity. However, for very short runs where the remainder of the circuit can function as a heat sink, the **NEC** allows the higher ampacity to be used.

Specifically, any time ampacity changes over a run, determine all points of transition. On one side of each point the ampacity will be higher than on the other side. Now measure the length of the wire having the higher ampacity (in this example, the portions *not in* the boiler room) and the length having the lower ampacity (in this example, *in* the boiler room). Compare the two lengths. **NEC 310.15(A)(2)** Exception allows you to use the higher ampacity value beyond the transition point for a length equal to 10 ft or 10 percent of the circuit length having the higher ampacity, whichever is less.

The 2017 has extended the reach of this exception to non-contiguous segments of the run. This preposterous change, which will be aggressively challenged in the 2020 cycle, means that the key feature justifying the exception, namely, the ability of an adjacent part of the run to be a heat sink, no longer applies. The drawing and discussion presented on this topic are still correct, but for the duration of the 2017 cycle there will be an additional, unjustified allowance to apply the allowed ampacity increase to a segment of the circuit it should never apply to. The exception had been in the **NEC** without change for ten Code editions (since 1990) without change. An installation made under the revised terms might be resisted under the general principles in 310.15(A)(3).

In this case of the 200-ft run beyond the 7 ft in the boiler room, 10 percent of the circuit length having the higher ampacity would be 20 ft, but you can't apply the rule to anything over 10 ft. Since 7 ft is less than or equal to 10 ft (and less than the 10 percent limit of 20 ft), the exception applies and you can ignore the ambient temperature in the boiler room in determining the allowable ampacity of the wires passing through it. In the words of the exception, the "higher ampacity" (which applies to the run outside the boiler room) can be used beyond the transition point (the boiler room wall) for "a distance equal to 3.0 m (10 ft) or 10 percent of the circuit length figured at the higher ampacity, whichever is less."

Choosing a conductor Now you can unlock the drawer and pull out the termination calculations. Put both sheets of paper in front of you, and design for the worst case by installing the largest conductor that results from those two independent calculations. The termination calculation ("Protecting devices under continuous loads") came out needing conductors sized, under the 75°C column, no less than 132 A even though the actual load was only 115 A. You could use 1/0, either THHN or THW.

Suppose you put two feeders (eight conductors) in a conduit, as in "Conductor ampacity derating," above and as in the left side of [Fig. 9-10](#). The termination calculation comes out 1/0, and as we've seen, the raceway adjustment calculation under ordinary ambient temperature conditions also comes out 1/0 AWG THHN. Here, the termination rules happen to agree with the raceway analysis. If the same raceway also goes through the area with high ambient temperature, however, you will need 2/0 THHN. Now the raceway conditions are limiting and you size accordingly. [Figure 9-10](#) shows the calculations under both conditions.

Minimum wire size in raceway
 $(47A+68A)/0.7$
 $= 164A$
(1/0 AWG @ 90°C)

if 30°C

if 35°C

Minimum wire size in raceway
 $(47A+68A)/0.7/0.96$
 $= 171A$
(2/0 AWG @ 90°C)

Minimum wire size at terminals:
 $47A+(1.25)68A$
 $= 132A$
(1/0 AWG @ 75°C)

Fig. 9-10. Calculations for termination limitations must be divorced from run calculations. In some cases the termination restrictions produce the worst case, and in others the run calculations will be the limiting factor. As previously, these calculations assume a raceway length greater than 24 in.

Finally, suppose for a moment that the neutrals do not carry heavy harmonic loading and therefore need not be counted, and suppose the ambient temperature does not exceed 30°C, as shown in the right side of Fig. 9-7. With only six countable conductors, the adjustment factor drops to 0.8, so the required ampacity becomes $115 \text{ A}/0.8 = 144 \text{ A}$, seemingly allowing 1 AWG THHN (90°C) conductors. Now the termination rules (as shown in the right side of Fig. 9-3 and mandating a 75°C temperature evaluation) would be the worst case and would govern the conductor selection process.

Remember, the terminations and the conductor ampacity are two entirely separate issues. Just because you need to use the 75°C column for the terminations doesn't mean you start in that column to determine the overall conductor ampacity. Go ahead and make full use of the 90°C temperature limits on THHN, and its resulting ampacity, to solve mutual conductor heating problems over the middle of a run.

Don't get confused by the fact that the derating factor for continuous loads (0.8) is the same as the adjustment factor for four to six conductors in a raceway (0.8). This is only a coincidence. One applies to terminal heating at the end of a wire, and the other applies over the interior of the raceway. They never apply at the same point in a circuit because the technical basis for each is entirely different. The middle is never the end, so never apply the rules for one to the other. The calculations in this discussion illustrate this through different instances of similar connected loading. Review again Figs. 9-5, 9-7, 9-8, and 9-10.

In one case the termination requirements force an increase in conductor size. In another case the termination requirements agree with the results of the ampacity calculations; and in yet another case the ampacity calculation forces you to use a larger conductor than what the termination rules would predict.

The conductor must always be protected Don't lose sight of the fact that the overcurrent device must always protect the conductor. For 800-A and smaller circuits, **NEC 240.4(B)** allows the next higher standard size overcurrent device to protect conductors. Above that point, **NEC 240.4(C)** requires the conductor ampacity to be no less than the rating of the overcurrent device. As a final check, be sure the size of the overcurrent device selected to accommodate continuous loads protects the conductors in accordance with these rules; if it doesn't you will need to increase the conductor size accordingly. Refer to the discussion of noncontinuous loads, in "Noncontinuous loads," below, for an example of where, even after doing both the termination and the ampacity calculations, this consideration forces you to change the result.

Small conductors Small conductors (14, 12, and 10 AWG) present an additional wrinkle. The **NEC** imposes special limitations on overcurrent protection beyond the values in the ampacity tables for these small wires. Generally, the overcurrent protective device for 14 AWG wire can't exceed 15 A; for 12 AWG wire, 20 A; for 10 AWG wire, 30 A. The higher ampacities of these conductors remain what the table says they are, however, and there are cases, notably including motor circuits, where this restriction doesn't apply. In general, perform all ampacity calculations as described previously, based on the ampacity table limits. But at the very end, make sure your overcurrent device doesn't exceed these specific ampere limits unless you fall into one of the

exceptions specifically tabulated in **NEC** 240.4(G).

Noncontinuous loads Suppose none of the 115 A load is continuous on our 150-A feeder in Example D3(a), and suppose the character of the load on the neutrals does not require them to be classified as countable conductors for derating/adjustment purposes. Looking at the two feeders in “Conductor ampacity adjustment,” above (and illustrated on the right side of Fig. 9-7), suppose the ambient temperature doesn’t exceed 30°C. The termination need not include any phantom load allowance, but it still needs to assume 75°C termination restrictions. A 1 AWG conductor (or even a 2 AWG conductor) will carry the actual 115-A load without exceeding 75°C, and therefore would seem to be usable until you consider the mutual effects of multiple conductors in the common raceway. Suppose you went to a 1 AWG THHN conductor, ampacity 145. Will it carry the 115-A load safely? Yes, because $145 \text{ A} \times 0.8$ (the adjustment factor for six conductors) = 116 A. Will it overheat the breaker terminations? No, because 1 AWG copper is 1 AWG copper no matter what insulation style it has around it, and it won’t rise to 75°C until it carries 130 A. But its final derated ampacity within the conduit is 116 A. The next higher standard-sized overcurrent device is 125 A. The 150-A breaker does not protect this wire under these conditions of use, and has to be reduced to 125 A, or else you need to increase the wire size to 1/0 AWG.

Neutral sizing As noted previously this example provided the basis for what is now Example D3(a) in **NEC** Annex D. The **NEC** example also calculates neutral sizing, based on a worst-case-scenario continuous neutral load of 42 A. The D3(a) example notes that this wire runs busbar to busbar and does not require upsizing by 25 percent (see “Grounded conductors have a special allowance,” stated earlier) leading to a preliminary size of 8 AWG under the 75°C column. However, this size would be inadequate to clear a line-to-neutral short circuit because 8 AWG is smaller than the minimum equipment grounding conductor that could be installed on a 150-A feeder as covered in **NEC** 250.122. Therefore, the minimum size becomes 6 AWG, as required in **NEC** 215.2(A)(2).

There is another issue to be addressed at this point. **NEC** 250.122(B) requires that if ungrounded conductors are increased in size, a proportional increase must be made in the size of the equipment grounding conductor, and as we have just seen, in the case of the Example D3(a) load profile, this size will control the size of the neutral. The size of the ungrounded conductors determined in this example (in some cases as large as 2/0 AWG copper) are the smallest size allowed by the **NEC** under the specified conditions. No increase for voltage drop or other design consideration has been made, and Example D3(a) does not show a further increase either. On the other hand, such sizes are larger than the sizes specified in **NEC** Table 310.15(B)(16). The historical context for the rule addressed instances where increases to lower voltage drop implied a similar benefit for a long equipment grounding conductor. Fortunately, the 2014 **NEC** changed 250.122(B) to clarify that the place to start is the minimum size required to meet **NEC** requirements and not necessarily a simple number printed in the ampacity tables. No further increase in size is required in this context.

INFORMATIVE ANNEX E. TYPES OF CONSTRUCTION

The information given in Table E.1 is taken from another **NFPA** standard, **NFPA** 5000, and can serve to help identify the “type” of building construction employed on a given project. The primary use for this table is determining whether or not Type NM cable (Romex) may be used. As given in

334.10, Type NM cable may be used in other than one- and two-family dwellings provided the “construction type” of the building in question is *permitted to be* either a Type III, IV, or V. Any building that can be so constructed under the prevailing building code, whether or not it actually was constructed that way, meets the threshold in 334.10 and may use Type NM cable, with certain restrictions.

As an alternative to deciphering Table E.1 and researching all applicable data from **NFPA 5000**, one could consult the local building department as its inspectors are completely familiar with such matters and will be able to clearly indicate the type of construction its building code mandates for any building or structure within its jurisdiction. If the building department identifies a particular structure as qualifying for Type III, IV, or V construction, then the permission given in 334.10 may be exercised and Romex may be used.

INFORMATIVE ANNEX F. AVAILABILITY AND RELIABILITY FOR OPERATIONS POWER SYSTEMS; AND DEVELOPMENT AND IMPLEMENTATION OF FUNCTIONAL PERFORMANCE TESTS (FPTS) FOR CRITICAL OPERATIONS POWER SYSTEMS

This new annex provides guidance in setting up functional performance tests that are required for Critical Operations Power Systems, and as referenced in informational notes in 708.1 (No. 8) and in 708.8(D).

INFORMATIVE ANNEX G. SUPERVISORY CONTROL AND DATA ACQUISITION (SCADA)

This new annex supports the provisions of new Art. 708, as referenced in 708.1, informational note No. 9.

INFORMATIVE ANNEX H. ADMINISTRATION AND ENFORCEMENT

80.1. Scope. Annex H provides a standardized approach for the makeup of the inspecting authorities including organization, operating procedures, means of redress, individual qualifications for board members and inspectors, as well as other administrative necessities related to the enforcement of the **National Electrical Code (NEC)**, also referred to here as the Code.

Coverage of this Annex is limited to those portions that may be useful to installers and designers. Sections not covered are either self-explanatory or don’t apply to designers and installers. The following sections express ideas and concepts that can serve to provide guidance for designers and installers on basic application and enforcement concerns.

80.5. Adoption. This part makes clear that Annex H must be specifically and separately adopted to be considered part of the Code. That is, if the legislative body responsible for adopting the **NEC** does not specifically and clearly call for the adoption of the wording in Annex H, then this annex is not a binding or mandatory part of the Code within that jurisdiction. Where the legislative body responsible for promulgation of electrical safety standards does adopt Annex H, all existing enforcement and administrative elements employed by the local inspection agency must be reviewed by the inspecting entity to determine whether their procedures, chain-of-command, personnel, and so

forth satisfy the various rules given herein.

80.9. Application. The wording here indicates exactly what parts of a given installation are subject to inspection and what standard applies. This is a question that has been raised many times in the past, but the concepts expressed by this wording were nowhere to be found within the **NEC** itself. Because these sections are intended to be used as guidance for enforcement where Annex H is accepted, even if it is not adopted, it seems reasonable to assume that the guidance provided here can be used by designers, installers, and inspectors to identify those installations, or parts of installations, that are intended to be subject to inspection and what edition of the Code must be satisfied.

As given in 80.9(A), all new construction is subject to inspection according to the Code edition (2002, 2005, 2008, etc.) that is in effect at the time the construction permit was dated. That is, if, say, the next edition of the Code was adopted on, say, 1 June, and a building permit was issued on 10 June, then the electrical installation within that building must conform to the new Code. Any permits issued before the adoption of the new Code—in the preceding example before 1 June—would be subject to the preceding edition of the **NEC** and must, in all ways, satisfy that edition of the Code. It's worth noting that such interpretation has been in place in the vast majority of jurisdictions across the United States. Inspection authorities have long applied this simple logic—especially at that point in time when a new Code is adopted—to establish which installations are subject to which Code.

Part **(B)** of 80.9 applies to “Existing Installations.” Here the wording gives a general statement regarding the circumstances under which an existing installation may continue to operate even though it is not compliant with the prevailing edition of the Code.

Retroactive compliance has not been mandated by any edition of the **NEC**. That is, if as the result of a Code change, a certain application is no longer acceptable, it is not generally necessary to change out equipment or otherwise rearrange system connections to conform to the new Code. This wording essentially states that the inspector may require corrective action for an existing installation only where the inspector determines that continued operation of the system, in its present configuration, presents a safety hazard. In such cases, the inspector is empowered to mandate corrective action, but must allow a reasonable amount of time to achieve compliance.

80.9(C) covers “Additions, Alterations, or Repairs.” This portion of Annex H states that all renovations, modernizations, or expansions of existing electrical systems are subject to the Code that is in effect at the time the work is performed. Additionally, any such projects must not “adversely affect” the existing system, as determined by the inspector. This essentially means that the inspector can require, say, a service upgrade if the existing service is incapable of supplying the additional load, or a higher-rated feeder and feeder protective device, or an up-sized panelboard or switchboard, or so forth to ensure that the existing system will not be “adversely affected” by the addition, alteration, or repair.

80.29. Liability for Damages. This section presents an extremely important point. Although not very clearly stated, what is said here is that “any party owning, operating, controlling, or installing any electrical equipment” must have an inspection of that completed installation by an authorized electrical inspector. And, such inspection does not relieve the owner, controller, operator, or installer from any legal liability.

This is a very important concept and one that prevails throughout the litigation of lawsuits filed as the result of electrical accidents or incidents. The electrical installer/designer is the party typically named as defendant in such suits—even though the completed installation was inspected and

satisfactorily “passed” the inspection. The point is: Regardless of whether Annex H is adopted within any given jurisdiction, the installer and designer are responsible for the integrity and safety of the work they perform. The inspector is never held legally liable, provided an inspection is performed. Therefore, be aware that if the local inspector accepts an eccentric or unconventional interpretation and application of a given Code rule, the designer and/or installer is still legally liable should an accident or incident occur. And the designer and/or installer may be asked, at some point, to explain why he or she chose the unconventional method. It may be hard to justify such action, and will be nearly impossible to do so to a jury should the accident or incident be attributed to some electrical safety deficiency that resulted from your interpretation and application. Don’t be fooled into thinking that the “green” sticker and issuance of a certificate of occupancy provides legal protection. Your best protection is strict adherence to the “letter” of Code rules where clearly identifiable, or the “spirit” or “intent” where the application is not clearly or specifically regulated by the Code rule in question.

INFORMATIVE ANNEX I. RECOMMENDED TIGHTENING TORQUE TABLES FROM UL STANDARD 486A-B

In general, always use the torque specifications that come with the equipment being installed. However, these tables are very useful for older equipment or for new equipment that, for whatever reasons, does not come with specifications.

This annex also notes that “because it is normal for some relaxation to occur in service, checking torque values sometime after installation is not a reliable means of determining the values of torque applied at installation.” This phenomenon is illustrated in [Fig. 9-11](#), where the resistance decreases on initial tightening of the connector, but as the connection relaxes, the resistance remains low until the connector becomes very loose. Connector torque specifications anticipate this phenomenon.

Fig. 9-11. Some relaxation of tightness in a connection is anticipated and does not degrade the quality of the connection. (Informative Annex I.)

The prior version of the torque table in the 2011 **NEC** had two columns, A and B; the values in Column A were for connector certification testing and were not relevant to field conditions. That column has been removed as of the 2014 **NEC**, and only the former Column B values go forward.

INFORMATIVE ANNEX J. ADA STANDARDS FOR ACCESSIBLE DESIGN

This annex, new with the 2014 **NEC**, presents ADA design criteria. They are not part of the minimum safety standards in the **NEC**, although they clearly inform some requirements. For example, 210.52(C)(5) Exception No. 1 (1) takes them into account relative to required receptacle placements on dwelling unit kitchen counters in “construction for the physically impaired.” They are presented as a service to users, but they do not constitute the full regulation set.

- Conduit stubups, [934](#)
- Connector strips, [1338–1340](#)
- Constant-voltage dc motors, [1034](#)
- Continuous-duty motors, [1035–1039](#)
- Continuous load:
 - CB ratings and, [212](#), [1677–1680](#)

- conductors and, [165–166](#), [1677–1680](#)
- defined, [30](#)
- of deicing and snow-melting equipment, [1015](#)
- from electric signs, [1392](#)
- on feeders, [208](#)
- overcurrent protection and, [358](#)
- water heaters as, [172](#)

Continuous plug-in busway, [828](#)

Control circuits:

- conductors opened by, [1084–1085](#)
- defined, [30](#)
- disconnection of, [1078–1081](#)
- electrical arrangement of, [1075–1078](#)
- fault-tolerant external, [1524](#)
- for fire pumps, [1535–1536](#)
- interlocking, [1080–1081](#)
- overcurrent protection, [1067–1075](#)
- protection from physical damage, [1075](#)

Control drawing, [1277](#)

Control relay, automatic load, emergency systems, [1558](#)

Control transformers, [1072–1074](#)

- in Class I locations, [1255–1256](#)
- in Class II locations, [1271](#)
- in Class III locations, [1275](#)

Controllers:

- for agricultural buildings, [1355–1356](#)
- compressor, [1120](#)
- defined, [1081–1082](#), [1088](#)
- design of, [1082](#)
- for electric signs, [1393](#), [1395](#)
- markings on, [1021](#)
- number of motors served by, [1085–1087](#)
- overcurrent protection, [1067–1075](#)
- ratings, [1048](#), [1082–1084](#)
- terminals, [1022](#)

Cooking appliances:

- branch circuit loads for, [248–252](#)
- branch-circuit wiring, [251](#)
- conductor ampacity for, [167–168](#)
- counter mounted, [989](#)
- countertop measurements and, [191](#)

Cooking hoods, commercial, [952](#)

Coordination (selective). *See* Selective coordination

Copper tape shielding, [642](#), [644](#)

COPS. *See* Critical operations power systems

Cord-and-plug connected appliances:

- disconnection of, [992](#)
- room air conditioners, [1122](#)
 - branch-circuit requirements, [1123](#)–[1129](#)
 - grounding, [1123](#)
- subject to immersion, [993](#)

Cord-and-plug connected equipment:

- grounding, [544](#)–[545](#)
- for swimming pools and fountains, [1453](#), [1487](#)

Cord-and-plug connected lighting assembly, [1450](#)

Cord-and-plug connected vending machines, [994](#)

Cord caps, [916](#)

Cord-connected lampholders and luminaires, [965](#)–[968](#)

Cord-connected loads, grounding, [524](#)

Cord-connected showcases, [964](#)–[965](#)

Cord connectors, [908](#), [917](#)

- grounding, [922](#)

Cords, for electrical vehicle charging systems, [1410](#)–[1411](#)

Corner-grounded systems, [399](#), [429](#), [430](#)

Corrosion protection, [598](#)

Corrosive conditions, [648](#)

- nonmetallic boxes and, [684](#)
- swimming pools and fountains and, [1456](#)

Counter mounted cooking units, [989](#)

Countertops:

- in corners, [188](#)–[189](#)
- measurement of, [191](#)
- peninsular, [188](#)–[191](#)
- receptacle placement and, [191](#)–[192](#), [917](#)
- receptacle spacing and, [179](#), [186](#)–[193](#)
- receptacles below, [192](#)

Cove lighting, [955](#)

Cover requirements, [583](#), [585](#)

Covered conductors, [270](#), [296](#)

Covers, for boxes, [715](#)

Cranes and hoists:

- disconnecting means, [1405](#)–[1406](#)

- festoon cable, [1404](#)
- grounding, [1406](#)
- hoistways, [1408](#)
- installation of contact conductors, [1405](#)
- rating and size of conductors, [1404–1405](#)
- wiring method, [1404](#)

Crawl spaces, [89–90](#), [143](#), [148](#)

Critical branches, [1319–1323](#)

Critical care areas, [1313–1317](#)

Critical operations power systems (COPS):

- accessibility, [1588](#)
- branch-circuit and feeder distribution equipment, [1587](#)
- branch circuits supplied by, [1588](#)
- commissioning, [1585](#)
- definitions, [1585](#)
- emergency communications wiring, [1587](#)
- emergency operations plan, [1589](#)

- HVAC wiring, [1587](#)
- physical security, [1585](#)
- power source capacity, [1588](#)
- power sources, [1587–1588](#)
- risk assessment, [1585](#)
- scope, [1585](#)
- security wiring, [1587](#)
- selective coordination, [1589](#)
- signaling systems wiring, [1587](#)
- testing and maintenance, [1585](#)
- transfer equipment, [1588](#)
- ventilation, [1588](#)

CT cabinets, [504](#)

Current-carrying capacities, [652](#)

Cutout boxes:

- scope, [675](#)
- wiring, [676–677](#)

Cutouts, medium voltage, [1194–1197](#)

Damp locations:

- boxes, conduit bodies, and fittings for, [685–686](#)

- enclosure placement, [675](#)
- luminaires for, [951–952](#)
- panelboards in, [942](#)
- receptacles in, [918–922](#)
- switches in, [898](#)

Danger marking, [80](#)

dc circuits, structural steel and, [541](#), [542](#)

dc grounding electrode conductors, [562](#)

- sizing, [559–560](#)

Decorative lighting, [233](#), [983](#)

Definitions, summary, [59](#)

Deicing equipment, [143](#), [147](#), [1014](#)

- continuous load, [1015](#)
- disconnecting means for, [1018](#)
- GFPE for, [1016–1017](#)
- identification, [1015](#)
- installation of nonheating leads for exposed equipment, [1015–1016](#)
- use of, [1015](#)
- voltage limitations, [1018](#)

Demand factor, [240](#), [241](#), [248](#), [251](#), [254](#), [256](#), [660](#)

- defined, [30–31](#), [32](#)
- feeders and, [237–238](#), [1032](#)
- for mobile homes, [1363](#)

Department stores, [1331](#)

Depth requirements, [584](#), [586](#), [638](#)

- direct burial cable, [646](#)
- under roads, [587](#)
- special conditions, [587–589](#)

Derating:

- conductor protection and, [353](#)
- continuous current load and, [165–166](#)
- for direct burial conductors, [593–596](#)
- equipment grounding conductors and, [670](#)
- feeder and panelboard sizing, [153](#)
- feeder conductors, [208](#)
- for multiple conductor feeders and, [652](#)
- for multiple conductors in raceways, [664–669](#)
- multiwire branch circuits and, [124](#)
- for mutual conductor heating, [667–668](#)
- phase conductor sizing and, [216](#)

Detached garages, [197](#), [203](#)

- Diesel oil, [1206–1207](#)
- Dimmer switches, [908](#)
- Dimmer systems, emergency systems, [1556](#)
- Dimmers:
 - emergency lighting, [1556](#)
 - nonlinear load, [44–45](#)
 - receptacles, controlled, [907](#)
 - solid-state sine wave, [1332–1333](#)
 - theater, [1335–1336](#)
- Dipping processes, [1305–1306](#)
- Direct burial cable:
 - depth requirements, [646](#)
 - shielding, [648](#)
 - splices in, [638](#), [639](#)
- Direct burial conductors, [645–648](#)
 - aboveground protection of, [633](#)
 - derating, [593–596](#)
- Direct burial splices, [591–592](#), [593](#)
- Direct buried cable, [586–587](#)
- Direct current microgrids:
 - arc-fault protection, [1591](#)
 - circuit conductor identification, [1590](#)
 - definitions, [1590](#)
 - directory, [1590](#)
 - disconnecting means, [1590–1591](#)
 - ground-fault detection equipment, [1591](#)
 - marking, [1591](#)
 - protection, [1591](#)
 - scope, [1589–1590](#)
 - system grounding, [1591](#)
- Direct-current systems:
 - ground-fault detection, [561–562](#)
 - point of connection for, [558–559](#)
 - snap switches rated for, [907](#)
- Directly controlled luminaires, emergency systems, [1556](#)
- Disconnecting means:

for A/C and refrigerating equipment:
location of, [1113](#)–[1114](#)
rating and interrupting capacity, [1111](#)–[1113](#)
appliances and, [990](#)
cord-and-plug connected, [992](#)
for buildings or other structures, [279](#), [280](#)
for busways, [834](#), [836](#)
CBs as, [1099](#)–[1101](#)
combined rating of, [327](#)
common, [124](#)–[125](#)
for cranes and hoists, [1405](#)–[1406](#)
for deicing and snow-melting equipment, [1018](#)
direct current microgrids, [1590](#)–[1591](#)
for electric signs and outline lighting, [1393](#)–[1396](#)
for electrical vehicle charging systems, [1412](#)
for elevators, dumbwaiters, escalators, moving walks, platform lifts, and stairway chair lifts,
[1408](#)–[1409](#)
energy storage systems, [1582](#)
fixed electric space heating, [996](#)–[998](#)
for fluorescent luminaires, [980](#)–[981](#)
for fuses, [391](#)
generators, [1134](#)
GFPE for, [334](#)
grouping and marking of, [282](#), [320](#)–[324](#), [325](#)
for high-voltage service, [347](#), [350](#)
information technology equipment rooms, [1428](#)–[1431](#)
interactive system, [1579](#)
for irrigation machines, [1448](#)–[1449](#)
locations of, [281](#)
lockable, [85](#)
maximum number of, [281](#), [316](#)–[319](#)
for medium-voltage supply wiring, [283](#)
for mobile homes, [1360](#)
for motor circuits, [1104](#)
for motor control centers, [1088](#)–[1093](#)
motor control circuits and, [1078](#)–[1081](#)
for motor fuel dispensing facilities, [1299](#)–[1300](#)
for multiwire branch circuits, [124](#)–[125](#), [369](#)
for permanently connected appliances, [150](#), [990](#)–[992](#)
for phase converters, [1177](#)–[1178](#)
for PV systems, [1503](#)–[1504](#)

- rating of, [326–327](#)
- remote, [321](#), [322](#)
- room air conditioners, [1129–1130](#)
- for split-wired receptacles, [127](#)
- for storage batteries, [1188–1189](#)
- for swimming pools and fountains, [1455–1456](#)
- for transformers, [1165](#)
- type of, [281–282](#)
- unit switches as, [992–993](#)
- for X-ray equipment, [1441](#)

Disconnection means, sources or equipment, [1578](#)

Discontinued outlets, [843](#), [845–846](#), [856](#)

Dishwashers, [989](#)

Dissimilar metals, [781](#), [785](#), [816](#)

Distribution cutouts, [1194–1197](#)

Distribution equipment, [1545](#)

Distribution points, electrical supply from, [1356–1358](#)

Distribution transformers, [1434–1435](#)

Diversity factor, [31](#), [32](#)

Domed luminaire canopies, [690](#)

Doorways, of transformer vaults, [1176](#)

Dormitories:

- AFCI requirements, [162](#)
- receptacle requirements, [199–200](#)

Double-insulated appliances, [520](#)

Double-pole switched lampholders, [973](#), [1591–1592](#)

Drain holes, [313](#)

Drain-wire-shielded cable, [644](#)

Drilled holes, [577](#)

Drip loops, [313–314](#), [640](#)

Driven ground rods, [463](#)

Drop boxes, [1338–1340](#)

Drop conductors, [295](#)

Drop wire and cable, [1642](#)

Dry-niche luminaires, [1467](#)

Dry-type transformers:

- indoor installations, [1165–1167](#)
- outdoor installations, [1167](#)

Drywall. *See* Plasterboard

Dual-fed services, single grounding points on, [425](#), [426](#)

Dual-service emergency provisions, [1549](#)

Ducts:

- concrete or masonry encased, [291–293](#)
- wiring in, [622–626](#)

Dumbwaiters, [1406–1410](#)

Duplex receptacles, [234](#)

- branch circuit rating and, [164](#)
- switched outlets and, [177–178](#)
- voltage limitations, [135](#)

Dust

- accumulations on motors, [1024](#)

- on portable generators, [1135](#)
- rooftop receptacles, [147](#)
- for swimming pools and fountains, [1453](#), [1463–1464](#), [1481](#)
- for temporary installations, [1383–1389](#)
- for underwater luminaires, [1463](#)
- Ground-fault current path, [37](#)
- Ground-fault detection equipment, direct current microgrids, [1591](#)
- Ground-fault detector interrupter (GFDI), [1511](#)
- Ground-fault detectors, [417](#)
 - dc, [561–562](#)
- Ground-fault protection of equipment (GFPE), [162](#), [220](#), [368–369](#), [446](#)
 - COPS, [1589](#)
 - defined, [37–38](#)
 - for deicing and snow-melting equipment, [1016–1017](#)
 - desensitizing, [436](#)
 - emergency systems, [1558](#), [1559](#)
 - for feeders, [227–229](#)
 - for fixed electric heating equipment, [1018](#)
 - in health care facilities, [1311–1312](#)
 - interconnected electric power production sources, [1579](#)
 - legally required standby systems, [1568](#)
 - for marinas, boatyards, and docking facilities, [1370](#)
 - performance testing, [340](#), [342](#)
 - for service entrances, [333–342](#)
 - time requirements for, [338](#)
 - transfer switches and, [436–437](#)
- Ground movement accommodation, [591](#), [592](#), [597–598](#), [647](#)
- Ground-resistance testing, [467](#), [468](#)
- Ground rings, [456](#), [459](#), [460](#), [489](#)
- Ground rods, [462](#), [463](#), [466](#), [467](#), [468](#), [471](#)
- Ground wires:
 - bonding, [558](#), [559](#)
 - counting, [689](#)
- Grounded circuit conductor, [443–444](#), [896](#)

- equipment grounding with, 547–551
- in raceways, 512
- service disconnects and, 547, 549
- on supply side of service disconnect, 547, 549

Grounded conductive covering, 1018

Grounded conductors, 509–518

- branch circuit identification, 129, 130
- color coding, 116–117
- connection polarity, 122
- connection to grounded system, 114
- continuity of, 113–114
- defined, 35–36
- disconnection of, 324
- equipment ground bonded to, 537
- in fixture wires, 891
- in flexible cords and cables, 890–891
- in high-impedance grounded neutral systems, 452
- identifying, 115–121, 890–891
- insulation voltage rating, 113
- load end connection to, 422
- motor circuits and, 1085
- overcurrent protection of, 386, 387
- as phase conductor, 429
- separately derived systems and, 521
- service disconnect enclosures and, 427
- sizing of, 429–430
- switchboards, 945
- terminals for, 121–122
- terminations, 945
- for underground service, 301

Grounded neutral systems, 418, 427, 562, 563

- high-impedance, 451–452, 453, 454
- impedance, 564

Grounded neutrals:

- continuity of, 603
- in multiwire branch circuits, 124

Grounded system conductor, 425

Grounded systems:

- in anesthetizing locations, 1327–1328
- high-impedance, 418
- transient overvoltages and, 418

ungrounded conductors tapped from, [149–150](#), [227](#)

Grounding:

air-conditioner units, [1111](#), [1123](#)

alternating-current systems not required to be, [416–419](#)

alternating-current systems required to be, [414–416](#)

for audio signal processing, amplification, and reproduction equipment, [1420](#)

autotransformers, [1152–1156](#)

bodies of water and, [1493](#)

boxes, [546](#), [547](#), [548](#)

buildings or structures supplied by feeders or branch circuits, [444–448](#)

cable trays and, [869–871](#)

cables, [1648–1649](#)

of capacitors, [1185](#)

case, [438](#)

Class I locations, [1249–1252](#)

Class II locations, [1270](#)

communications circuits, [1638–1639](#)

conductor enclosures and raceways, [493](#), [495](#)

connections, [1648](#)

cranes and hoists, [1406](#)

in critical-care areas, [1315–1316](#)

defined, [35](#)

definitions for, [407](#)

distribution points and, [1357–1358](#)

electric signs and outline lighting, [1396–1397](#)

of equipment, [564](#)

equipment connected by cord and plug, [524](#)

equipment fastened in place, [539–541](#)

equipment ground or safety ground, [409](#)

equipotential planes and, [1359](#)

flexible metal conduit, [795](#), [797–798](#)

fountains, [1487](#)

frames of ranges and clothes dryers, [545–547](#)

general requirements for, [407–412](#)

hazards of ineffective, [472](#), [473](#)

in health care facilities, [1307–1309](#)

high-impedance, [451–452](#)

for information technology equipment, [1432](#)

interconnected electric power production sources, [1580](#)

intrinsically safe systems, [1279](#)

liquidtight flexible metal conduit, [801–802](#)

- luminaires, [963](#)
- for marinas, boatyards, and docking facilities, [1371](#)
- medium-voltage systems, [564](#)
- metal enclosures, [497](#)
- metal faceplates, [715](#), [904](#)
- metallic entrance conduit, [1626](#)–[1627](#)
- metallic sheath communications cables, [1638](#)
- of metallic sheathing, [628](#)
- mobile and manufactured homes, [1362](#)–[1363](#)
- motor fuel dispensing facilities, [1300](#)
- motors, [1106](#)–[1107](#)
- optical fiber, [1627](#)
- outbuilding equipment, [441](#)
- outdoor sources and, [444](#)
- of panelboards, [943](#)–[944](#)
- permanently installed generators, [451](#)
- permanently wired equipment, [539](#)–[541](#)
- portable and vehicle-mounted generators, [448](#)–[451](#)
- portable equipment, [544](#)–[545](#)
- for PV systems, [1510](#)–[1515](#)
- raceways, [497](#)
- receptacles and, [544](#)–[545](#), [911](#), [912](#)
- rules, [1657](#)
- for sensitive electronic equipment, [1437](#)–[1438](#)
- separately derived alternating-current systems, [433](#)–[444](#)
- service-supplied alternating-current systems, [562](#)–[563](#)
- soil chemistry and, [463](#)
- surface metal raceways, [854](#)
- for swimming pools and fountains, [1453](#)
- of switch enclosures, [906](#)
- transfer switches and, [436](#)
- transformer secondaries, [437](#)–[444](#)
- transformers, [1161](#)
- for ungrounded systems, [444](#)
- wiring system ground, [408](#)–[409](#)
- Grounding adapters, [922](#)
- Grounding bushings, [515](#)
- Grounding conductor, [423](#), [514](#)
 - branch circuit identification, [131](#)–[134](#)
 - conduit in parallel with, [485](#)
 - induced currents and, [611](#)–[612](#)

- sizing of, [410](#)
- for surge arresters, [567](#)
- Grounding connections, [419](#), [420](#), [421](#), [559](#), [560](#)
- Grounding devices, radio and television, [1643](#), [1644](#)
- Grounding electrode conductors, [408](#), [419](#), [422](#), [425](#), [523](#)
 - for bonding, [430](#)
 - common, [431](#), [442](#), [506](#), [521–522](#)
 - conduit and, [483–484](#), [486](#)
 - connection to grounding electrode, [490–493](#)
 - continuous length rule, [478–480](#)
 - dc, [562](#)
 - size of, [559–560](#)
 - defined, [39](#)
 - electrical continuity importance for, [482–483](#)
 - installation, [477–484](#)
 - materials, [474](#), [477](#)
 - metal building framework as, [443](#), [455](#)
 - metal water pipes as, [442–443](#)
 - physical damage to, [478](#)
 - in separately derived systems, [521](#)
 - service disconnects and, [490](#)
 - services with multiple enclosures, [480–482](#)
 - sizing, [442](#), [445](#), [448](#), [479–480](#)
 - for alternating-current systems, [484–490](#)
 - for surge arresters, [567–568](#)
 - for transformer secondaries, [442](#)
 - for ungrounded systems, [430](#), [444](#)
- Grounding electrode system, [452](#), [454–459](#)
 - installation of, [464–472](#)
 - for PV systems, [1513–1515](#)
- Grounding electrodes, [408](#)
 - auxiliary, [472](#)
 - for bonding, [430](#)
 - bonding jumpers between, [469](#)
 - building components and equipment as, [459–464](#)
 - buildings supplied by feeders or branch circuits and, [444–448](#)
 - common, [472](#)
 - concrete-encased, [455–456](#), [460](#), [464](#), [465](#), [489](#)
 - defined, [39](#)
 - grounding electrode conductor and bonding jumper connection to, [490–493](#)
 - pipes, [462](#), [467](#), [468](#)

- plate, [462](#), [467](#)
- rods, [462](#), [463](#), [466](#), [467](#), [468](#), [471](#)
- service entrance connection, [419](#)
- underground piping systems as, [462](#)
- water pipes as, [456](#), [458–459](#)

Grounding equipment, connection of, [413–414](#)

Grounding impedance, [452](#)

Grounding locknuts, [501](#)

Grounding points, [419](#), [420](#)

- on dual-fed services, [425](#), [426](#)
- generator or vehicle frames as, [448](#)

Grounding-screw terminal, [553](#)

Grounding switches, [715](#)

Guarded, [16](#)

Guarding:

- of live parts, [98–99](#)
- transformers, [1159–1160](#)
- work space and, [107–108](#)

Guest rooms and suites, [40](#)

- lighting outlets, [205](#)
- outlet circuiting and receptacle placement requirements, [162](#)
- overcurrent protection locations and, [390](#)
- receptacle requirements, [199–200](#)

Guide Information for Electrical Equipment (White Book), [64](#)

Gypsum board. *See* Plasterboard

Hallways, receptacles in, [197](#)

Handhole enclosures, [727–728](#)

- defined, [40](#)

Handle tie, [150](#), [319](#), [369](#), [371](#)

Hanger bars, [603](#)

Harmonic loading, [259](#), [260](#), [658](#)

Hazard sources, [1206](#)

Hazardous Location Equipment Directory (Red Book), [64](#)

Hazardous (classified) locations. *See also* Class I locations; Class II locations; Class III locations

- bonding in, [509](#)
- classification of, [1206–1210](#)
- documentation requirement, [1205–1206](#)
- enclosure joints, [1219–1222](#)
- equipment for, [1212–1219](#)
- Intrinsically safe equipment for, [1211–1212](#)

- in marinas, boatyards, and docking facilities, [1374](#)
- material groups, [1210](#)
- optical fiber cable in, [1224](#)
- OSHA on, [1214–1216](#)
- protection techniques for, [1210–1212](#)
- scope, [1205](#)
- specific locations, [1288](#)
- UL on, [1216–1218](#)
- zone system, [1280–1288](#)

HDCI. *See* Heat detecting circuit interrupter

Health care facilities, [1306](#)

- bonding in, [1316–1317](#)
- code applicability, [1307](#)
- critical care areas, [1313–1317](#)
- definitions for, [1307](#)
- essential electrical systems, [1318–1323](#)
- general care areas, [1312–1313](#)
- GFCIs in, [1318](#)
- GFPE in, [1311–1312](#)
- grounding in, [1307–1309](#), [1315–1316](#)
- IG receptacles in, [1310](#)
- isolated power systems, [1329–1331](#)
- panelboard bonding, [1309–1310](#)
- wet procedure locations, [1318](#)
- wiring methods for, [1323–1327](#)

Heat detecting circuit interrupter (HDCI), [1130](#)

Heated appliances, signals for, [993](#)

Heating, air-conditioning, and refrigeration equipment, [263](#)

- receptacles for, [200](#), [201](#)

Heating cable, [996](#)

- area restrictions on installation of, [1001–1004](#)
- installation in concrete or poured masonry floors, [1007–1009](#)
- installation on dry board, in plaster, and on concrete ceilings, [1004–1007](#)
- installation under floor coverings, [1009–1010](#)
- marking, [1001](#)

Heating oil, [1206–1207](#)

Heavy-duty-type lampholders, [174](#)

Hermetic motors, [1120](#), [1121](#)

Hermetic refrigerant motor-compressors, [40](#), [1110](#)

- with additional motor loads, [1119](#)
- marking on, [1110](#)

- overcurrent protection for, [1121–1124](#)
- overload relay devices for, [1121–1122](#)
- short-circuit protection for, [1114–1118](#)
- single, [1118–1119](#)

Hickeys, [690](#)

HID lighting. *See* High-intensity discharge lighting

HID type circuit breakers, [398](#)

High-bay manufacturing buildings, [380–382](#)

High-density polyethylene (HDPE) conduit, [811–812](#)

High-impedance grounded neutral systems, [451–452](#), [453](#), [454](#)

High-impedance grounded systems, [418](#)

High-intensity discharge lighting (HID lighting), [138](#), [170](#), [232](#), [1553](#)

- thermal protection for recessed luminaires, [978](#), [980](#)

High legs:

- color coding, [314](#)
- marking, [79](#)

High-pressure sodium lighting, [137](#)

High-pressure-spray washers, [994](#)

High-voltage service:

- conductors for, [346–347](#)
- disconnecting means for, [347](#), [350](#)
- overcurrent protection for, [350–351](#)
- protection requirements, [350–351](#)

High-voltage starters, [574](#)

Hospital-grade devices, [1313](#), [1326](#)

Hospital-grade receptacles, [1324–1326](#)

Hospitals, GFCI requirements, [147](#)

Hot conductors, branch circuit identification, [129](#), [131](#)

Hot tubs. *See* Spas and hot tubs

Hotels:

- AFCI requirements, [162](#)
- lighting outlet requirements, [205](#)

Household electric clothes dryers, [236](#)

HVAC wiring, COPS, [1587](#)

Hybrid systems:

- defined, [40](#)
- interconnected electric power production sources, [1580](#)

Hydromassage bathtub, [1451](#), [1490–1491](#)

Hydrotherapeutic tanks, [1488–1490](#)

This eBook was posted by AlenMiler on AvaxHome!

Many New eBooks in my Blog: <https://avxhm.se/blogs/AlenMiler>

Mirror: <http://avxhome.in/blogs/AlenMiler>

IAEI News, selective coordination article, [1563](#)–[1564](#)
Identification of disconnecting means, [81](#)–[84](#)
Identified, [19](#)–[20](#), [40](#)
IG receptacles. *See* Isolated-ground receptacles
IGS cable. *See* Integrated gas spacer cable
Illumination, emergency, [1553](#)
IMC. *See* Intermediate metal conduit
Impedance grounded neutral systems, [564](#)
In sight from (within sight from, within sight), [40](#)–[41](#)
In-sink waste disposer, [988](#)–[989](#)
In-use covers, [919](#)
Incandescent lighting, [137](#)
 feeder neutral conductor sizing and, [261](#)–[262](#)
Incandescent luminaires, voltage limitations, [135](#)–[136](#)
Induced currents:
 in ferrous metal enclosures or raceways, [611](#)–[614](#)
 preventing, [572](#)
Induction heating, [611](#), [614](#), [626](#), [1441](#)–[1444](#)
Industrial control assemblies, [108](#)–[109](#), [1201](#)–[1204](#)
Industrial control panels, [41](#), [949](#)–[951](#)
Industrial machinery, [1447](#)–[1448](#)
Information technology equipment, [1423](#)
 bonding, [1432](#)
 disconnecting means, [1428](#)–[1431](#)
 grounding, [1432](#)
 PDUs, [1432](#)
 special requirements, [1424](#)
 supply circuits and interconnecting cables, [1424](#)–[1427](#)
 UPSs, [1431](#)–[1432](#)
 wiring methods for, [1426](#)–[1427](#)
Informational notes, [12](#)
Infrared heating units, [173](#)–[174](#), [254](#)
Infrared lamp industrial heating, [988](#)
 voltage limitations, [138](#)
Innerduct, [1636](#)
 for optical fiber cables, [1625](#)
Inspections, [109](#)–[110](#)
Instantaneous trip CBs, [1049](#)–[1051](#)
Instrumentation tray cable, [1615](#)–[1616](#)
Insulated conductors, [270](#), [296](#)
 for Class I locations, [1249](#)

- in metal wireways, [848–849](#)
- multioutlet assemblies and, [851](#)
- service-entry conductors, [308](#)
- for underground service, [301](#)

Insulated neutrals, [546](#)

Insulated-throat bushings, [581](#)

Insulation shielding, [627–629](#)

Insulators, open wiring on, [879–880](#)

Integral enclosures, [607](#)

Integral threaded fittings, [816](#)

Integrated electrical systems, [1494–1495](#)

Integrated gas spacer cable (IGS cable), [743](#)

Interactive inverters, [1573–1574](#)

- mounted in not readily accessible locations, [1580](#)

Interconnected electric power production sources:

- ampacity of neutral conductor, [1580](#)
- circuit size and current, [1580](#)
- definitions, [1572–1573](#)
- directory, [1573](#)
- disconnect device, [1578–1579](#)
- disconnection means, [1578](#)
- ground-fault protection, [1579](#)
- grounding, [1580](#)
- hybrid systems, [1580](#)
- interactive inverters mounted in not readily accessible locations, [1580](#)
- interactive system disconnecting means, [1579](#)
- interrupting and short-circuit current rating, [1578](#)
- loss of 3-phase primary source, [1579–1580](#)
- loss of primary source, [1579](#)
- output characteristics, [1578](#)
- overcurrent protection, [1579](#), [1581](#)
- point of connection, [1573–1578](#)
- scope, [1572](#)
- synchronous generators, [1581](#)
- system installation, [1573](#)
- unbalanced interconnections, [1581](#)
- utility-interactive power systems employing energy storage, [1580](#)

Interconnected power sources, [329](#)

Interconnected smoke detectors, [175](#)

Interconnecting breaker, [1574](#)

Interlocking control circuits, [1080–1081](#)

Intermediate metal conduit (IMC), [575](#), [626](#), [634](#)
in Class I locations, [1223](#)
in Class II locations, [1267](#)
direct burial of, [783](#)–[784](#)
dissimilar metals, [781](#)
number of conductors in, [782](#)
securing and supporting, [782](#)–[783](#)
size, [782](#)
uses permitted, [779](#)–[781](#)

Interrupting, short-circuit current rating and, [1578](#)

Interrupting capacity, for A/C and refrigerating equipment, [1111](#)–[1113](#)

Interrupting rating, [41](#), [66](#), [67](#)

Intersystem bonding termination, [503](#), [505](#)

Intrinsically safe conductors, separation of, [1278](#)–[1279](#)

Intrinsically safe equipment, [1211](#)–[1212](#), [1215](#)

Intrinsically safe systems:
bonding, [1280](#)
definitions for, [1276](#)–[1277](#)
equipment installation, [1277](#)–[1278](#)
grounding, [1279](#)
identification, [1280](#)
sealing, [1280](#)
wiring methods in, [1278](#)–[1279](#)

Irrigation machines, [1448](#)–[1449](#)

Isolated-ground receptacles (IG receptacles), [555](#), [689](#)–[690](#), [909](#)
in health care facilities, [1310](#)

Isolated grounding terminals, [555](#)

Isolated phase installations, [596](#)–[597](#)

Isolated power systems, [1329](#)–[1331](#)

Isolating means, [1200](#)

Isolating switches, [347](#), [349](#), [1097](#)

Joist space, [623](#)

Joists, [577](#)

Jumper, defined, [22](#)–[23](#)

Junction boxes:
enclosure connection with, [679](#), [680](#)
for fountains, [1486](#)
free conductor length at, [605](#)
number of conductors in, [686](#)–[701](#)
sizing, [718](#)–[727](#)

for swimming pools, [1468–1471](#)
for systems over 1000V, [729–730](#)

Kitchens:

branch circuits for, [154–155](#), [186](#)
commercial, [251](#), [254–255](#), [256](#)
countertop receptacle placements, general, [186–188](#)
GFCI requirements, [144–146](#)
islands, [191](#)
islands and peninsulas, [188–191](#)
lighting outlets, [201–202](#), [205](#)
mirror image construction and, [620](#)
wall counters, [191–192](#)
wall-switch-controlled receptacles and, [184](#)

Knife switches, [906](#)

position and connection of, [899–901](#)

Knockouts, [676](#), [702](#)

bonding jumpers around, [499](#)
concentric knock-outs, [499](#)

Labeled, defined, [41](#), [42](#), [43](#)

Ladder trays, [867](#)

Lamp guards, [1344](#)

Lampholders:

cord-connected, [965–968](#)
double-pole switched, [973](#), [1591–1592](#)
near combustible material, [973](#)
outdoor, [278](#)
rating requirements, [170](#)
screw-shell type, [973](#)

Landscape lighting systems, [589](#)

Large-area buildings, [288](#)

Large-scale PV farms, [1516–1518](#)

Laundry areas:

branch circuit requirements, [155](#)
feeder and service loads, [241–242](#)
GFCI requirements, [146](#)
receptacle requirements, [195](#)

Lay-in lighting fixtures, [616](#)

LCDI. *See* Leakage current detector

Lead-acid batteries, [1186](#)

Lead-antimony batteries, [1186](#)

Lead-calcium batteries, [1187](#)

Leakage current detector (LCDI), [1130](#)

LED luminaires:

connection of, [958–959](#)

drop-in, [874](#)

voltage limitations, [135](#), [137](#)

Legally required standby systems:

accessibility, [1568](#)

capacity of, [1567](#)

coordination, [1568](#)

general requirements, [1568](#)

ground-fault protection of equipment, [1568](#)

scope, [1567](#)

signals, [1568](#)

tests and maintenance, [1567](#)

transfer equipment, [1567–1568](#)

wiring, [1568](#)

- securing and supporting, [601–603](#)
- for sensitive electronic equipment, [1437](#)
- for service-entrance conductors, [310](#), [346](#)
- for spray areas, [1304–1305](#)
- in suspended ceiling, [16](#)
- for theaters, [1333](#)
- for traveling carnivals, [1346](#)
- underground installations, [582](#)
 - under buildings, [590–591](#)
 - cover requirements, [583](#), [585](#)
 - depth requirements, [584](#), [586](#), [587–589](#)
 - derating, [593–596](#)
 - isolated-phase, [596–597](#)
 - in wet locations, [589](#)
- for wind electric systems, [1523](#)
- zone 0, 1, and 2 locations, [1284–1286](#)

Wiring system ground, [408–409](#)

Wiring systems:

- computed load on, [151–152](#)
- conductor to be grounded, [430](#)
- manufactured, [1400–1402](#)
- modular, [1400–1402](#)
- separately derived ac:
 - defined, [433](#)
 - grounding, [433–444](#)

Wood members, [575](#), [576](#), [577](#), [578](#)
Work space, [104–107](#)
Work surfaces, [179](#), [186](#), [917](#). *See also* Countertops
Workshops, [142](#)
Wound-rotor secondaries, [1027–1028](#)

X-ray equipment, [1440–1441](#)
XHHW conductors, [724](#)

Zener diodes, [1277](#)
Zig-zag transformers, [1152–1154](#)
Zone 0, 1, and 2 locations, [1280](#)
 classification of locations, [1281](#)
 definitions, [1281](#)
 equipment, [1284](#)
 requirements, [1286](#)
 flexible cables, cords, and connections, [1286](#)
 material groups, [1282](#)
 motors and generators and, [1286](#), [1287](#)
 special precautions, [1282–1284](#)
 wiring methods, [1284–1286](#)
Zone 20, 21, and 22 locations, [1287–1288](#)
Zone classification system, [1280–1288](#)
Zone-selective interlocking, [403](#)
