Introduction to the National Electrical Code®

Brief History of the National Electrical Code®

About the 2017 National Electrical Code®

90. Introduction

Chapter 1 _____

100. Definitions

110. Requirements for Electrical Installations

Chapter 2 _____

200. Use and Identification of Grounded Conductors

210. Branch Circuits

215. Feeders

220. Branch-Circuit, Feeder, and Service Load Calculations

225. Outside Branch Circuits and Feeders

230. Services

240. Overcurrent Protection

250. Grounding and Bonding

280. Surge Arresters, Over 1 kV

285. Surge-Protective Devices, 1 kV or Less

Chapter 3 _____

300. General Requirements for Wiring Methods and Materials

310. Conductors for General Wiring

312. Cabinets, Cutout Boxes, and Meter Socket Enclosures

314. Outlet, Device, Pull, and Junction Boxes; Conduit Bodies; Fittings; and Handhole Enclosures

320. Armored Cable: Type AC

322. Flat Cable Assemblies: Type FC

324. Flat Conductor Cable: Type FCC

326. Integrated Gas Spacer Cable: Type IGS

328. Medium-Voltage Cable: Type MV

330. Metal-Clad Cable: Type MC

- 332. Mineral- Insulated, Metal- Sheathed Cable: Type MI
- 334. Nonmetallic- Sheathed Cable: Types NM, NMC, and NMS
- 336. Power and Control Tray Cable: Type TC
- 338. Service- Entrance Cable: Types SE and USE
- 340. Underground Feeder and Branch- Circuit Cable: Type UF
- 342. Intermediate Metal Conduit: Type IMC
- 344. Rigid Metal Conduit: Type RMC
- 348. Flexible Metal Conduit: Type FMC
- 350. Liquidtight Flexible Metal Conduit: Type LFMC
- 352. Rigid Polyvinyl Chloride Conduit: Type PVC
- 353. High-Density Polyethylene Conduit: Type HDPE Conduit
- 354. Nonmetallic Underground Conduit With Conductors: Type NUCC
- 355. Reinforced Thermosetting Resin Conduit: Type RTRC
- 356. Liquidtight Flexible Nonmetallic Conduit: Type LFNC
- 358. Electrical Metallic Tubing: Type EMT
- 360. Flexible Metallic Tubing: Type FMT
- 362. Electrical Nonmetallic Tubing: Type ENT
- 366. Auxiliary Gutters
- 368. Busways
- 370. Cablebus
- 372. Cellular Concrete Floor Raceways
- 374. Cellular Metal Floor Raceways
- 376. Metal Wireways
- 378. Nonmetallic Wireways
- 380. Multioutlet Assembly
- 382. Nonmetallic Extensions
- 384. Strut- Type Channel Raceway
- 386. Surface Metal Raceways
- 388. Surface Nonmetallic Raceways
- 390. Underfloor Raceways
- 392. Cable Trays
- 393. Low-Voltage Suspended Ceiling Power Distribution Systems
- 394. Concealed Knob- and- Tube Wiring
- 396. Messenger- Supported Wiring
- 398. Open Wiring on Insulators
- 399. Outdoor Overhead Conductors over 600 Volts

Chapter 4

- 400. Flexible Cords and Flexible Cables
- 402. Fixture Wires
- 404. Switches
- 406. Receptacles, Cord Connectors, and Attachment Plugs (Caps)

- 408. Switchboards and Panelboards
- 409. Industrial Control Panels
- 410. Luminaires, Lampholders, and Lamps
- 411. Low-Voltage Lighting
- 422. Appliances
- 424. Fixed Electric Space- Heating Equipment
- 425. Fixed Resistance and Electrode Industrial Process Heating Equipment
- 426. Fixed Outdoor Electric Deicing and Snow- Melting Equipment
- 427. Fixed Electric Heating Equipment for Pipelines and Vessels
- 430. Motors, Motor Circuits, and Controllers
- 440. Air- Conditioning and Refrigerating Equipment
- 445. Generators
- 450. Transformers and Transformer Vaults (Including Secondary Ties)
- 455. Phase Converters
- 460. Capacitors
- 470. Resistors and Reactors
- 480. Storage Batteries
- 490. Equipment over 1000 Volts, Nominal

Chapter 5

- 500. Hazardous (Classified) Locations, Classes I, II, and III, Divisions 1 and 2
- 501. Class I Locations
- 502. Class II Locations
- 503. Class III Locations
- 504. Intrinsically Safe Systems
- 505. Zone 0, 1, and 2 Locations
- 506. Zone 20, 21, 22 Locations for Combustible Dusts or Ignitable Fibers/Flyings
- 510. Hazardous (Classified) Locations—Specific
- 511. Commercial Garages, Repair and Storage
- 513. Aircraft Hangars
- 514. Motor Fuel Dispensing Facilities
- 515. Bulk Storage Plants
- 516. Spray Application, Dipping, Coating, and Printing Processes Using Flammable or Combustible Materials
- 517. Health Care Facilities
- 518. Assembly Occupancies
- 520. Theaters, Audience Areas of Motion Picture and Television Studios, Performance Areas, and Similar Locations
- 522. Control Systems for Permanent Amusement Attractions
- 525. Carnivals, Circuses, Fairs, and Similar Events
- 530. Motion Picture and Television Studios and Similar Locations
- 540. Motion Picture Projection Rooms

- 545. Manufactured Buildings
- 547. Agricultural Buildings
- 550. Mobile Homes, Manufactured Homes, and Mobile Home Parks
- 551. Recreational Vehicles and Recreational Vehicle Parks
- 552. Park Trailers
- 553. Floating Buildings
- 555. Marinas, Boatyards, and Commercial and Noncommercial Docking Facilities
- 590. Temporary Installations

Chapter 6

- 600. Electric Signs and Outline Lighting
- 604. Manufactured Wiring Systems
- 605. Office Furnishings
- 610. Cranes and Hoists
- 620. Elevators, Dumbwaiters, Escalators, Moving Walks, Platform Lifts, and Stairway Chair Lifts
- 625. Electrical Vehicle Charging Systems
- 626. Electrified Truck Parking Spaces
- 630. Electric Welders
- 640. Audio Signal Processing, Amplification, and Reproduction Equipment
- 645. Information Technology Equipment
- 646. Modular Data Centers
- 647. Sensitive Electronic Equipment
- 650. Pipe Organs
- 660. X-Ray Equipment
- 665. Induction and Dielectric Heating Equipment
- 668. Electrolytic Cells
- 669. Electroplating
- 670. Industrial Machinery
- 675. Electrically Driven or Controlled Irrigation Machines
- 680. Swimming Pools, Fountains, and Similar Installations
- 682. Natural and Artificially Made Bodies of Water
- 685. Integrated Electrical Systems
- 690. Solar Photovoltaic (PV) Systems
- 691. Large-Scale Photovoltaic (PV) Electric Power Production Facility
- 692. Fuel Cell Systems
- 694. Wind Electric Systems
- 695. Fire Pumps

Chapter 7

- 700. Emergency Systems
- 701. Legally Required Standby Systems
- 702. Optional Standby Systems

- 705. Interconnected Electric Power Production Sources
- 706. Energy Storage Systems
- 708. Critical Operations Power Systems (COPS)
- 710. Stand-Alone Systems
- 712. Direct Current Microgrids
- 720. Circuits and Equipment Operating at Less Than 50 Volts
- 725. Class 1, Class 2, and Class 3 Remote-Control, Signaling, and Power-Limited Circuits
- 727. Instrumentation Tray Cable: Type ITC
- 728. Fire-Resistive Cable Systems
- 750. Energy Management Systems
- 760. Fire Alarm Systems
- 770. Optical Fiber Cables and Raceways

Chapter 8 _____

- 800. Communications Circuits
- 810. Radio and Television Equipment
- 820. Community Antenna Television and Radio Distribution Systems
- 830. Network-Powered Broadband Communications Systems
- 840. Premises-Powered Broadband Communications Systems

About the Authors

Frederic P. Hartwell is a working electrician, is President of Hartwell Electrical Services, Inc., and has been certified by the International Association of Electrical Inspectors as a Certified Master Electrical Inspector. He is the senior member of NEC® CMP 9. He is coauthor of *McGraw-Hill's American Electricians' Handbook, 16th Edition*.

Joseph F. McPartland *McGraw-Hill's National Electrical Code® Handbook, 25th Edition*.

Brian J. McPartland ® *McGraw-Hill's National Electrical Code® Handbook, 25th Edition*.

Preface

The 29th edition of *McGraw-Hill's National Electrical Code® Handbook* has been thoroughly revised to reflect the changes given in the 2017 **National Electrical Code**. This is a reference book of commentary, discussion, and analysis on the most commonly encountered rules of the 2017 **National Electrical Code**. Designed to be used in conjunction with the 2017 NE Code book published by the National Fire Protection Association, this Handbook presents thousands of illustrations—diagrams and photos—to supplement the detailed text in explaining and clarifying **NEC** regulations. Description of the background and rationale for specific Code rules is aimed at affording a broader, deeper, and readily developed understanding of the meaning and application of those rules. The style of presentation is conversational and intended to facilitate a quick, practical grasp of the ideas and concepts that are couched in the necessarily terse, stiff, quasi-legal language of the **NEC** document itself.

This Handbook follows the order of “articles” as presented in the NE Code book, starting with “Article 90” and proceeding through the various “Informative Annexes.” The Code rules are referenced by “section” numbers (e.g., “250.138. Cord- and Plug-Connected Equipment”). This format ensures quick and easy correlation between **NEC** sections and the discussions and explanations of the rules involved. This companion reference to the **NEC** book expands on the rules and presents common interpretations that have been put on the many difficult and controversial Code requirements. A user of this Handbook should refer to the **NEC** book for the precise wording of a rule and then refer to the corresponding section number in this Handbook for a practical evaluation of the details.

Because many **NEC** rules do not present difficulty in understanding or interpretation, not all sections are referenced. But the vast majority of sections are covered, especially all sections that have proved troublesome or controversial. And particular emphasis is given to changes and additions that have been made in Code rules over recent editions of the **NEC**. Although this new edition, *McGraw-Hill's National Electrical Code® 2017 Handbook*, does not contain the complete wording of the NE Code book, it does contain much greater analysis and interpretation than any other so-called Handbook contains.

Today, the universal importance of the NE Code has been established by the federal government (OSHA and other safety-related departments), by state and local inspection agencies, and by all kinds of private companies and organizations. In addition, national, state, and local licensing or certification as an electrical contractor, master electrician, or electrical inspector will require a firm and confident knowledge of the **NEC**. With requirements for certification or licensing now mandated in nearly every jurisdiction across the country, the need for Code competence is indispensable. To meet the great need for information on the **NEC**, McGraw-Hill has been publishing a handbook on

the **National Electrical Code** since 1932. Originally developed by Arthur L. Abbott in that year, the Handbook has been carried on in successive editions for each revision of the **National Electrical Code**.

One final point—words such as “workmanlike” are taken directly from the Code and are intended in a purely generic sense. Their use is in no way meant to deny the role women already play in the electrical industries or their importance to the field.

Frederic P. Hartwell
Joseph F. McPartland
Brian J. McPartland

Introduction to the National Electrical Code®

McGraw-Hill's National Electrical Code® 2017 Handbook is based on the 2017 edition of the **National Electrical Code** as developed by the **National Electrical Code** Committee of the American National Standards Institute (ANSI), sponsored by the National Fire Protection Association® (NFPA®). The National Electrical Code is identified by the designation **NFPA** No. 70-2017. The **NFPA** adopted the 2017 Code at the **NFPA** Technical Meeting held in June, 2016.

The **National Electrical Code**, as its name implies, is a nationally accepted guide to the safe installation of electrical wiring and equipment. The committee sponsoring its development includes all parties of interest having technical competence in the field, working together with the sole objective of safeguarding the public in its utilization of electricity. The procedures under which the Code is prepared provide for the orderly introduction of new developments and improvements in the art, with particular emphasis on safety from the standpoint of its end use. The rules of procedure under which the **National Electrical Code** Committee operates are published in each official edition of the Code and in separate pamphlet form so that all concerned may have full information and free access to the operating procedures of the sponsoring committee. The Code has been a big factor in the growth and wide acceptance of the use of electrical energy for light and power and for heat, radio, television, signaling, and other purposes from the date of its first appearance (1897) to the present.

The **National Electrical Code** is primarily designed for use by trained electrical people and is necessarily terse in its wording.

The sponsoring **National Electrical Code** Committee is composed of a Technical Correlating Committee and 19 Code-making panels, each responsible for one or more Articles in the Code. Each panel is composed of experienced individuals representing balanced interests of all segments of the industry and the public concerned with the subject matter. In an effort to promote clarity and consistency of field interpretations of **NEC** passages, the **National Electrical Code** Style Manual was completely rewritten in 1999, with the current version effective in 2015. All Code-making panels have been asked to review their articles for usability and editorial conformity to this publication, and copies are available from the **NFPA**, Batterymarch Park, Quincy, MA 02269.

The National Fire Protection Association also has organized an Electrical Section to provide the opportunity for **NFPA** members interested in electrical safety to become better informed and to contribute to the development of **NFPA** electrical standards. This new Handbook reflects the fact that the **National Electrical Code** was revised for the 2017 edition, requiring an updating of the previous Handbook, which was based on the 2014 edition of the Code. The established schedule of the **National Electrical Code** Committee contemplates a new edition of the **National**

Electrical Code every 3 years. Provision is made under the rules of procedure for handling urgent emergency matters through a Tentative Interim Amendment Procedure. The Committee also has established rules for rendering Formal (sometimes called Official) Interpretations. Two general forms of findings for such Interpretations are recognized: (1) those making an interpretation of literal text and (2) those making an interpretation of the intent of the **National Electrical Code** when a particular rule was adopted. All Tentative Interim Amendments and Formal Interpretations are published by the **NFPA** as they are issued, and notices are sent to all interested trade papers in the electrical industry.

The **National Electrical Code** is purely advisory as far as the National Fire Protection Association is concerned but is very widely used as the basis of law and for legal regulatory purposes. The Code is administered by various local inspection agencies, whose decisions govern the actual application of the **National Electrical Code** to individual installations. Local inspectors are largely members of the International Association of Electrical Inspectors, 901 Waterfall Way, Suite 602, Richardson, TX 75080-7702. This organization, the National Electrical Manufacturers Association, the National Electrical Contractors Association, the Edison Electric Institute, the Underwriters' Laboratories Inc., the International Brotherhood of Electrical Workers, governmental groups, and independent experts all contribute to the development and application of the **National Electrical Code**.

Brief History of the National Electrical Code®

The **National Electrical Code** was originally drawn in 1897 as a result of the united efforts of various insurance, electrical, architectural, and allied interests. The original Code was prepared by the National Conference on Standard Electrical Rules, composed of delegates from various interested national associations. Prior to this, acting on an 1881 resolution of the National Association of Fire Engineers' meeting in Richmond, Virginia, a basis for the first Code was suggested to cover such items as identification of the white wire, the use of single disconnect devices, and the use of insulated conduit.

In 1911, the National Conference of Standard Electrical Rules was disbanded, and since that year, the National Fire Protection Association (**NFPA**) has acted as sponsor of the **National Electrical Code**. Beginning with the 1920 edition, the **National Electrical Code** has been under the further auspices of the American National Standards Institute (and its predecessor organizations, United States of America Standards Institute, and the American Standards Association), with the **NFPA** continuing in its role as Administrative Sponsor. Since that date, the Committee has been identified as “ANSI Standards Committee C1” (formerly “USAS C1” or “ASA C1”).

Major milestones in the continued updating of successive issues of the **National Electrical Code** since 1911 appeared in 1923, when the Code was rearranged and rewritten; in 1937, when it was editorially revised so that all the general rules would appear in the first chapters followed by supplementary rules in the following chapters; and in 1959, when it was editorially revised to incorporate a new numbering system under which each Section of each Article is identified by the Article Number preceding the Section Number. The 1937 edition also included an introduction for the first time, and many of its most important provisions survive, almost verbatim, in Art. 90 today. That article number, together with much of what is familiar about the Code today, began with the 1959 organizational changes.

In addition to an extensive revision, the 1975 **NEC** was the first Code to be dated for the year following its actual release. That is, although it was released in September of 1974, instead of being called the 1974 Code—as was done for the 1971 and all previous editions of the **NEC**—this Code was identified as the 1975 Code. That's the reason there appears to be 4 years, instead of the usual 3, between the 1971 and 1975 editions. The purpose was to have the named code year agree with the effective dates of adoption in, at least, the early adopting jurisdictions.

Due to the proliferation of premises-owned medium-voltage systems, the 1999 Code notably moved those requirements out of the old Art. 710 and into [Chapters 1](#) through [4](#). The 2005 **NEC** made a notable reorganization of almost all of [Chapter 3](#), resulting in new article numbers for almost every wiring method.

The 2017 edition of the **NEC** continues to modernize in response to developments in the usage of electric power, with five new articles unveiled. Industrial process heating equipment covered in Art. 425 applies to fixed resistance and electrode heating, but only in industrial occupancies. Article 691 covers solar farms with a generating capacity of at least 5000 kW. Article 706 centralizes the requirements applicable to the burgeoning field of on-site electrical storage, including new technologies such as flow batteries. Article 710 will be a central repository for stand-alone system provisions that formerly repeated themselves in other articles, especially Art. 690. Finally, Art. 712 on DC Microgrids will be of use where multiple on-site dc sources such as solar or wind or fuel cells supply functional dc power for utilization.

For many years the **National Electrical Code** was published by the National Board of Fire Underwriters (now American Insurance Association), and this public service of the National Board helped immensely in bringing about the wide public acceptance that the Code now enjoys. It is recognized as the most widely adopted Code of standard practices in the U.S.A. The National Fire Protection Association first printed the document in pamphlet form in 1951 and has, since that year, supplied the Code for distribution to the public through its own office and through the American National Standards Institute. The **National Electrical Code** also appears in the National Fire Codes, issued annually by the National Fire Protection Association.

About the 2017 National Electrical Code®

The trend for very large numbers of proposals for changes and adopted changes in successive editions of the **NEC** has not reversed itself. The 2017 **NEC** is based on 4012 public inputs and 1513 public comments that have resulted in literally hundreds of additions, deletions, and other modifications—both minor and major. There are completely new articles covering equipment and applications not previously covered by the Code. There are also new regulations and radical changes in old regulations that affect the widest possible range of everyday electrical design considerations and installation details.

The process of development of the 2017 **NEC** makes it a watershed edition as **NFPA** looks to an electronic future in terms of standards development. The process has been transformed into one that is largely based on internet transactions. Instead of the former “proposals,” suggestions for **NEC** changes are now styled as “public inputs” (or, if developed at a panel meeting, as “panel inputs”). Paper submittals are still permitted, but the deadline for submittal is significantly shorter than for the preferred electronic submittals. The panels still meet in an open session to consider the inputs, and a two-thirds vote on a subsequent ballot (now submitted electronically) is still required to advance a change in the **NEC**. The result (after the customary Correlating Committee review) is a “First Draft Report” instead of the former “Report on Proposals.” A customary comment period then opens, and as previously, the panels meet again to consider them prior to issuance of a “Second Draft Report” instead of the former “Report on Comments.” This documentation represents the principal source of information relative to the motivation for changes in the Code. This book contains literally thousands of explanations for how Code sections are intended to be applied, and in the vast majority of cases, those explanations were developed from the first and second draft reports, or their predecessors in prior cycles.

The change of title for the reports is of no consequence, but the format is. Both draft reports, as well as all submitted inputs, comments, and related documentation, are only available for review online. **NFPA** does not make these reports available for download, so even printing them out as a collected report (single inputs and actions can be downloaded) from one’s computer is not possible. They can be worked only from an active on-line connection. Another procedural issue relates to the expanded use of task groups prior to the panel meetings under the new process. All public inputs and comments received initial evaluation by appointed task groups comprised of subsets of the panel membership, which met online and through conference telephone calls prior to the meetings. The task groups were not balanced by interest categories, and their reports lacked transparency and frequently had a disproportionate influence on the final results. In general, the task group process was popular because it significantly reduced the workload during the meetings, but has proved problematic in terms of the quality of the final product.

Even the input submittal process is a work in progress. The software is plainly not yet up to the

task. The submittals must be formulated using legislative text with changes underlined and deletions struck out, but frequently the software would underline additional text that was unaffected by the input. As a result, many submitters had to resort to explaining in plain English in the substantiation field exactly what they were intending to change in the text field. The software was also problematic for the panel process, presenting such annoyances as not allowing for carriage returns in a ballot comment. This resulted in carefully crafted, properly punctuated voting comments being posted as a single run-on paragraph, and in addition legislative or other formatting options were unavailable as well. The software also imposed restraints on the length of comments, which meant some were relegated to separate Microsoft Word documents almost impossible for the public to find. In many instances the software carried errors that were difficult to detect in the ballot process due to the presentation, and then into print. Because they, technically, were balloted, a TIA will be required to correct them. The new Art. 425 is a case in point, with no fewer than six missed paragraph divisions spread throughout the article, each having substantive impact and in one case making an entire section unusable. This author awaits future improvements in this process.

Everyone involved in the layout, selection, estimation, specification, inspection, as well as installation, maintenance, replacement, etc., of electrical systems and equipment must make every effort to become as thoroughly versed in and completely familiar with the intimate details related to the individual change as is possible. And, this must be done as soon as possible.

Clearly, compliance with the **NEC** is more important than ever, as evidenced by the skyrocketing numbers of suits filed against *electrical* designers and installers. In addition, inspectors everywhere are more knowledgeable and competent and they are exercising more rigorous enforcement and generally tightening control over the performance of electrical work. Another factor is the Occupational Safety and Health Administration's *Design Safety Standards for Electrical Systems*. That standard, which borrowed heavily from the rules and regulations given in the **NEC**, is federal law and applies to all places of employment in general industry occupancies. Although the OSHA *Design Safety Standards for Electrical Systems* is based heavily on the **NEC**, due to the relatively dynamic nature of the **NEC**, there will eventually be discrepancies. But, for those instances where a more recent edition of the Code permits something that is prohibited by the OSHA standard, OSHA officials have indicated that such an infraction—although still an infraction—will be viewed as what OSHA refers to as a “de minimus violation,” which essentially boils down to no fine. Of course that is not always the case. “Listing” and “labeling” of products by third-party testing facilities is *always permitted but frequently not required* by the **NEC**, but it is made *mandatory* in most places of employment by the Occupational Safety and Health Administration (OSHA) *Design Safety Standards for Electrical Systems*. The OSHA requirement for certification may take precedence over the less stringent position of the **NEC** regarding listing of equipment. The impact of the **NEC**—even on OSHA regulations, which are federal law—is a great indicator of the Code's far reaching effect.

The fact that the application of electrical energy for light, power, control, signaling, and voice/data communication, as well as for computer processing and computerized process-control continues to grow at a breakneck pace also demands greater attention to the Code. As the electrical percentage of the construction dollar continues upward, the high-profile and very visible nature of electrical usage demand closer, more penetrating concern for safety in electrical design and installation. In today's sealed buildings, with the entire interior environment dependent on the electrical supply, reliability and continuity of operation has become critical. Those realities demand not only a concern for eliminating shock and fire hazards, but also a concern for continuity of supply, which is essential for

the safety of people, and, in today's business and industry, to protect data and processes, as well.

And, of course, one critical factor that, perhaps, emphasizes the importance of Code-expertise more than anything else is the extremely competitive nature of construction and modernization projects, today. The restricted market and the overwhelming pressure to economize have caused some to employ extreme methods to achieve those ends without full attention to safety. The Code represents an effective, commendable, and, in many instances, legally binding standard that *must* be satisfied, which acts as a barrier to any compromises with basic electrical safety. It is a democratically developed consensus standard that the electrical industry has determined to be the essential foundation for safe electrical design and installation; and compliance with the **NEC** will dictate a minimum dollar value for any project.

In this Handbook, the discussion delves into the letter and intent of Code rules. Read and study the material carefully. Talk it over with your associates; engage in as much discussion as possible. In particular, check out any questions or problems with your local inspection authorities. It is true that only time and discussion provide final answers on how some of the rules are to be interpreted. But now is the time to start. Do not delay. Use this Handbook to begin a regular, continuous, and enthusiastic program of updating yourself on this big new Code.

This Handbook's illustrated analysis of the 2017 **NEC** is most effectively used by having your copy of the new Code book at hand and referring to each section as it is discussed. The commentary given here is intended to supplement and clarify the actual wording of the Code rules as given in the Code book itself.

Introduction

ARTICLE 90. INTRODUCTION

90.1. Purpose

(A). Practical Safeguarding. The intent of this section is to establish a clear and definite relationship between the National Electrical Code® and electrical system design as well as field installation. Basically stated, the **NEC** is intended only to assure that electrical systems installed in commercial, industrial, institutional, and residential occupancies are safe. That is, to provide a system that is “essentially free from hazard.” The Code (throughout this manual, the words “Code,” “NE Code,” and “NEC®” refer to the **National Electrical Code**) sets forth requirements, recommendations, and suggestions and constitutes a minimum standard for the framework of electrical design. As stated in its own introduction, the Code is concerned with the “practical safeguarding of persons and property from hazards arising from the use of electricity” for light, heat, power, computers, networks, control, signaling, and other purposes.

The **NEC** is recognized as a legal criterion of safe electrical design and installation. It is used in court litigation and by insurance companies as a basis for insuring buildings. The Code is an important instrument for safe electrical system design and installations. It must be thoroughly understood by all electrical designers and installers. They must be familiar with all sections of the Code and should know the latest accepted interpretations that have been rendered by inspection authorities and how they impact the design and/or installation of electrical systems. They should keep abreast of Formal Interpretations, as well as the issues addressed by Tentative Interim Amendments (TIA) that are issued, periodically, by the **NEC** committees. They should know the intent of Code requirements (i.e., the spirit as well as the letter of each provision) and be familiar with the safety issue at the heart of the matter. And, most important, they should keep a copy of the **NEC** and this Code handbook close by for ready reference and repeated study.

The **NEC** is not written for nor intended to be used by untrained individuals. Qualified electricians and engineers spend many years reviewing and thinking about its provisions. It should be noted that the language in Article 90, although considerably embellished over the years, has changed little substantively over the years since this sort of introduction was first presented in the 1937 edition.

(B). Adequacy. It’s worth noting that compliance with the provisions of the **National Electrical Code** can effectively minimize fire and accident hazards in any electrical system. A code-compliant installation will be “essentially free from hazard,” but not absolutely so. This provision is essentially unchanged since the 1937 edition, and has stood the test of time. Many installations with substantial code violations exist for protracted periods of time without loss

experience through good fortune and the fact that protective systems frequently overlap. On the other hand, occasionally a fully compliant installation can fail, usually due to an unforeseen circumstance. Perfect safety is only achievable at infinite cost. Every three years the National Electrical Code Committee wrestles with the concept of “essentially free” as it considers proposed changes to the next edition.

Although the Code assures minimum safety provisions, actual design work must constantly consider safety as required by special types or conditions of electrical application. For example, effective provision of automatic protective devices and selection of control equipment for particular applications involve engineering knowledge above routine adherence to Code requirements. Then, too, designers and installers must know the physical characteristics—application advantages and limitations—of the many materials they use for enclosing, supporting, insulating, isolating, and, in general, protecting electrical equipment. The task of safe application based on skill and experience is particularly important in hazardous locations. Safety is not automatically made a characteristic of a system by simply observing codes. Safety must be designed into a system.

In addition to safety considerations, the need for future expansion and other common sense aspects—such as voltage drop—must be considered and factored into the overall system design. The Code in this section makes it clear that more than Code compliance will be necessary to ensure a system that is not only safe but also functional and capable of providing for future needs, without compromising system-operating continuity or integrity. It is up to the designer and installer, in consultation with the owner, to provide adequate capacity, selectivity, isolation, and protection beyond its minimum requirements in order to achieve the desired system characteristics. Remember, it is always permissible to do more than the Code requires, but *never* permissible to do less than the Code-prescribed minimum.

Addressing voltage drop illustrates these principles. No definite standards have been adopted for the maximum allowable voltage drop in most instances. There is a good reason for this. In most cases, voltage drop is an inefficiency or inconvenience, but it does not rise to the level of a safety hazard. For example, a motor run at 10 percent voltage drop, but with appropriate running overload protection, will have a greatly reduced life span, but not create a shock, fire, or electrocution hazard. The **National Electrical Code** does note, however, in a nonmandatory explanatory note, that if the voltage drop from the point of service entrance to the final outlet does not exceed 5 percent, there will be “reasonable efficiency of operation.” The note also explains that not more than 3 percent voltage drop should occur in the feeder system ahead of the branch-circuit supply points, which leaves the other 2 percent for the branch circuit. In the end, the extent to which voltage drop in an electrical system is to be tolerated is the owner’s decision, because the **NEC** does not mandate design flexibility.

There are some instances, however, where voltage drop does directly bear on safety and the **NEC** contains mandatory rules accordingly. For example, if the conductors to a fire pump are not sized to prevent the voltage drop while starting (i.e., while under locked-rotor conditions) from exceeding 15 percent, measured at the controller terminals, the control contactor for the motor may chatter and not reliably hold in, resulting in a failure to start with disastrous consequences.

(C). Relation to Other International Standards. This section simply states that the **National Electrical Code** addresses the same safety issues addressed by the International Electrotechnical Commission (IEC) Standard for “Electrical Installations of Buildings.” Because the

NEC covers the same consideration for safety as related to protection against electrical shock, protection against thermal effects, protection against overcurrent, protection against fault current, protection against overvoltage, faults between circuits, and so forth that are covered by the IEC Standard, it was considered necessary to establish that fact. This statement in this section facilitates the adoption of the Code by foreign countries and is consistent with the ongoing process of harmonizing the **NEC** and other accepted standards from around the world.

90.2. Scope

(A). Simply stated, the Code applies to all electrical work—indoors and outdoors—other than that work excluded by the rules of part (B) in this section. Installation of conductors and equipment, anywhere on the load-side of the point of connection to the serving utility, must comply with the provisions given in the **NEC**. As of the 2017 **NEC**, the words “and removal” are added after “installation” to reflect that some **NEC** rules require wiring to be removed. For example, 590.3(D) requires removal of temporary wiring upon the completion of its function, and numerous limited energy provisions, such as 800.25, require accessible portions of abandoned wiring to be removed.

The scope of the **NEC** includes the installation of optical fiber cable, part (A). As part of the high-technology revolution in industrial and commercial building operations, the use of light pulses transmitted along optical fiber cables has become an alternative method to electric pulses on metal conductors for data, voice, and video networks, as well as for control and signaling. Although the technology of fiber optics has grown dramatically over recent years, it is still primarily used as a “trunk line” or “backbone” for high-speed networks, while horizontal distribution is generally accomplished via a twisted-pair or coaxial copper medium. Although coaxial cable can handle high rates of data transmission involved in data processing and computer control of machines and processes, optical fiber cables far outperform metallic conductors—even coaxial cable—when it comes to bandwidth as well as cost of materials. (See Fig. 90-1.) **NEC** Art. 770, “Optical Fiber Cables,” covers the installation and use of fiber-optic cables.

A telephone conversation is first transformed into an electrical signal. This input signal is scanned by a digital encoder, which reduces it to a series of “on’s” and “off’s.” The driver, which activates the laser light source, transmits the digital “on’s” as a pulse of light

and the “off’s” as the absence of a pulse. The light travels through the optical fiber cable to its destination, where it is received, amplified, and fed into a digital decoder. The decoder translates the pulses back into the original electrical signal.

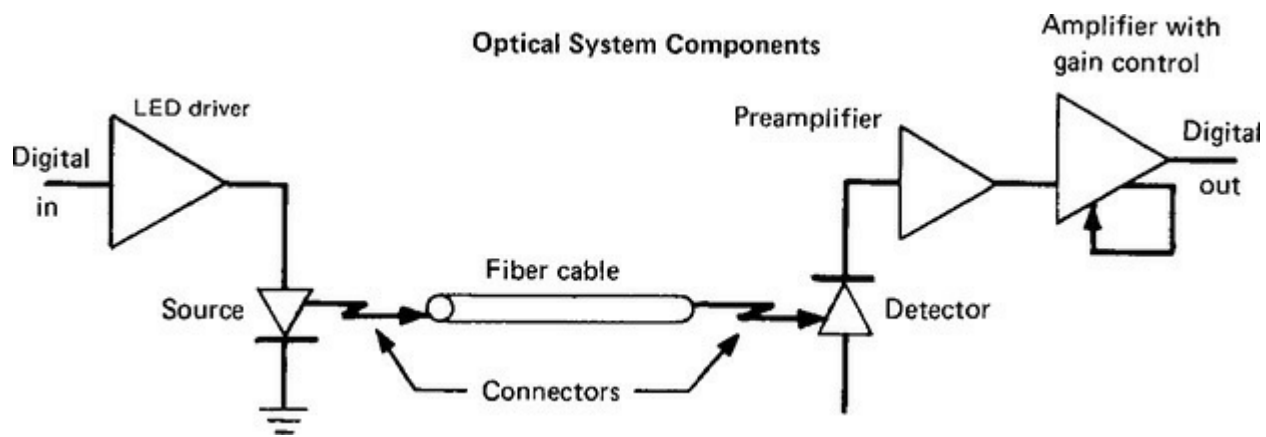

Fig. 90-1. The **NEC** covers the technology of fiber optics for communication and data transmission.

Part (A)(1) provides a laundry-list of specific indoor installations that must be in compliance with the applicable requirements given in the Code. Note that this section makes clear that the **NEC** also applies to “floating buildings” because the safety of Code compliance is required for all places where people are present. Coverage of floating buildings is contained in **NEC** Art. 553.

Part (A)(2) identifies specific outdoor installations, including carnivals and industrial substations, while part (A)(3) mandates that supply equipment and conductors—whether supplied from a utility as a service or from on-site generators as a separately derived system—as well as all other outside equipment and conductors must satisfy the rules and regulations of the **NEC**. Use of the word “equipment” in parts (A)(2) and (A)(3) makes clear that the **NEC** applies to electrical circuits, systems, and components in their manner of installation as well as use.

The following discussion and the discussion in 90.2(B)(5) are very closely related and often hotly debated. Information has been provided from both sides of the discussions as well as the commentary from the Code-making panels (CMPs) where available. The purpose is to allow each designer and installer to make his or her own judgment with regard to how these matters will be resolved based on a full understanding of both sides of the arguments.

Although generally exempt from compliance with the **NEC**, according to 90.2(A)(4) certain utility-owned or -operated occupancies must be wired per the **NEC**. The wording in this section along with the companion rule of 90.2(B)(5) is intended to identify those utility electrical installations that are subject to the rules of the **NEC** and those that are not. Basically stated, any utility occupancy that is not an “integral part” of a “generating plant, substation, or control center” must comply with the **NEC** in all respects. Clearly, any office space, storage area, garage, warehouse, or other nonpower-generating area of a building or structure is not an “integral part” of the generation, transmission, or distribution of electrical energy and therefore is covered by the **NEC**.

There has been discussion and disagreement over the meaning of the phrase, “*not an integral part of a generating plant ... etc.*” Some feel that the phrase “not an integral part of” applies to the process of generation, and so forth. Others believe that it applies to the building. That is, if an occupancy identified in 90.2(B)(4) is part of a generating plant, it is exempt from compliance with the **NEC**. Although that doesn’t seem to make sense, past comments made by the CMP indicate that it is the intent of this rule to exempt, say, office spaces within a generating plant. However, this is not completely clear from the wording used. To prevent any problem with this section, one could choose

to interpret this rule to require **NEC** compliance for any occupancy that is “not an integral part of the process” and wire such spaces in accordance with the **NEC**. Such interpretation cannot be disputed. That is, satisfying the more rigorous **NEC** requirements cannot be construed as a violation. But, if one does not comply, the potential for legal liability exists.

Some may feel that the term *integral part* should be interpreted to mean “integral part of the process” (i.e., generation, transformation, or distribution of electric energy), according to commentary in the **NEC** Committee Reports for the 1987 **NEC**. Others feel that it should be taken to mean an “integral part” of the building or structure. Be aware that the first contention seems more reasonable. That is, just because an office is *in* a generating plant, it shouldn't be exempt from the **NEC**, especially since these areas will be occupied by the general public. And it seems logical that the same should apply to the cafeteria, bathrooms, and other areas within the plant that are not directly related to the task of generating and delivering electrical energy and will be occupied by other than qualified plant electrical personnel.

With that said, it should be noted that the wording here could be read both ways and it will be up to the local authority having jurisdiction (AHJ) to interpret what is and what is not required to comply with the **NEC**.

It should be noted that equipment installed by the utility to perform associated functions, such as outdoor lighting at an outdoor substation, is intended to be considered as an “integral” part to the process and is therefore exempt from compliance with the **NEC** (Figs. 90-2 and 90-3).

Fig. 90-2. *Circuits and equipment* of any utility company are exempt from the rule of the **NEC** when the particular installation is part of the utility's system for transmitting and distributing power to the utility's customers—*provided* that such an installation is accessible only to the utility's personnel and access is denied to others. Outdoor, fenced-in utility-controlled substations, transformer mat installations, utility pad-mount enclosures, and equipment isolated by elevation are typical utility areas to which the **NEC** does not apply. The same is also true of indoor, locked transformer vaults,

or electric rooms (Sec. 90.2). But electrical equipment, circuits, and systems that are involved in supplying lighting, heating, motors, signals, communications, and other load devices that serve the needs of personnel in buildings or on premises owned (or leased) and operated by a utility are subject to **NEC** rules, just like any other commercial or industrial building, provided that the buildings or areas are not integral parts of a generating plant or substation.

Fig. 90-3. Those buildings and structures that are directly related to the generation, transmission, or distribution of energy are intended to be excluded from compliance with the **NEC**. However, the rules covering this matter also indicate that functionally associated electrical equipment—such as the outdoor lighting for the utility-owned and -operated outdoor substation—is also exempt from the **NEC**.

(B). Not Covered. The rules of the Code do not apply to the electrical work described in **(1)** through **(5)**. The most common controversy that arises concerns exclusion of electrical work done by electric utilities (power companies), especially outdoor lighting.

This rule emphatically explains that not all electrical systems and equipment belonging to utilities are exempt from Code compliance. Electrical circuits and equipment in buildings or on premises that are used exclusively for the “generation, control, transformation, transmission, energy storage, or distribution of electric energy” are considered as being safe because of the competence of the utility engineers and electricians who design and install such work. Code rules do not apply to such circuits and equipment—nor to any “communication” or “metering” installations of an electric utility. But, any conventional electrical systems for power, lighting, heating, and other applications within buildings or on structures belonging to utilities *must* comply with Code rules where such places are not “used

exclusively by utilities” for the supply of electric power to the utilities’ customers.

An example of the kind of utility-owned electrical circuits and equipment *covered* by Code rules would be the electrical installations in, say, an office building of the utility. But, in the Technical Committee Report for the 1987 **NEC**, the Code panel for Art. 90 stated that it is not the intent of this rule to have **NEC** regulations apply to “office buildings, warehouses, and so forth that *are* an *integral* part of a utility-generating plant, substation, or control center.” According to comments from the CMP, **NEC** rules would not apply to any wiring or equipment in a utility-generating plant, substation, or control center and would not apply to conventional lighting and power circuits in office areas, warehouses, maintenance shops, or any other areas of utility facilities used for the generation, transmission, or distribution of electric energy for the utility’s customers. But **NEC** rules would apply to all electrical work in *other* buildings occupied by utilities—office buildings, warehouses, truck garages, repair shops, etc., that are in separate buildings or structures on the generating facility’s premises. And that opinion was reinforced by the statements of the CMP that sat for the 1996 **NEC**. With that said, it should be noted that the actual wording used here in the Code could be read both ways and it will be up to the local AHJ to interpret what areas are and what areas are not required to comply with the **NEC**.

The wording used in 90.2(B)(5)(c) recognizes non-**NEC**-complying utility installations “in legally established easements or rights-of-way.” This clearly exempts utility activities on public streets, alleys, and similar areas, even for street and area lighting for adjacent parking lots. However, the 2008 **NEC** deleted the phrase “or by other agreements” from this list. The concern was that this provision opened the door to utility noncompliance throughout a facility, provided an agreement could be struck with the owner and ratified by the governmental authority having jurisdiction over utility practice. Because utilities are governed by the National Electrical Safety Code (NESC), whose provisions are entirely inappropriate for premises wiring, this concern is not inconsequential.

In the 2011 version, an elaborate compromise was struck that addressed numerous areas where formal easements are impractical, including federal lands and military bases, Indian reservations, railroad property, and state agencies, departments, and port authorities. This successfully covered many instances where the removal of the “other agreements” permission caused problems. Its list of governmental entities that are unique to the United States may, unfortunately, create adoption issues in foreign jurisdictions in which the **NEC** is or may in the future be adopted.

However, the change remains extremely controversial because it has the potential to unravel over a century of established precedent regarding site lighting by utilities, where all of the work is on the line side of any service point, or where there is no service point whatsoever, as illustrated in [Fig. 90-4](#). Virtually, every electric utility has permission to supply outdoor lighting according to rates established by the governing authority, and that lighting need not be in a public way or in an easement, provided it is not premises wiring. The key to understanding the problem is the concept of a service point, defined in Art. 100. The NESC applies on the supply side of service points, where they exist. The **NEC** applies on the load side of service points, where they exist. It is instructive to review the premises underlying the 2005 **NEC** language.

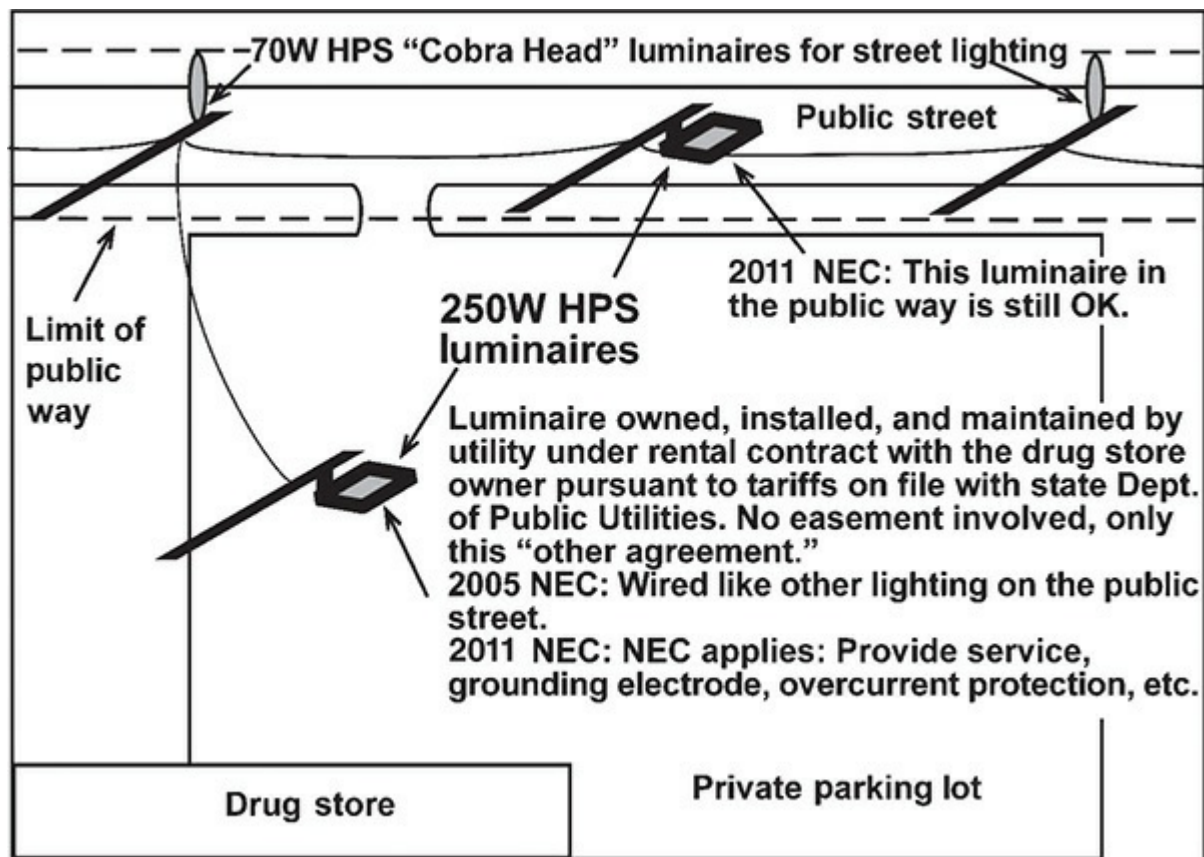

Fig. 90-4. This drawing shows an actual example of a practice that is widespread throughout the United States and many other countries. There is no service point, the parking lot luminaire is not premises wiring, and the maintenance will be performed by a utility line crew in the same bucket truck as services the street lighting, at the same time. The drug store is, in effect, buying the 27,500-lm output from each of the two 250-W high-pressure sodium (HPS) lamps. The **NEC** purports to claim jurisdiction over this portion of the parking lot lighting.

The entire premise behind allowing the **NESC**, substantially different from the **NEC**, to apply to utility work is a simple one: The organizational permanence, engineering supervision, and workforce training in the utility environment are fundamentally different than for premises wiring. Therefore, different standards can be applied to installations under their exclusive control. Whether this also applies to an Energy Service Company (ESCO) doing maintenance under contract with the utility is a regulatory matter that will depend on the degree of command and control exercised by the regulated utility.

Area lighting wired to the **NESC** will lack local disconnects, specific overcurrent protection, and separate equipment grounding conductors, for just a few examples. Is this a safety issue if a utility line crew does the maintenance? Apparently not, given the ubiquitous presence of street lighting wired this way. Would it be a safety issue if it were premises wiring, maintained by others?

Certainly, given that the **NEC** has never allowed such practices over its long history. The fact that these two statements are self-evidently both true leads to this conclusion: You cannot write and apply installation rules without taking the operational context into account. The **NEC** does exactly the same thing over and over again when it creates special exceptions and allowances for work that will be performed under qualified maintenance and supervision.

Part (C) gives the AHJ the discretion to permit other than "utilities" the option to install conductors between the utility supply and the service conductors for individual buildings without

complying with the **NEC**. Any such waiver is limited to outdoor portions of the electrical installation, or to conductors inside a building but only to the extent necessary to terminate at the nearest readily accessible point to where the conductors enter the building. And as discussed at 230.6(5), as soon as wiring penetrates the outer membrane of a building, whether or not it has fully entered occupied space, it is inside the building for code enforcement purposes. Essentially, it allows the inspector to permit the use of another standard such as in the utilities code, the NESC. Such permission is typically limited to campus-type environments where the utility supply to the premises is medium-voltage and distribution to, and between, buildings is installed and maintained by on-site personnel. It's worth noting that any such permission granted by the AHJ must be *written* permission to satisfy the definition of "special permission," as given in Art. 100. Today, however, such occupancies frequently take service at an elevated voltage at a central point, and all the medium-voltage feeders to serve the buildings are just that, feeders. As soon as the service point becomes a central medium-voltage switch, this provision can no longer be applied to the individual buildings.

There are far more mundane uses for this permission. Many CATV (see Art. 820) companies rely on powered amplifiers mounted near the top of utility poles to keep their signal strength where it needs to be. Those amplifiers will have a small disconnect and overcurrent protective device located adjacent to the amplifiers. There are no provisions within the body of the **NEC** that allow for a service disconnect to be located at such a location, which is certainly not readily accessible. However, the entire installation is confined to the pole top, and special permission under 90.2(C) is routinely granted in such cases.

90.3. Code Arrangement. This section provides guidance on which rule takes precedence where two rules covering a particular installation are at odds. Basically, the rules in **Chaps. 1** through **4** apply at *all* times, except for installations covered by **Chap. 8**, which stands alone. Installations covered by **Chaps. 5, 6, and 7** must always comply with the requirements given in **Chaps. 1** through **4**, *unless* a specific rule in **Chaps. 5** through **7** requires or permits an alternate method. One implication of this principle is that exceptions in **Chaps. 1** through **4** that allow for different procedures in **Chaps. 5** through **7** are unnecessary. The **NEC** Style Manual has been rewritten to take this into account, and such exceptions are disappearing from the **NEC** for this reason. Provisions in **Chaps. 1** through **7** of the **NEC** only apply in **Chap. 8** when a **Chap. 8** article specifically cites them, and the numbers of such citations in **Chap. 8** articles are steadily increasing for this reason. **Chapter 9** consists of tables that are mandatory, but only applicable as referenced in earlier articles. The graphic provided in this section facilitates understanding of the relationship between various Code chapters.

As of the 2017 **NEC**, there is permission granted for **Chaps. 5, 6, and 7** articles to modify not just **Chapters 1** through **4**, but to modify **Chapters 5** through **7** as well. This may appear to be of no great effect, but it will prove problematic until inevitable conflicts are sorted out. For example, 517.30(G) relaxes selective coordination rules on essential electrical systems in hospitals. These systems include life-safety systems, which are also within the scope of Article 700, which for its part has extremely strict requirements. Under this rewrite of 90.3, it is arguable whether 517.30(G) amends 700.28, or vice versa. In this particular case, where the Art. 517 provision is there at the direction of the **NFPA** Standards Council following action in a different **NFPA** Technical Committee, the ultimately enforceable test is in Art. 517. However, other conflicts will be harder to resolve without clarifying actions in subsequent Code cycles.

90.4. Enforcement. This is one of the most basic and most important of Code rules because it

establishes the necessary conditions for use of the Code.

The **NEC** stipulates that when questions arise about the meaning or intent of any Code rule as it applies to a particular electrical installation, including signaling and communication systems covered by **Chap. 8**, the electrical inspector having jurisdiction over the installation is the only one authorized by the **NEC** to make interpretations of the rules. The wording of Sec. 90.4 reserves that power for the local inspection authority along with the authority to approve equipment and material and to grant the special permission for methods and techniques that might be considered alternatives to those Code rules that specifically mention such “special permission.”

It should be noted that any deviation from standard Code enforcement *must be* done in accordance with the provisions given in Art. 100 by the definition of “Special Permission.” The most salient requirement is the need for documentation. That is, in order to comply with the definition of “special permission,” such permission must be in writing. This will serve to provide a written record of the circumstances surrounding the granting of a waiver.

The **NEC** permits the electrical inspector to “waive specific requirements” or “permit alternate methods” in any type of electrical installation. In residential, commercial, and institutional electrical systems—as well as in industrial—inspectors may accept design and/or installation methods that do not conform to a specific Code rule, provided they are satisfied that the safety objectives of the Code rule are achieved. In other words, there must be a finding of equivalent safety before the permission is granted, and the permission to deviate from them must be provided in writing as required by the first sentence of the second paragraph in this section and stated by the definition of “special permission” given in Art. 100 (**Fig. 90-5**).

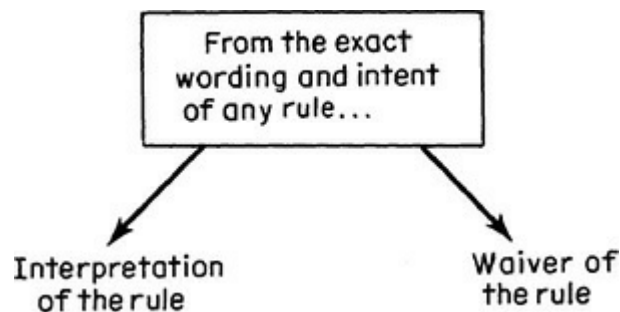

Fig. 90-5. *Inspector’s authority* may be exercised either by enforcement of that individual’s interpretation of a Code rule or by waiver of the Code rule when the inspector is satisfied that a specific non-Code-conforming method or technique satisfies the safety intent of the Code. (Sec. 90.4.)

This recognition of practices at variance with the Code is provided only for special conditions and must not be interpreted as a general permission to engage in non-Code methods, techniques, or design procedures. In fact, it is likely that inspectors will exercise this authority only with reluctance and then with great care, because of the great responsibility this places on the inspector. This is especially true because such permission may only be granted in writing. Clearly, this requirement for documentation will give many inspectors pause for reflection and reconsideration. It seems almost certain for the exercise of this prerogative.

This section also covers instances when the **NEC** has changed and new products are not yet available in the local market to comply with the revised terms. The AHJ may, but is not required to, permit the use of previously compliant products.

90.5. Mandatory Rules and Explanatory Material. This section provides guidance regarding proper application of the **NEC**. Although the **NEC** consists essentially of specific regulations on details of electrical design and installation, there is much explanatory material in the form of notes to rules.

Part **(A)** of this section addresses “mandatory” rules, which typically employ the phrases “shall” or “shall not.” Compliance with the Code consists of satisfying all requirements and conditions that are stated by use of the word “shall” or “shall not” where used in the body of a Code rule or exception. Those words, anywhere in any rule or exception, designate a mandatory rule. Failure to comply with any mandatory Code rule constitutes a “Code violation.”

Part **(B)** of this section indicates the wording that is used in “permissive rules.” These rules are typified by the use of phrases such as “shall be permitted” or “shall not be required.” Such rules typically provide or accept alternate measures or suspend requirements under certain conditions. It is not necessary to do what these rules permit; it is essentially an optional approach.

Note that under the provisions of the **NEC** Style Manual, the word “may” is not to be used to set forth a permissive rule. When “may” is being used to indicate permission, it can only be used in the context of a discretionary action of the authority having jurisdiction. For example, **NEC** 430.26 authorizes, but does not require, an AHJ to permit the application of a demand factor to the loads on a motor feeder being sized under 430.24. This is an excellent example of the appropriate use of the word, as in “... the authority having jurisdiction may grant permission for feeder conductors”

Part **(C)** explains that informational notes [formerly called “fine-print notes” (FPNs), a change that has been applied throughout the **NEC** as of the 2011 edition] are included, following certain Code rules, to provide additional information regarding related rules or standards. This information is strictly advisory or “explanatory” in nature and presents no rule or additional requirement. The same is true for bracketed information that references other NFPA[®] standards. The inclusion of the referenced standard is to inform the reader of the origin of “extracted text,” where that text is taken from an **NFPA** standard. However, the reference to another **NFPA** standard in no way makes the referenced standard part of the Code; nor does such reference oblige compliance with other rules in the referenced standard. Informational notes explain **NEC** rules, they do not change **NEC** rules. If, in reading an informational note, it appears to allow or require something different from the rule that precedes it, then you are misreading the rule and you should read the rule again.

Part **(D)**, as of the 2011 edition, covers the annexes at the end of the **NEC**, changing their titles to include the word “Informative.” This paragraph, in concert with the terminology change regarding informational notes, attempts to clarify a distinction between actual rules and merely informative text providing background or interpretive assistance.

90.6. Formal Interpretations. Official interpretations of the **National Electrical Code** are based on specific sections of specific editions of the Code. In most cases, such official interpretations apply to the stated conditions on given installations. Accordingly, they would not necessarily apply to other situations that vary slightly from the statement on which the official interpretation was issued.

As official interpretations of each edition of the Code are issued, they are published in the *NFPA News*, and press releases are sent to interested trade papers.

All official interpretations issued on a specific Code edition are reviewed by the appropriate CMP. In reviewing a request for a formal interpretation, a Code panel may agree or disagree. The

panel will render a simple “yes” or “no” to the question, which places the burden on the questioner to provide a question that can be answered in the affirmative or negative. At some point in future Codes, the CMP might clarify the Code text to avoid further misunderstanding of intent. On the other hand, the Code panel may not recommend any change in the Code text because of the special conditions described in the request for an official interpretation. For these reasons, the **NFPA** does not catalog official interpretations issued on previous editions of the Code within the Code itself. Such Formal Interpretations can be obtained through the National Fire Protection Association®.

Under **NFPA** rules, Formal Interpretations require a four-fifths vote, which can easily result in sufficient dissent to preclude their issuance. They are issued on a specific edition of a standard, and are retained until the wording to which they applied changes. In addition, when a Formal Interpretation is issued, the technical committee (in this case a CMP) is encouraged (but not required) to review the disputed text that provoked the request for interpretation when it processes the next edition. A classic example of a Formal Interpretation, on the text of the 1978 **NEC**, asked whether reinforcing steel in a concrete foundation was “available” for connection after the concrete had hardened. It was common for inspection authorities in Florida at the time to insist that footings be jackhammered and connections be made so as to bring these concrete-encased electrodes into the grounding electrode system. The panel’s answer was “No” and that interpretation retained its validity until the 2005 **NEC** changed the word “available” to “present” in what is now 250.50.

It should be remembered that, according to 90.4, the authority having jurisdiction has the prime responsibility of interpreting Code rules in its area and disagreements on the intent of particular Code rules in its area; and disagreements on the intent of particular Code rules should be resolved at the local level if at all possible. A Formal Interpretation is not really a viable avenue for a couple of reasons. One is the amount of time it will take for the CMP to render its decision, which is generally months. The other is that even if you request a Formal Interpretation and the CMP agrees with your application, there is no guarantee that the authority having jurisdiction will accept the findings of an official interpretation, nor is it required to do so.

Although this section deals with Formal Interpretations, it should be noted that changes in the Code are promulgated in a very similar manner. That is, changes to Code rules are generally precipitated by a request for change from the field. Guidance for submittal of a Code change is provided closely following the Index in the back of the Code.

90.7. Examination of Equipment for Safety. It is not the intent of the **National Electrical Code** to include the detailed requirements for internal wiring of electrical equipment. Such information is usually contained in individual standards for the equipment concerned. Note that Annex A at the end of the Code book includes the recognized product standards that the testing laboratories use to evaluate the products for which **NEC** rules require listings.

The last paragraph does not intend to take away the authority of the local inspector to examine and approve equipment, but rather to indicate that the requirements of the **National Electrical Code** do not generally apply to the internal construction of devices that have been listed by a nationally recognized electrical testing laboratory. Indeed, the last sentence (new as of the 2017 **NEC**) goes on to require that the testing lab must design its testing protocol in ways that are compatible with the **NEC**, and the third informational note following specifies that Informative Annex A lists only product standards so conceived.

Although the specifics of Code rules on examination of equipment for safety are presented in 110.2

and 110.3, the general Code statement on this matter is made here in 90.7. Although the Code does place emphasis on the need for third-party certification of equipment by independent testing laboratories, it does not make a flat rule to that effect. However, the rules of the U.S. Occupational Safety and Health Administration (OSHA) are very rigid in insisting on product certification.

Codes and standards must be carefully interrelated and followed with care and precision. Modern work that fulfills these demands should be the objective of all electrical construction people.

90.8. Wiring Planning. These two sections address concepts that are essentially design oriented. Part (A) alerts the reader to the fact that simply designing to Code-mandated minimums will not provide for any future expansion. Additional capacity in raceways, boxes, enclosures, and so forth, should be considered, but spare capacity is not required. Part (B) points out the fact that minimizing the number of circuits within any given enclosure will minimize the consequences of a fault in one or more of those circuits. Additionally, extra room in your raceways (i.e., fewer conductors than the maximum permitted) will also facilitate pulling of the conductors into the raceway. Again, providing extra room in raceways or limiting the number of circuits is only required as indicated elsewhere in the Code (e.g., 314.16 on box fill).

90.9. Metric Units of Measurement. Part (A) identifies metric measurements as the preferred measurement, although English units (i.e., inch-pounds-feet) are also provided as indicated by part (B).

In part (C), the Code discusses when one is required to use a “soft” conversion and where a “hard” conversion is permitted. A “soft conversion” is direct mathematical conversion, for example, $1\text{ m} = 39.3\text{ in.}$; a “hard conversion” is more practical, for example, $1\text{ m} = 3\text{ ft.}$ It may seem counterintuitive to have a “hard” conversion as the inexact conversion. Another way to express the concept is that a hard conversion is the conversion a hard-core metric user would do, that is, use a round number for his or her metric measurement. The various explanations that follow in the **NEC** at this point regarding “hard” and “soft” conversion are primarily aimed at CMPs. They must make the decisions around which metric unit would unacceptably degrade safety, or cause wholesale changes in industry specifications. For example, CMP 9 used soft conversions in Table 314.16 because hard conversions would result in every steel box being at variance from **NEC** provisions, not by much, but enough to force extensive redesign of manufacturing facilities with no real safety benefit. CMP 1 made the decision that reducing the minimum workspace width in front of a panel from 762 mm (the soft conversion from 30 in.) to 750 mm (the hard conversion) would unacceptably degrade safety, and so that dimension has been retained as a soft conversion.

The rule of part (D), Compliance, addresses the coexistence of the two systems of measurement. There the Code states that use of either SI or English units “shall constitute compliance with this Code.” Clearly, designers and installers may use either of the designated values. However, it should be noted that only one, or the other units of measure should be used throughout a given project. Inspectors have raised objection to mixing and matching units of measure.

Chapter One

ARTICLE 100. DEFINITIONS

The **NEC** reserves Art. 100 to cover the essential definitions required to properly apply its provisions. Not included are general terms that are commonly defined, or technical terms that are used in the same way as in related codes and standards. In addition, if a term is used in only one article, it will be defined within that article and not in Art. 100. Part I of the article applies throughout the **NEC**; Part II covers definitions that apply only to installations operating over 600 V, nominal. Consult Art. 100 if you are unclear as to how a specialized electrical term is defined that appears in the NEC.

The 2017 **NEC** began a new practice of calling out the responsible code making panel for each definition. The Correlating Committee, many cycles previous, began assigning actions on specialized definitions to the various panels based on specific expertise. Now these assignments will be transparent to code users.

The Code Making Panel responsible for the requirements in hazardous (classified) locations (CMP-14) is responsible for a group of articles at the beginning of [Chap. 5](#). In the past, relevant definitions were set out in [Chap. 5](#), usually but not exclusively in 500.2. This meant that the same term would commonly appear in at least two articles. Following an instruction from the Correlating Committee for the 2017 cycle, based on the **NEC** Style Manual but frankly regardless of impact on user friendliness, all such terms are now defined in Article 100. For terminology needing additional explanation, this handbook will continue to address them in their operational locations in [Chap. 5](#). For a summary, refer to Table 100-1 in this handbook located at the end of its coverage of Article 100. Most of the relocated definitions include the following qualifying phrase in their titles: “[as applied to Hazardous (Classified) Locations]” in an attempt to clarify the limited scope of their coverage. However, as noted in Table 100-1, some do not have that qualification.

Accessible (as Applied to Wiring Methods):

Accessible (as Applied to Equipment):

Accessible, Readily (Readily Accessible):

The best way to look at these definitions is to consider all three at the same time because although they are necessarily related, there are important differences. Each of the three terms involves the concept of unimpeded approach. That is, accessible items, whether wiring methods, equipment, or either of these, if readily accessible, must be capable of unimpeded approach as required, but that is about the extent of what these terms have in common.

Wiring methods are accessible if they can be removed or exposed without damaging the building finish or structure. Wiring methods are any of the NEC-recognized techniques for running circuits between equipment, as covered in the articles in [Chap. 3](#) of the Code. Wiring methods are also accessible if they are not permanently closed in by the building structure or finish. Any surface wiring method would obviously qualify if in plain view, but what about above a suspended ceiling? The definition uses the word “exposed,” which is also defined in Art. 100 as being on or attached to the surface, or behind panels designed to allow access. Because suspended ceiling panels are clearly designed for that purpose, wiring such as that shown in [Fig. 100-1](#) above a suspended ceiling is exposed, and because it is exposed, it is also accessible.

Fig. 100-1.

The same word used to describe equipment does not mean quite the same thing. *Equipment* covers all the products that are connected or hooked up by a recognized wiring method, together with the other components of the wiring system. Equipment *is accessible* if it allows close approach. It is not accessible if it is guarded by a locked door or by height or other barrier that effectively precludes approach by personnel. The word *guarded* is also defined in Art. 100, and it means protected by any of various means to remove the likelihood of “approach or contact by persons or objects to a point of danger.”

Consider the busbars in a panelboard located chest high in a corridor, and then think about the panelboard itself, including its enclosing cabinet. Are the busbars themselves “accessible”? No, because they are guarded by the deadfront. Is the panel accessible? Yes, the deadfront makes it safe to approach, and nothing about its location precludes approach. What if the panelboard is for a tenancy, and is located in another tenancy for which access to the supplied tenancy is forbidden? Such a panel would still be accessible, but not to those for whom access is required by the NEC.

This brings us to the final concept, *readily accessible*. This term also applies to equipment, and requires access without climbing over or removing obstacles, or arranging for a ladder or lift to reach the equipment, as covered in [Fig. 100-2](#). Equipment in the open and reachable only by ladder is probably accessible, but could never be considered “readily accessible.” Overcurrent (OC) devices are usually required to be readily accessible, but what about a fused switch on an air-conditioning compressor high in the air? This is the reason for the special allowance in 240.24(A)(4). It is

understood that such equipment is not readily accessible, and a special allowance permits it to be so. Figure 100-3 shows other examples of these special allowances.

Fig. 100-2.

Fig. 100-3.

The 2014 **NEC** first included the concept that the use of tools as a requisite to access disqualified a location as being readily accessible. This was a logical extension of the overall concept of ready access. After all, if local conditions require that those for whom ready access is intended must first find and then operate tools, the inherent delays would likely defeat the purpose. Unfortunately, the sentence structure could have been read to simply require that the location allow for appropriate tools to be used. This has been corrected as of the 2017 **NEC**. The 2017 **NEC** also adds “or under” after “to climb over” which may require some discussion with the inspector regarding when an overhead obstruction is low enough to disqualify the access.

There is one other provision in the ready access definition that neatly ties some of the key concepts together. Readily accessible equipment must be reachable quickly by those for *whom ready access is requisite*. This pointedly does not mean everyone. A locked electrical room is a very well-understood concept, and perfectly acceptable as long as those who belong in the room have a key. The 2017 **NEC** clarified this by adding the parenthetical note “(other than keys)” to the tool restriction, and then adding an informational note that expressly addresses these concepts.

Adjustable Speed Drive (and System):

These two definitions used to be located in Article 430, and were moved to Article 100 in the 2014 cycle in order to apply in both Article 430 and Article 440. The informational note between them properly removes some of the text from the former definition location and reformats it as explanatory material.

Ampacity:

Ampacity is the maximum amount of current in amperes that a conductor may carry continuously under specific conditions of use without exceeding the temperature rating of its insulation. The word “ampacity” is actually a made-up word that does not appear in normal dictionaries and that was first formally defined in the 1965 edition of the **NEC**. It should be thought of as a logical combination of “amperes” and “capacity.” Refer to the discussion on **NEC** 310.15 in [Chap. 3](#) of this book, together with coverage at the end of this book on Annex D, Example D3(a), for a detailed analysis of ampacity calculations. The calculation of conductor ampacities is one of the most important skills to be learned in the electrical trade, and unfortunately it is also one of the most complicated. There are two key points to raise here, however, in terms of the actual content of the definition.

First, ampacity applies to electrical conductors. Other parts of an electrical system may have current ratings, such as switches, circuit breakers, and motor contactors, but only electrical conductors have an ampacity. Second, ampacity in its true sense cannot be defined by a table in a code book, or even a hundred tables. Every condition of use defines a different ampacity. And every time a condition changes, such as when the ambient temperature changes, the applicable ampacity changes. For example, 12 AWG THHN has an allowable ampacity of 30 A at 30°C with three (or fewer) current-carrying conductors in a raceway. Raise the number of current-carrying conductors in the raceway, or raise the ambient temperature, or both, and the ampacity will decrease by varying degrees, all based on the conditions of actual use.

Approved:

Identified (as Applied to Equipment):

Listed:

These three definitions are covered together in one location, because they cover the three methods of product acceptance recognized by the **NEC**. They are crucial to the proper application of the Code. Code-making panels (CMPs) have robust discussions every code cycle about which one to apply in a given situation.

The word *approved* means acceptable to the inspectional authority [technically, the authority having jurisdiction (AHJ)], and nothing more or less. It does not mean “identified” unless the inspector chooses to use compliance with the definition of “identified” as the basis for his or her decision. Similarly, it does not mean “listed” unless the inspector chooses that standard as the basis for his or her decision. For this reason, any statements in product literature (and they are common) that something is “approved” by some testing laboratory are necessarily fallacious. A product may be listed by a testing laboratory, but never approved.

The word *identified* is routinely confused with the normal usage in the English language of the word *marked*. It does not mean marked. It means what Art. 100 says it means. It means generally recognizable as suitable for the specific application called out in the **NEC** requirement. This often comes from product literature generated by manufacturers. This use of the term also correlates with the informational note in 100.3(A)(1), where suitability is explained first in terms of “a description marked on or provided with a product to identify the suitability of the product for a specific purpose, environment, or application.” The note goes on to indicate that suitability may also be evidenced by listing or labeling, an additional possibility.

For an example of correct usage of this term in a Code rule, the **NEC** requires two-winding transformers reconnected in the field as autotransformers to be *identified* for use at elevated voltage in 450.4(B). These transformers are frequently listed, but as two-winding transformers. They could not be listed as autotransformers because they do not leave the factory this way, and they have wide application as two-winding transformers. A listing would be excessive because the transformer manufacturers would have to run two production lines with two different labels for the same product. The installer needs to rely on product literature from the manufacturer to verify suitability for reconnection, and fortunately, these manufacturers all provide specific information on how to make the reconnections so the transformers will buck or boost the voltage as desired.

The word *listed* covers the most specific method of product acceptance, because it means that a qualified testing laboratory, usually with testing facilities that an inspector could not possibly duplicate, has performed exhaustive tests to judge the performance of the product under the conditions contemplated in a specific Code rule. The Code note that follows the definition needs some explanation as well. Although the note is written in a general and explanatory manner, in fact, all qualified testing laboratories operating under the current North American electrical safety system do require a label as evidence of the listing. It follows, then, that if a label falls off, the product no longer has the status of being listed. Further, the only way a label can be reapplied is in the presence of an employee of the testing laboratory. Sending labels through the mail is not an option and will result in disciplinary action against the manufacturer by the testing laboratory. The testing laboratories will all send personnel into the field to witness the reapplication of labels.

Be aware that OSHA rules governing workplaces generally require a “listed,” “labeled,” or otherwise “certified” product to be used in preference to the same “kind” of product that is not recognized by a national testing lab (Fig. 100-4). UL is beginning to use the word “certified” (undefined in the **NEC**) as a synonym for “listed” because the term is more widely recognized in international commerce. See Fig. 100-25(c). As of now, the defined term of art in the **NEC** remains “listed.”

Fig. 100-4.

Arc-Fault Circuit Interrupter (AFCI):

These are devices designed to protect against arcing failures by recognizing the unique electrical characteristics of the arc and opening the circuit when damaging arcs are present. The definition is not new, but was relocated from 210.12 in the 2011 cycle.

Authority Having Jurisdiction (AHJ):

This definition clarifies the meaning of this term, which is used repeatedly throughout the Code. As indicated by the informational note, the authority having jurisdiction (AHJ) is not necessarily the electrical inspector. In some instances, it may be the head of a fire department or an insurance company representative.

Most jurisdictions have procedures in place that allow for taking an appeal from an adverse decision of an inspectional authority. However, there are inevitable trade-offs in terms of time lost in such a proceeding, so usually only the most compelling instances end up in appellate hearings.

Bathroom:

As defined here and used in the rule of 210.8, a *bathroom* is “an area” (which means it could be a room or a room plus an adjacent space that constitutes a collective area), that contains first a “basin” (usually called a *sink*) and then at least one more plumbing fixture—a toilet, a tub, and/or a shower. A small room with only a basin (a “washroom”) is not a bathroom. Neither is a room that contains only a toilet and/or a tub or shower (Fig. 100-5). The 2011 **NEC** added more examples of plumbing fixtures, including showers, urinals, bidets, and then the catch-all wording “similar plumbing fixtures.” Figure 100-6 shows applications in hotel and motel bathrooms.

GFCI-protected receptacles are required ...

THIS IS HOW
A "BATHROOM" IS DEFINED

NOTE: If a room is not a bathroom according to the definition, then the requirement of 210.52(D) for "at least one receptacle outlet... within 900 mm (3 ft) of the outside edge of each basin" does not apply. If, however, a receptacle is installed in a room that is not a bathroom, such as the one to the left that only contains a toilet or the one in the center with a toilet and a tub, GFCI protection is not required. A receptacle in the room to the right with a sink does not require GFCI protection unless it is within 6 ft of the sink, where it will be required under a different rule.

... In a "bathroom" of a dwelling unit...

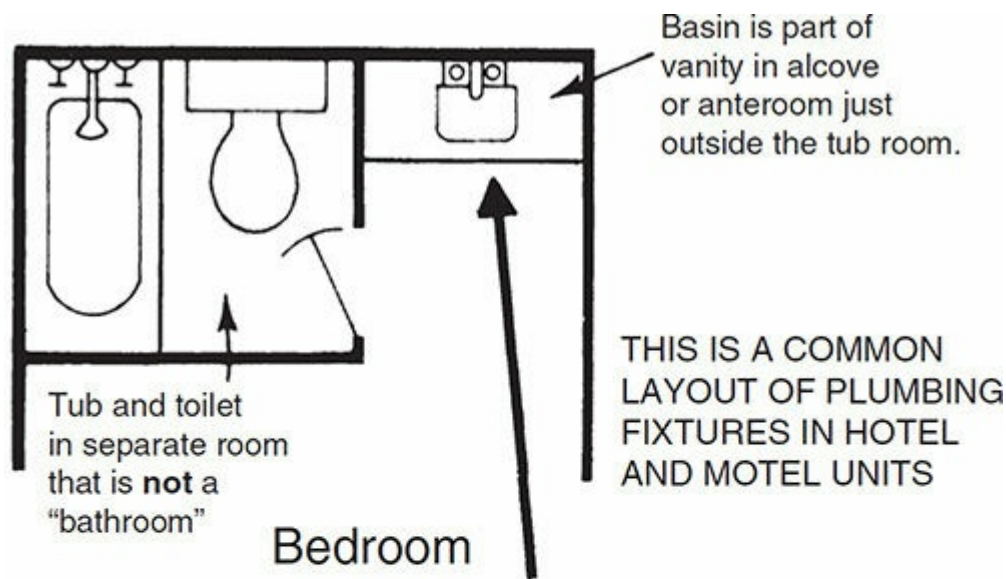

TYPICAL BEDROOM SUITE IN ONE-FAMILY HOUSE OR APARTMENT UNIT

Although this area with basin is **outside** the room with tub and toilet, the intent of 210.52 requires a receptacle at basin; and 210.8(A) requires that it be GFCI-protected.

NOTE: It is important to understand that the *Code* meaning of "bathroom" refers to the total "area" made up of the basin in the alcove *plus* the "room" that contains the tub and toilet. A receptacle is *not* required in the "room" with the tub and toilet. If one is installed in that room, it must be GFCI-protected because such a receptacle is technically "in the bathroom," just as the one at the basin location is "in the bathroom."

Fig. 100-5.

Guest rooms or suites in hotels and motels are required by 210.60 to have the same receptacle outlets required by 210.52 (A) and (D) for "dwelling units." The requirement for a wall receptacle outlet at the "basin location" applies to bathrooms; and the anteroom area with only a basin is, by definition and intent, part of the "bathroom." Where a guest room or suite has permanent cooking facilities, all receptacle requirements in 210.52 must be satisfied.

... and in a "bathroom" of a hotel/motel guest room.

Fig. 100-6.

Battery System:

These comprise storage batteries and chargers, at a minimum, and can also include electrical power-processing equipment such as inverters and converters and related control equipment. The definition was relocated from Article 480, and in addition to that article it is also used in Articles 517, 690, 694, 700, and 701.

Bonded (Bonding):

This definition has been simplified and now simply covers the connection of parts in an electrical system to provide continuity and conductivity. This is one of the many definitions and other rules that were impacted by a special task group on grounding and bonding. The definitions have been simplified and the requirements placed in Art. 250, with only special exceptions remaining in other parts of the NEC. The performance criteria for a bonded connection are covered in 250.4.

Bonding Conductor or Jumper:

This is the means of connection between noncurrent-carrying metallic components of the electrical system that are provided to ensure continuity. Examples of bonding jumpers are given in [Figs. 100-7](#) and [100-8](#). They may be bare, covered, or insulated conductors, or it may be a mechanical device, such as the 10-32 screws often provided to connect a neutral terminal bar to a service enclosure.

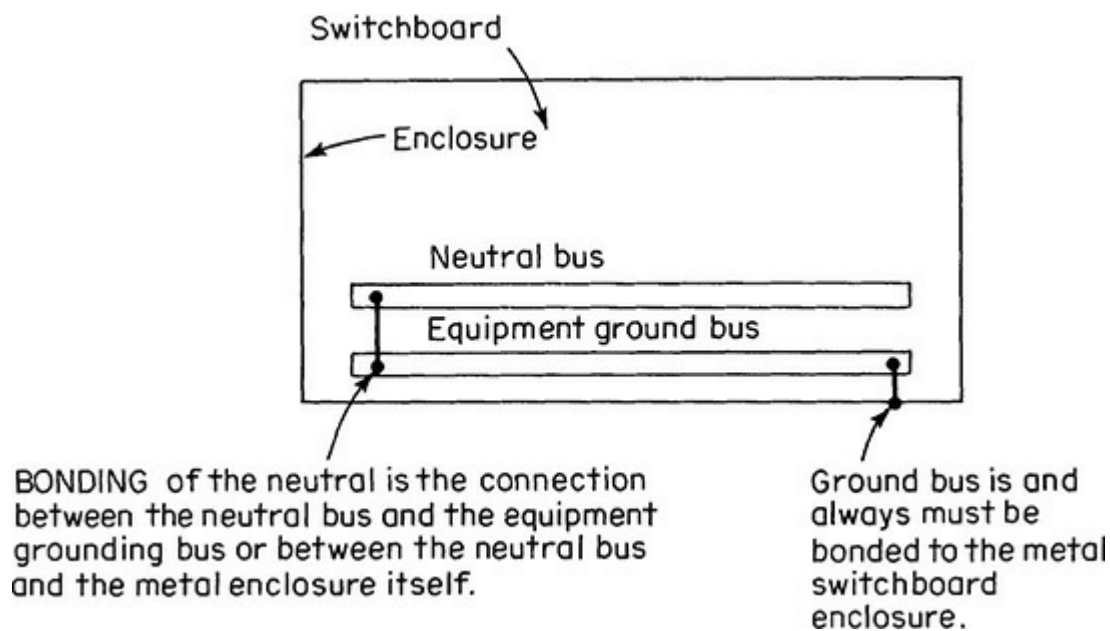

Fig. 100-7.

NOTE: Bonding – the connection of the neutral terminal to the enclosure or to the ground terminal that is, itself, connected to the enclosure – might also be done in an individual switch or CB enclosure.

Fig. 100-8.

Bonding Jumper, Equipment:

These are bonding connections made between two portions of the equipment grounding system. For example, bonding jumpers are routinely used to ensure an electrically conductive connection between a metal switchboard enclosure and metal conduits entering the open bottom from a concrete floor. If [Fig. 100-9](#) depicted a feeder and not a service, the jumpers from each conduit to the enclosure frame would be equipment bonding jumpers.

Fig. 100-9.

Bonding Jumper, Main; System:

A main bonding jumper provides the Code-required connection between the grounded system conductor and the equipment ground bus at the service equipment for a building or structure. The connection between equipment ground and the grounding electrode system in ungrounded services is a “bonding jumper,” but not a “main bonding jumper.” The connection between the equipment ground bus and the neutral bus in the drawing shown in Fig. 100-9 is an example of a main bonding jumper. The NEC maintains a distinction between a main bonding jumper and the same conductor performing the identical function at a separately derived system, which is a *system bonding jumper*. This definition has been relocated from 250.2 to here because it is also used in 708.20(C) Exception, which creates the required second article reference for an Art. 100 definition. Note that the connection may also occur between a grounded circuit conductor and a supply-side bonding jumper, and this is reflected in the current wording.

Branch Circuit:

A branch circuit is that part of a wiring system that (1) extends beyond the final Code-required automatic overcurrent protective device (i.e., fuse or breaker) which qualifies for use as branch-circuit protection and (2) ends at an outlet, which is another defined term in Art. 100. Thermal cutouts

or motor overload devices are not branch-circuit protection. Neither are fuses in luminaires nor in plug connections, which are used for ballast protection or individual fixture protection. Such supplementary overcurrent protection is on the load side of the outlet and is not required by the Code, nor a substitute for the Code-required branch-circuit protection and does not establish the point of origin of a branch circuit. The extent of a branch circuit is illustrated in Fig. 100-10.

Fig. 100-10.

Branch Circuit, Appliance:

The point of differentiation between “appliance” branch circuits and “general” branch circuits is related to what is actually connected. For a circuit to be considered an “appliance” branch circuit, it may not supply any lighting, unless that lighting is part of an appliance. Refer to Fig. 100-11.

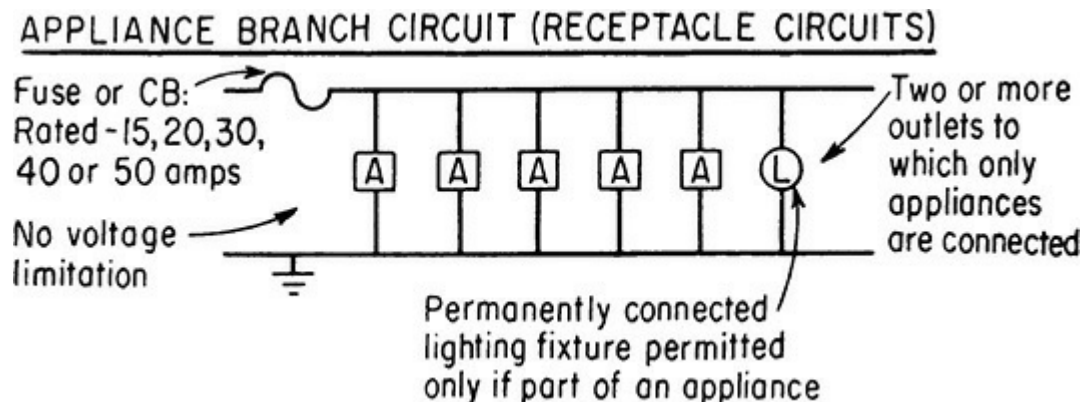

Fig. 100-11.

Branch Circuit, General Purpose:

Such circuits are identified by the fact that they supply two or more outlets for receptacles, lighting, or appliances. Refer to [Fig. 100-12](#).

Circuit voltage shall not exceed 150 volts to ground for circuits supplying lampholders, fixtures or receptacles of standard 15-amp rating. For fluorescent, incandescent or mercury lighting under certain conditions, voltage to ground may be as high as 300 volts. In certain cases, voltage for electric discharge lighting may be up to 600 volts ungrounded.

Fig. 100-12.

Branch Circuit, Individual:

As indicated by the term itself, such a branch circuit supplies a single, or “individual” piece of equipment. Refer to [Fig. 100-13](#). A circuit supplying both halves of a duplex receptacle is not an individual branch circuit in most cases, because each half of the duplex is classified as a separate device.

Fig. 100-13.

Branch Circuit, Multiwire:

A multiwire branch circuit must be made up of a neutral or grounded conductor—as in corner-grounded delta systems—and at least two ungrounded or “hot” conductors. The most common multiwire circuits are shown in [Fig. 100-14](#).

Fig. 100-14.

A 3-wire, 3-phase circuit (without a neutral or grounded conductor) ungrounded delta system is not a “multiwire branch circuit,” even though it does consist of “multi” wires, simply because there is no “neutral” or other grounded conductor. Remember, such a circuit must, by definition, also contain a “grounded” conductor, which may be a neutral, as in the typical 3-phase, 4-wire systems, or a grounded phase conductor, such as in a “corner-grounded” delta system (Fig. 100-15).

Fig. 100-15.

Note also that a corner-grounded 3-phase circuit might be interpreted as a multiwire circuit because the grounded phase conductor, while not connected to a neutral, is connected to a grounded conductor. The word “or” at this location originated in the 1993 NEC and is only supposed to recognize that neutrals are grounded circuit conductors. It was never intended to describe a 3-phase corner-grounded power circuit. Now that the word “neutral” is formally defined in Art. 100, the simplest way to correct this would be to delete the words “or grounded” from the definition.

Building:

Most areas have building codes to establish the requirements for buildings, and such codes should be used as a basis for deciding the use of the definition given in the **National Electrical Code**. The use of the term *fire walls* in this definition has resulted in differences of opinion among electrical inspectors and others. Since the definition of a fire wall may differ in each jurisdiction, the processing of an interpretation of a “fire wall” has been studiously avoided in the National Electrical Code because this is a function of building codes and not a responsibility of the National Electrical Code.

In most cases, a “building” is easily recognized by its stand-alone nature. However, one or more “fire walls” also establishes two (or more) buildings in one structure. It is frequently crucial to distinguish between a “fire-separation wall” (or however the local building code describes it) and a

“fire wall.” As discussed here, a “fire wall” is made of concrete and masonry and will still be standing after a conflagration on one side proceeds to complete destruction. A “fire-separation wall” may consist of several layers of drywall and will have a rating in hours, designed to assure time for the occupants to exit. They are fundamentally different, in kind and not just degree.

Many, many code rules depend on whether a structure comprises multiple buildings, such as whether multiple services will be permitted, which grounding rules will apply at which locations, and whether residential occupancies separated by such construction will be classified as single-family or multiple-family housing. Where in doubt, check with your local electrical inspector for guidance. If the electrical inspector doesn’t know, or doesn’t have jurisdiction over this particular decision, then the electrical inspector should be able to direct you to the proper authority for a determination. This is a good example of where the AHJ may be the local building commissioner and not the electrical inspector.

Cabinet/Cutout Box:

There are two distinguishing characteristics that differentiate a “cabinet” from a “cutout box.” The first is the *physical construction*. The door of a cabinet is (or could be) hinged to a trim covering wiring space, or gutter. The door of a cutout box is hinged (or screwed) directly to the side of the box. The other distinction is *mounting*. Cabinets may be surface- or flush-mounted, while cutout boxes may only be surface-mounted. In terms of use, cabinets usually contain panelboards; cutout boxes contain cutouts, switches, or miscellaneous apparatus.

Cable Routing Assembly:

This is a “channel” and not a raceway that serves as a support and routing mechanism for a variety of power-limited cabling methods, including all forms of communications cabling. It was relocated from Art. 770 because these assemblies apply to wiring covered throughout the limited energy articles in [Chap. 7](#) as well as [Chap. 8](#). Note that when this definition made the trip into Art. 100, the former qualification that it support “high densities” of wiring was dropped. Although such assemblies frequently carry high cable densities, they may start off with few cables. The density aspect is plainly irrelevant to the description of the physical assembly.

Communications Equipment:

Although the definition remains relatively self explanatory, the 2017 **NEC** added an informational note that will be of increasing importance as the technology of communications increasingly comes to rely on digital processing of information. The distinction between a *signaling circuit* covered in [Chap. 7](#) (Art. 725) and a *communications circuit* covered in [Chap. 8](#) (defined in Art. 800) continues to blur. Pay particular attention to the aspect of the communications utility source as a key factor in the latter definition.

Communications Raceway:

This definition, also relocated from the back end of the Code (in this case Art. 800), describes an “enclosed channel” designed to contain communications cables along with optical fiber cables and data communications wiring for Class-2 and -3 circuits. This is the raceway counterpart to the cable-

routing assembly.

Concealed:

Any electrical equipment or conductors that are closed in by structural surfaces are considered to be “concealed,” as shown in [Fig. 100-16](#).

Fig. 100-16.

Circuits run in an unfinished basement or an accessible attic are not “rendered inaccessible by the structure or finish of the building,” and are therefore considered as exposed work rather than a concealed type of wiring. Equipment and wiring in hung-ceiling space behind lift-out panels and underneath raised floors beneath removal tiles are also considered “exposed.”

Conduit Body:

The last sentence notes that FS and FD boxes—as well as larger cast or sheet metal boxes—are not considered to be “conduit bodies,” as far as the **NEC** is concerned. Although some manufacturers’ literature refers to FS and FD boxes as conduit fittings, care must be used to distinguish between “conduit bodies” and “boxes” in specific Code rules. For instance, the first sentence of 314.16(C)(2) limits splicing and use of devices to conduit bodies that are “durably and legibly” marked with their cubic inch capacity by the manufacturer. However, FS and FD boxes are not conduit bodies and may contain splices and/or house devices. Table 314.16(A) lists FS and FD boxes as “boxes.” See [Fig. 100-17](#).

Fig. 100-17.

Continuous Load:

Any condition in which the maximum load current in a circuit flows without interruption for a period of not less than 3 h. Although somewhat arbitrary, the 3-h period establishes whether a given load is continuous. If, for example, a load were energized for 2 h, 59 min, 59 s, then switched off and immediately reenergized, it would technically be a “noncontinuous” load. This is an extreme example, but that is the Code-prescribed evaluation for this important definition.

Control Circuit:

Although this terminology is used in 18 different code articles, it was only defined in Art. 430 prior to the 2014 NEC. It now clearly is to be applied in a consistent way.

Coordination (Selective):

This term refers to the design concept whereby an individual fault will be cleared by the OC protective closest to the faulted circuit or equipment. This design goal is achieved by studying the time–current trip curves of the selected devices and ensuring that the operating characteristics of all selected OC devices are such that the fuse or breaker closest to a fault will blow or open before OC devices upstream (toward the service) operate. This has become mandatory for the main overcurrent protective devices for elevators (620.62), and for protective devices generally for applications covered by 700.32, 701.27, and 708.54, and also for some fire-pump feeders as covered in 695.3(C) (3).

The 2014 **NEC** removed any doubt that this terminology applies to the effect of any fault, regardless of duration. The intent of those who have made selective coordination mandatory in various code sections is that it be applied in exactly this way. This has far-reaching effects on the design of electrical circuits that are ensnared in this definition. Refer to the discussion of 700.32 in [Chap. 7](#) of this book for an extensive discussion of the significant policy issues raised by code requirements that rely on this definition.

Demand Factor:

The following discussion provides a distinction between two very closely related, but different concepts. For the purposes of **NEC** application, any design or application of “demand factors” that results in a feeder or service smaller than would be permitted by the applicable rules of the **NEC**, such as Art. 220, is a violation. From a practical standpoint in new construction, this generally should

not be a problem because **NEC** requirements are essentially bare minimums and provide absolutely no additional capacity. That precludes system expansion and supply of additional loads in the future, which, of course is poor design. Because design goals should, and typically do, include consideration of potential future needs, actual ratings and sizes of selected equipment and conductors should be larger than the Code-required minimum. BUT, if a designer calculates a load that is less than would be permitted by the Code, the larger, Code-mandated load shall be accommodated by selection of equipment and conductors that are adequate to supply the Code-complying load.

Two terms constantly used in electrical design are “demand factor” and “diversity factor.” Because there is a very fine difference between the meanings for the words, the terms are often confused.

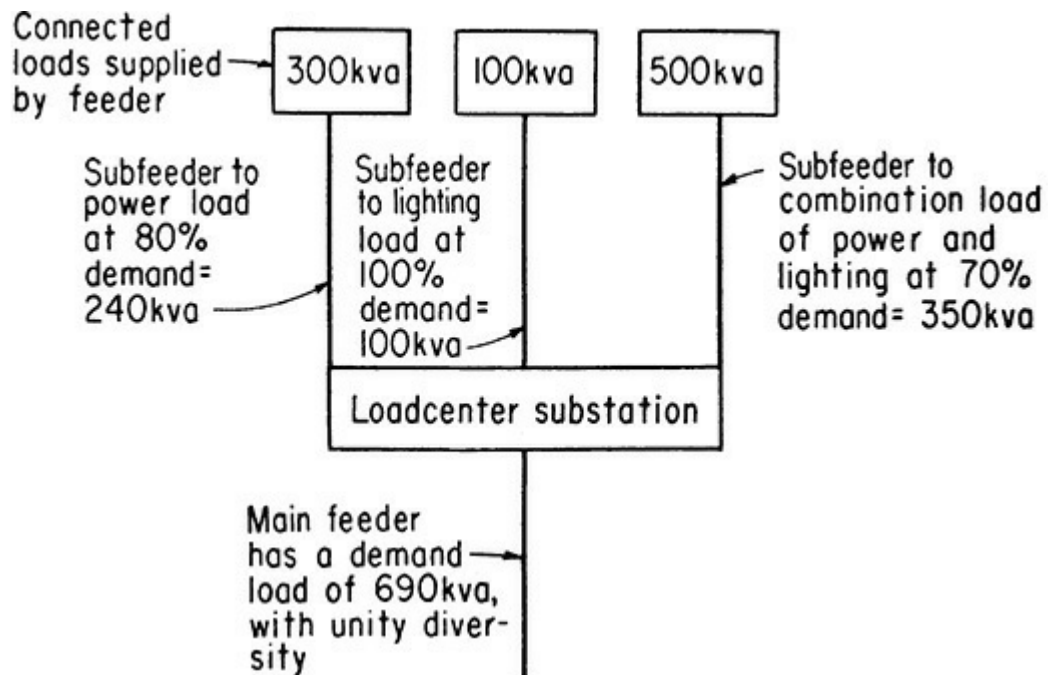

Demand factor is the ratio of the maximum demand of a system, or part of a system, to the total connected load on the system, or part of the system, under consideration. This factor is always less than unity.

Diversity factor is the ratio of the sum of the individual maximum demands of the various subdivisions of a system, or part of a system, to the maximum demand of the whole system, or part of the system, under consideration. This factor generally varies between 1.00 and 2.00.

Demand factors and diversity factors are used in design. For instance, the sum of the connected loads supplied by a feeder is multiplied by the demand factor to determine the load for which the feed must be sized. This load is termed the maximum demand of the feeder. The sum of the maximum demand loads for a number of subfeeders divided by the diversity factor for the subfeeders will give the maximum demand load to be supplied by the feeder from which the subfeeders are derived.

It is a common and preferred practice in modern design to take unity as the diversity factor in main feeders to loadcenter substations to provide a measure of spare capacity. Main secondary feeders are also commonly sized on the full value of the sum of the demand loads of the subfeeders supplied.

From power distribution practice, however, basic diversity factors have been developed. These provide a general indication of the way in which main feeders can be reduced in capacity below the sum of the demands of the subfeeders they supply. On a radial feeder system, diversity of demands made by a number of transformers reduces the maximum load that the feeder must supply to some value less than the sum of the transformer loads. Typical application of demand and diversity factors for main feeders is shown in [Fig. 100-18](#).

1. Sum of individual demands = 240 + 100 + 350 = 690 kva.
2. Sizing the substation at unity diversity, the required

$$\text{kva} = \frac{690}{1.00} = 690 \text{ kva.}$$

3. To meet this load, use a 750-kva substation.
4. If analysis dictates the use of a diversity factor of 1.4 , the

$$\text{required kva} = \frac{690}{1.40} = 492 \text{ kva.}$$

5. To meet this load, use a 500-kva substation.
6. Primary feeder to unit substation must have capacity to match the substation load.

Fig. 100-18.

Device:

Switches, fuses, circuit breakers, controllers, receptacles, and lampholders are examples of “devices” that “carry or control” electricity as their principal function. The fact that they may use incidental quantities of power in the process does not affect their principal function.

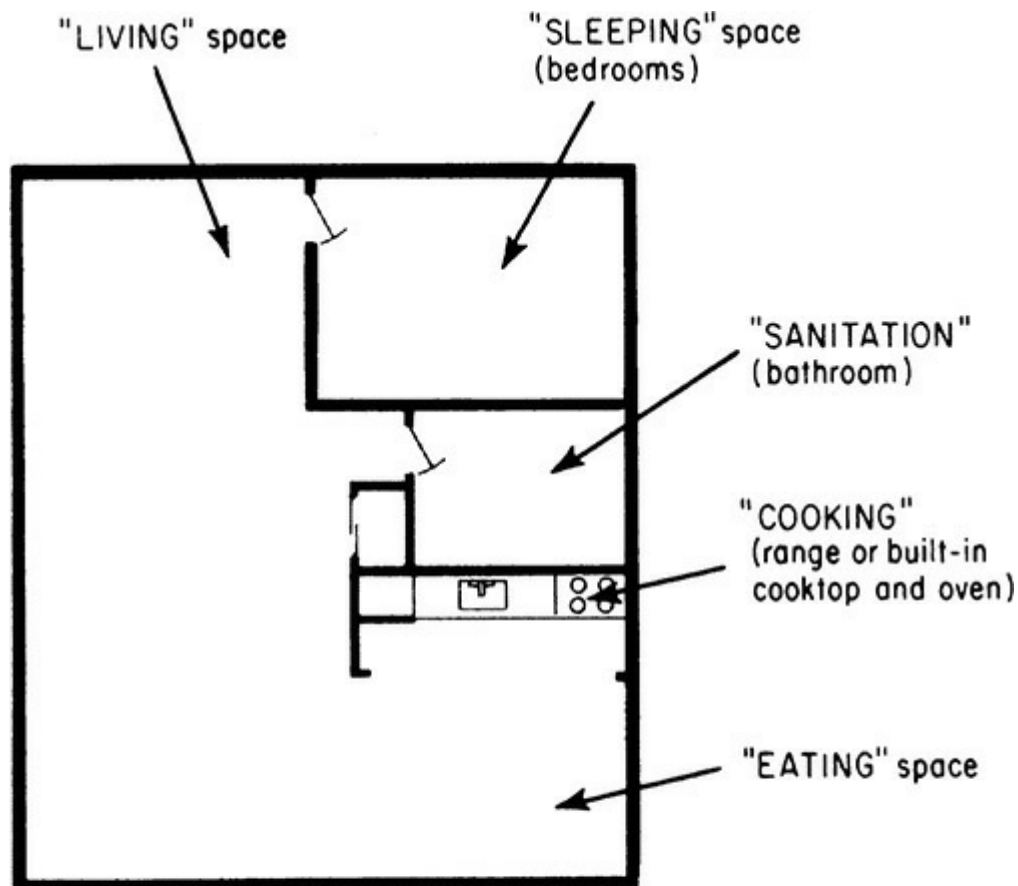

Dwelling:

Because so many Code rules involve the words “dwelling” and “residential,” there have been problems applying Code rules to the various types of “dwellings”—one-family houses, two-family houses, apartment houses, condominium units, dormitories, hotels, motels, etc. The NEC includes terminology to eliminate such problems and uses definitions of “dwelling” coordinated with the words used in specific Code rules.

A *dwelling unit* is defined as a single unit that provides “complete and independent living facilities for one or more persons.” It must have “permanent provisions for living, sleeping, cooking, and sanitation.” A one-family house is a “dwelling unit.” So is an apartment in an apartment house or

a condominium unit. And a guest room in a hotel or motel or a dormitory room or unit is a “dwelling unit” if it contains permanent provisions for “cooking.” Refer to the commentary on guest rooms for more information on this point.

Any “dwelling unit” must include all the required elements shown in [Fig. 100-19](#).

NOTE: Eating, living, and sleeping space could be one individual area, as in an efficiency apartment. But the unit must contain a “bathroom,” defined in Art. 100 as “an area including a basin with one or more of the following: a toilet, a tub, or a shower.” And the unit must contain permanent cooking equipment.

Fig. 100-19.

Effective Ground-Fault Current Path:

This definition was relocated from 250.2, because it applies in numerous locations in the **NEC**. It was modified by removing the final phrase “on high-impedance grounded systems” because it may apply in other locations. For example, it is a mandatory feature of most ungrounded systems because a ground fault that develops into simultaneous faults from conductors fed from two different phases must clear as quickly as a faulted phase conductor on a grounded system. Refer to the discussion in 250.4 for more information.

Electrical Circuit Protective System:

This definition was relocated in the 2017 NEC. It is a very important concept to which many

provisions in the **NEC** refer, either implicitly or by express reference. Now that the NEC has an article devoted to a key aspect involving this topic, this book covers it at 728.4.

Exposed (as Applied to Wiring Methods):

Wiring methods and equipment that are not permanently closed in by building surfaces or finishes are considered to be “exposed.” See [Fig. 100-20](#).

Fig. 100-20.

Feeder:

A *feeder* is a set of conductors that carry electric power from the service equipment (or from a transformer secondary, a battery bank, or a generator switchboard where power is generated on the premises) to the overcurrent protective devices for branch circuits supplying the various loads. Basically stated, any conductors between the service, separately derived system, or other source of supply and the branch-circuit protective devices are “feeders.”

A feeder may originate at a main distribution center and feed one or more subdistribution centers, one or more branch-circuit distribution centers, one or more branch circuits (as in the case of plug-in busway or motor circuit taps to a feeder), or a combination of these. It may be a primary or secondary voltage circuit, but its function is always to deliver a block of power from one point to another point at which the power capacity is apportioned among a number of other circuits. In some systems, feeders may be carried from a main distribution switchboard to subdistribution switchboards or panelboards from which subfeeders originate to feed branch-circuit panels or motor branch circuits. In still other systems, either or both of the two foregoing feeder layouts may be incorporated with transformer substations to step the distribution voltage to utilization levels. In any of these described scenarios, the conductors would be considered to be feeders because they interconnect the service and branch circuit.

Field Evaluation Body (FEB):

Field Labeled (as applied to evaluated products):

These definitions (the first being actually extracted text) come from comparatively new **NFPA** standards addressing the long-standing, and heretofore poorly regulated, process of providing field evaluations of equipment by testing laboratories. **NFPA 790** is the Standard for Competency of Third-Party Field Evaluation Bodies, and **NFPA 791** is the Recommended Practice and Procedures for Unlabeled Electrical Equipment Evaluation. The inspector now has written standards on which to base an evaluation of the qualifications of a third-party intending to judge the performance suitability of unlabeled equipment.

Ground:

In another example of the major reevaluation of definitions involving grounding concepts, the ground is now simply the planet earth. There is no longer any reference to a conductive body that serves in its place. For example, a little portable generator is no longer classified as being connected to ground just because a connection may have been made to the generator frame. Since the definition no longer refers to connections to the earth, it is no longer correct to refer to insulation failures and the like as grounds; instead, they should be described as the ground faults they really are.

Grounded (Grounding):

Here again, the concept of a conductive body serving in place of the earth has been discontinued. The definition now applies only to connections to the planet earth, either directly or through a conductive body that extends the ground connection. Although the concept of conductive entities serving in place of the earth still survives in such areas as motor vehicles and railroad rolling stock, these areas are generally beyond the scope of the **NEC**. Recreational vehicles (RVs) are covered, but even there most of the equipment and systems affected by this change are those connected to premises wiring in RV parks, for which a connection to the earth is routine.

Grounded Conductor:

Here the Code distinguishes between a “grounding” conductor and a “grounded” conductor. A grounded conductor is the conductor of an electrical system that is intentionally connected to earth via

a grounding electrode conductor and a grounding electrode at the service of a premises, at a transformer secondary, or at a generator or other source of electric power. See Fig. 100-21. It is most commonly a neutral conductor of a single-phase, 3-wire system or 3-phase, 4-wire system but may be one of the phase legs—as in the case of a corner-grounded delta system.

Fig. 100-21.

Grounding one of the wires of the electrical system is done to limit the voltage upon the circuit that might otherwise occur through exposure to lightning or other voltages higher than that for which the circuit is designed. Another purpose in grounding one of the wires of the system is to limit the maximum voltage to ground under normal operating conditions. Also, a system that operates with one of its conductors intentionally grounded will provide for automatic opening of the circuit if an accidental or fault ground occurs on one of its ungrounded conductors.

Selection of the wiring system conductor to be grounded depends upon the type of system. In 3-wire, single-phase systems, the midpoint of the transformer winding—the point from which the system neutral is derived—is grounded. For grounded 3-phase, 4-wire wiring systems, the neutral point of the wye-connected transformer(s) or generator is usually the point connected to ground. In delta-connected transformer hookups, grounding of the system can be affected by grounding one of the three phase legs, by grounding a center-tap point on one of the transformer windings (as in the 3-phase, 4-wire “red-leg” delta system), or by using a special grounding transformer, which establishes a neutral

point of a wye connection that is grounded.

Ground-Fault Circuit Interrupter (GFCI):

This revised definition makes clear that the device described is a GFCI (breaker or receptacle) of the type listed by Underwriters Laboratories Inc. (UL) and intended to eliminate shock hazards to people. “Class A” devices must operate within a definite time from initiation of ground-fault current above the specified trip level (4–6 mA, as specified by UL). See [Fig. 100-22](#). It should be noted that this is *not* the protective device called for by the rule of 210.12. That section calls for the use of a device called an *arc-fault circuit interrupter*, or AFCI, which is required for protection specifically against high-resistance arcing-ground-faults, particularly in residential applications. (See 210.12.)

Fig. 100-22. GFCI protection required for temporary power applications, as covered in 590.6, should be *listed* for temporary power use. Refer to the caption for [Fig. 590-13](#) at the end of [Chap. 5](#) for more information on this topic.

There are essentially two types of Class A GFCIs: those intended to be permanently installed and those intended for temporary power use. It is important that only those listed as “temporary power” GFCIs be used to satisfy the rules of 590.6 and 525.23(A). That caution is based on the fact that GFCIs listed for temporary power are tested differently than those intended for permanent installation and, as a result, only those listed for temporary power applications may be used for temporary power. There are also “Class B” GFCIs with 20-mA trips; these are only for use with underwater swimming pool luminaires installed before local adoption of the 1965 NEC and they are seldom applied today. For all other Code rules requiring GFCIs, those Class A devices listed for permanent installation may be used.

Ground-Fault Current Path:

This definition, like “Effective Ground-Fault Current Path,” was also relocated from Art. 250. Unlike its companion, which described the intentionally constructed path, this definition covers what actually happens during a ground fault even if the return is too ineffective to open a circuit-protective device. The informational note bears this out, and the functional differences between these definitions must be kept clearly in mind. This terminology is now included within the definition of equipment grounding conductors.

Ground-Fault Protection of Equipment:

Although any type of ground-fault protection is aimed at protecting personnel using an electrical system, the so-called ground-fault protection required by 215.10, 230.95, and 240.13 for 480Y/277-V disconnects rated 1000 A or more, for example, is identified in 230.95 as “ground-fault protection of equipment (GFPE).” This is essential because a 480/277-V system has an instantaneous peak voltage to ground of $277\text{ V} \times \sqrt{3} = 392\text{ V}$. This voltage is frequently enough to constantly reignite an arc powered by a failed phase leg. The result is an arcing burndown that is extremely destructive. The so-called ground-fault circuit interrupter (GFCI), as described in the previous definition and required by 210.8 for residential receptacles and by other **NEC** rules, is essentially a “people protector” and is identified in 210.8 as “ground-fault protection for personnel.” Because there are Code rules addressing these distinct functions—people protection versus equipment protection—this definition distinguishes between the two types of protection.

Note that there are other protective devices that provide equipment protection and not personnel protection, but that typically operate in the 30-mA range. For example, pipe tracing circuits covered in 427.22 require this protection because a ground fault in a pipe tracing cable can sputter for a very long time without tripping an overcurrent device, given the inherent resistance of this equipment. A GFPE device will de-energize the failed cable promptly.

Grounding Conductor, Equipment (EGC):

The phrase “equipment grounding conductor” is used to describe any of the electrically conductive paths that tie together the noncurrent-carrying metal enclosures of electrical equipment in an electrical system. The term *equipment grounding conductor* includes bare or insulated conductors, metal raceways [rigid metal conduit, intermediate metal conduit, electrical metallic tubing (EMT)], and metal cable jackets where the Code permits such metal raceways and cable enclosures to be used for equipment grounding—which is a basic Code-required concept as follows:

Equipment grounding is the intentional electrical interconnection of all metal enclosures that contain electrical wires or equipment with the grounding electrode conductor (all systems) and with the grounded conductor of the system (grounded systems only). When an insulation failure occurs in such enclosures on ungrounded systems, the result is the system simply becomes corner or otherwise system grounded at the fault, and no hazardous voltage will be present on the enclosures. However, it is still important to correct the insulation failure promptly and the **NEC** now requires ground detectors on all such systems for this reason. If a second insulation failure happens to occur on a second phase before the first one is fixed, the result will be a line-to-line short circuit flowing through a potentially very long equipment grounding run, perhaps between opposite ends of the factory. A single loose locknut or forgotten setscrew could easily generate a sustained arc in such a case before overcurrent devices operate, with severe consequences and a dangerous voltage on the

intervening enclosures while the failure is in progress.

When the insulation failure occurs on a grounded system, equipment grounding serves to ensure adequate current flow to cause the affected circuit's overcurrent protective device to "open," usually in the instantaneous portion of the overcurrent device tripping curve. This prevents the enclosures from remaining energized, which would otherwise constitute a shock or fire hazard. Simply stated, proper connections of all metallic enclosures of electric wires and equipment to each other and to the system grounded conductor (shown in Fig. 100-23) prevent any potential-above-ground on the enclosures.

Fig. 100-23.

Workmanship and attention to detail are crucial to the proper implementation of these concepts; a single poor connection can easily reduce the current flowing in a ground fault so it falls into the overload portion of the overcurrent device trip curve. In effect, the fuse or circuit breaker acts as though the arcing fault is a motor trying to start, and by the time the device finally trips a fire is in progress and the damage to the electrical system can easily involve an outage lasting many weeks.

Grounding Electrode:

The grounding electrode is any one of the building or structural elements recognized in 250.52 that is in actual physical contact with the earth.

Grounding Electrode Conductor:

Basically stated, this is the connection between either the grounded conductor of a grounded electrical system (typically the neutral) and the grounding electrode system, or the connection between the equipment ground bus and the grounding electrode system for ungrounded systems. The conductor that runs from the bonded neutral block or busbar or ground bus at service equipment, separately derived systems, or main building disconnects to the system grounding electrode is clearly and specifically identified as the "grounding electrode conductor." See Fig. 100-24. It should be noted that "main building disconnects" referred to here are those that would be required where one building receives its supply from another as covered in Part II of Art. 225.

Fig. 100-24.

Guest Room:

The only difference between a dwelling unit and a guest room hinges on whether or not provisions for cooking—either permanently installed or cord-and-plug connected—are present. Where microwaves or other types of cooking equipment are not present, then the location is a guest room. If such items are present, then the occupancy is a dwelling unit if the cooking equipment is permanently installed. A loose cord-and-plug-connected microwave oven will not trigger a reclassification, unless it is permanently installed into or below a cabinet.

Handhole Enclosure:

This definition describes any one of a number of small to medium-sized in-ground pull and junction boxes for use in underground distribution, covered in detail in 314.30.

Hermetic Refrigerant Motor-Compressor:

This definition was relocated from Art. 440 and describes a motor operating in its own refrigerant, and which can therefore operate under load conditions that would overload a conventional motor cooled by air.

Hybrid System:

This definition appeared in both Art. 690 and in Art. 705, and has been relocated here where it belongs. The definition clarifies that energy storage mechanisms are not elements of a hybrid power source for code purposes. In addition the 2014 **NEC** made clear that regenerative power supplied by a descending elevator does not create a hybrid system. The amount of regenerated power is not significant and what is recovered is quickly taken up by adjacent elevators while in ascent.

Identified (as Applied to Equipment):

This term is covered together with “Approved” (and also “Listed”) as part of the discussion of “Approved” and related standards for product acceptance near the beginning of this chapter.

In Sight From (Within Sight From, Within Sight):

The phrase “in sight from” or “within sight from” or “within sight” means visible and not more than 50 ft away. These phrases are used in many Code rules to establish installation location of one piece of equipment with respect to another. A typical example is the rule requiring that a motor-circuit disconnect means must be in sight from the controller for the motor [430.102(A)]. This definition in Art. 100 gives a single meaning to the idea expressed by the phrases—not only that any piece of equipment that must be “in sight from” another piece of equipment must be visible, but also that the distance between the two pieces of equipment must not be over 50 ft. If, for example, a motor disconnect is 51 ft away from the motor controller of the same circuit, it is not “within sight from” the controller even though it is actually and readily visible from the controller. In the interests of safety, it is arbitrarily defined that separation of more than 50 ft diminishes visibility to an unacceptable level.

There are places in the **NEC** where the wording of rules takes these limitations into account. For example, 610.32(2) allows certain crane disconnects to be “within view” (and not “within sight”) of certain equipment. This is because on large cranes it may be impossible to meet the 50 ft limitation, and yet the disconnect can still be seen and will be capable of being locked in the open position.

Industrial Control Panel:

This definition was moved from Art. 409 because the term is also used Art. 110. Essentially, an industrial control panel is an enclosure that houses motor starters and/or other control equipment. The definition incorporates all control assemblies of two or more components as being within the scope of these rules. To provide some context, all combination starters, with a disconnect switch and fuse block or a circuit breaker and contactor with running overload protection are included.

Interrupting Rating:

This definition covers both “interrupting ratings” for overcurrent devices (fuses and circuit breakers) and “interrupting ratings” for control devices (switches, relays, contactors, motor starters, etc.).

Labeled:

The label of a nationally recognized testing laboratory on a piece of electrical equipment is a sure and ready way to be assured that the equipment is properly made and will function safely when used in accordance with the application data and limitations established by the testing organization. Each label used on an electrical product gives the exact name of the type of equipment as it appears in the listing book of the testing organization.

Typical labels are shown in [Fig. 100-25\(a\)](#).

Fig. 100-25(a).

Underwriters Laboratories Inc., the largest nationally recognized testing laboratory covering the electrical field, describes its "Identification of Listed Products," as shown in [Fig. 100-25\(b\)](#).

The Listing Mark may appear in various forms as authorized by Underwriters Laboratories Inc. Typical forms which may be authorized are shown below:

UNDERWRITERS LABORATORIES INC. ®

UND. LAB. INC. ®

Underwriters
Lab. Inc. ®

Underwriters Laboratories Inc. ®

Underwriters Laboratories Inc.®

LISTED

**Underwriters
Laboratories Inc.®**

**UNDERWRITERS
LABORATORIES
INC.®**

Listing Marks include one of the forms illustrated above, the word "Listed", and a control number assigned by UL. The product name as indicated in this Directory under each of the product categories is generally included as part of the Listing Mark text, but may be omitted when in UL's opinion, the use of the name is superfluous and the Listing Mark is directly and permanently applied to the product by stamping, molding, ink-stamping, silk screening or similar processes.

Separable Listing Marks (not part of a name plate and in the form of decals, stickers or labels) will always include the four elements: UL's name and/or symbol, the word "Listed", the product or category name, and a control number.

The complete four element Listing Mark will appear on the smallest unit container in which the product is packaged when the product is of such a size that only the symbol  can be applied to the product or when the product size, shape, material or surface texture makes it impossible to apply any legible marking to the product.

LOOK FOR THE LISTING MARK

Fig. 100-25(b).

Fig. 100-25(c). Example of the next generation of UL labels, using the word “certified” and modular elements. The term is more easily understood in international commerce. Its use is not mandatory and all existing marks are and will remain valid.

It should be noted that the definitions for “labeled” and “listed” in the **NEC** do not require that the testing laboratory be “nationally recognized.” But OSHA rules do require such “labeling” or “listing” to be provided by a “nationally recognized” testing lab. Therefore, even though those **NEC** definitions acknowledge that a local inspector may accept the label or listing of a product by a testing organization that is qualified and capable even though it operates in a small area or section of the country and is not “nationally recognized,” OSHA requirements may only be satisfied when “labeling” or “listing” is provided by a “nationally recognized” testing facility.

By universal test lab policies, the *label* is the field evidence of the listing. If the label falls off, the product is no longer presumed to be listed and it can only be relabeled by or in the presence of a test lab employee; labels cannot simply be sent through the mail. The test labs will send personnel to field locations to witness the application of a label.

Listed:

This term is covered together with “Approved” (and also “Identified”) as part of the discussion of “Approved” and related standards for product acceptance near the beginning of this chapter.

Live Parts:

This definition indicates what is meant by that term as it is used throughout the Code. An insulated conductor contains a live part at any time by definition if it is energized (the conductor itself), even if the live part is insulated. For example, 312.2 requires that wiring entries to cabinets, cutout boxes, and meter sockets in wet locations use fittings listed for wet locations if the entry point is above the level of *uninsulated* live parts. The focus of this rule is not insulated conductors that are wet, but only

the impact of moisture on uninsulated meter jaws and lugs, etc.

Luminaire:

This definition indicates all elements that are covered by the term *luminaire*. This term was adopted to correlate the **NEC** with other international standards and replace the term “fixture” used in the **NEC** prior to the 2002 Code. There was no intent on the part of the Code-making panels involved to require any change in application; this is simply an editorial revision. In this cycle the definition has been additionally revised to refer to a “light source such as” (but not necessarily) “a lamp or lamps.” This allows for light-emitting diode (LED) and other sources that do not involve lamps as technology continues to move ahead.

Motor Control Center:

This definition indicates the necessary elements that would identify a piece of equipment as a motor control center. Such equipment would be subject to all rules aimed at comparable equipment such as 110.26(A) covering required workspace in front of certain types of equipment.

Neutral Conductor:

Neutral Point:

At long last the NEC has actually defined the term *neutral*. It does so by first defining a “neutral point” in a way that is sensible and not controversial, but the definition of “neutral conductor” is more problematic. Refer back to [Fig. 100-21](#). The top two drawings show the most common neutral points, namely the star point of a wye and the center point of a single-phase system. No one would argue that those are neutral points. Since such star or center points must be grounded by rules in Art. 250, any conductor connected to such a point must be a grounded circuit conductor, and must be identified in accordance with 200.6. Therefore, any white wire run in conjunction with a grounded system is now a neutral, whether or not it is neutral between two (or more) associated ungrounded conductors. A 2-wire branch circuit that includes a white wire connected on a neutral bus is now an official neutral all the way to the outlet.

Although this certainly legitimizes common trade slang, it may lead people to believe all white (or gray) wires are neutrals. Not so. Look now at the bottom drawing in [Fig. 100-21](#). That corner-grounded delta system has a white phase conductor, which is not and cannot ever be a neutral because the delta system shown has no neutral point. It remains to be seen whether this effort will add or reduce confusion.

Nonlinear Load:

Those loads that cause distortion of the current waveform are defined as *nonlinear loads*. A typical nonlinear load current and voltage waveform are shown in [Fig. 100-26](#). As can be seen, while the voltage waveform [[Fig. 100-26\(b\)](#)] is a sinusoidal, 60-Hz wave, the current waveform [[Fig. 100-26\(a\)](#)] is a series of pulses, with rapid rise and fall times, and does not follow the voltage waveform.

Fig. 100-26(a).

Fig. 100-26(b).

The informational note following this definition is not intended to be a complete list, but rather, just a few examples. There are many more such loads. The substantiation for inclusion of this note stated in part:

It has been known within the entertainment industry for some time that due to the independent single-phase phase-control techniques applied to 3-phase, 4-wire feeder, solid-state dimming can cause neutral currents in excess of the phase currents. This is in addition to the harmonics generated. This situation is dealt with in theaters in 520.27 and 520.51, etc. Dimming is also used in non-theatrical applications such as hotel lobbies, ballrooms, and conference centers. This effect must be taken into account wherever solid-state dimming is employed.

Outlet:

This term refers to a point on a wiring system where current is taken to supply utilization equipment. This is a critical definition because the term is frequently misapplied. For example, a hard-wired fluorescent luminaire set in a suspended ceiling in an office is an outlet and the branch circuit ends at the ballast channel. Article 400 covering flexible cord appears in [Chap. 4](#) (equipment for general use) and not [Chap. 3](#) (wiring methods and materials) because (with limited exceptions) flexible cord is not supposed to substitute for [Chap. 3](#) wiring methods. The terminal housing on a motor, even a motor operating on a 4160-V branch circuit, is the outlet at the end of that medium-voltage branch circuit. Receptacles are outlets, but only a small fraction of the category.

Overcurrent:

Overload:

This is a very important concept. Overcurrent considers current in excess of rated current or ampacity in three different ways. A *short circuit* is a direct line-to-line connection between two circuit conductors, and if it occurs, it can be extremely destructive because of the enormous amounts of energy that will be released unless it is cleared immediately. A *ground fault* is a connection from an ungrounded conductor and an equipment grounding conductor. Although the available energy is somewhat lower, it may be just low enough so that overcurrent devices do not respond immediately. This type of arcing burndown is extremely destructive if not cleared immediately. The third variety of overcurrent is an *overload*. These are sustained currents that are above an equipment full load rating or the ampacity of a conductor, but low enough that it will only cause a problem if it persists for an extended period of time, the period being inversely proportional to the degree of overload.

Overcurrent Device, Branch-Circuit; Supplementary:

Branch-circuit protective devices are capable of providing protection over the full range of overcurrents between the device rating and its interrupting rating, but never less than 5000 A. They are far more robust than the supplementary overcurrent protective devices that offer limited protection for certain applications such as limiting the amount of energy that could enter a luminaire.

Photovoltaic (PV) System:

This term was relocated after the word “Solar” was removed from its title. This refers to the equipment involved in a particular application of solar energy conversion to electric power. This definition correlates to **NEC** Art. 690 covering design and installation of electrical systems for direct conversion of the sun’s light into electric power. While the proliferation of such installations accelerates, remember that any and all installations of photovoltaic equipment at premises covered by the NEC must be performed in accordance with all general requirements given in [Chaps. 1](#) through [4](#) and the specific requirements given in Art. 690.

Plenum:

The wording of this definition creates an unfortunate inference in the minds of many suggesting that a plenum is something deliberately fabricated to distribute air, in the sense of a piece of duct work to which other ducts are connected. That inference is inconsistent with the way the word is frequently used in **NFPA 90A**, which is the conditioned air standard. A review of that standard shows four subdefinitions immediately following, which set the appropriate context. Three of the four, namely, “Air Handling Unit Room Plenum,” “Ceiling Cavity Plenum,” and “Raised Floor Plenum” clearly describe spaces that were not specifically fabricated for air distribution. Since this definition must be used in concert with both **NFPA 90A** and 300.22(C), as well as other places in the code with similar exposures, it is very important that code users clearly understand that the “compartment or chamber” referred to could be, but is not necessarily, a space specifically fabricated for air transport.

Premises Wiring (System):

Published discussions of the Code panel’s meaning of this phrase make clear the panel’s intent that premises wiring includes all electrical wiring and equipment on the load side of the “service point,” including any electrical work fed from a “source of power”—such as a transformer, generator, computer power distribution center, an uninterruptible power supply (UPS), or a battery bank. Premises wiring includes all electrical work installed on a premises. Specifically, it includes all circuits and equipment fed by the service or fed by a separately derived electrical source (transformer, generator, etc.). This makes clear that all circuiting on the load side of a so-called computer power center or computer distribution center (enclosed assembly of an isolating transformer and panelboard[s]) must satisfy all **NEC** rules on hookup and grounding, unless the power source in question is listed as “Information Technology Equipment,” in which case the rules of Art. 645 would apply. When a “computer power center” is specifically “listed” and supplied with or without factory-wired branch-circuit “whips” (lengths of flexible metal conduit or liquidtight flex—with installed conductors), such equipment may be grounded as indicated by the manufacturer as given in the rules of Art. 645, Information Technology Equipment.

Other sources, such as solar photovoltaic systems or storage batteries, also constitute “separately derived systems.” All **NEC** rules applicable to premises wiring also pertain to the load side wiring of batteries and solar power systems.

Qualified Person:

Here the Code spells out the necessary elements that designate someone as a “qualified person.” This rule is used in many sections of the Code and typically compliance with any such rule hinges on the personnel involved being a “qualified person.” Notice that it is not simply enough to be knowledgeable about the equipment and/or application, but also, such persons must have “received safety training.” Presumably that means attending formal or informal training, or even on-the-job-training, all of which, presumably, must be documented and maintained in a personnel file on “Qualifications” or “Training” or the like. An informational note directs the reader to another **NFPA** standard (70E) for additional guidance with regard to training requirements.

Raceway:

Whenever this term is used in the Code, it applies to the various enclosed channels that are designed specifically for running conductors between cabinets and housings of electrical distribution components, including busbars, as covered in the relevant wiring method articles in [Chap. 3](#). Prior to the 2014 **NEC**, the clear implication presented by the choice of wiring methods listed is that raceways are for extended lengths of run, and that more limited enclosed channels such as those within equipment are not to be so classified. This interpretation has been thoroughly tested. If any such enclosed channel were classified as a raceway, then surely an auxiliary gutter would be so classified. In the 1993 NEC cycle, the panel initially accepted a proposal to place “auxiliary gutters” into the list, and then unanimously reversed course in the face of negative comments from the current author, NEMA, and others. The issues of auxiliary gutters and panelboard gutter spaces are particularly pressing because 230.7 forbids the sharing of raceways between service conductors and other conductors. If such enclosures are deemed to be raceways, then service panel wiring, as we know it, would be contrary to the NEC.

There were other wiring methods omitted from the list as well, and for good reason. A cable tray is a “support system” and not a “raceway.” When the Code refers to “conduit,” it means only those raceways containing the word “conduit” in their title. Therefore, “EMT” is not conduit. Table 1 of [Chap. 9](#) in the back of the Code book refers to “Conduit and Tubing.” The Code, thus, distinguishes between the two. “EMT” is tubing. Notice that cable trays and cablebus are not identified as “raceways.” The consequence of their omission is that general rules applying to “raceway” do not apply to cable trays or cablebus.

The 2014 **NEC** deleted the list of raceways from the informational note in favor of a reference to the definitions within the various [Chap. 3](#) articles. However, the intent has not changed; it just requires a little more work to sort out the results. For example, the definitions of a wireway in 376.2 and 378.2 now specifically describe it as a raceway, and the definitions of an auxiliary gutter in 366.2 pointedly do not use that word, relying on the word “enclosure” instead. Similarly, the definition of a cable tray system in 392.2 describes something that fastens or supports cables or raceways, but that is not to be described as a raceway.

Receptacle:

Each place where a plug cap may be inserted is a “receptacle,” as shown in [Fig. 100-27](#). Multiple receptacles on one strap are just that, multiple receptacles.

Each box is one receptacle outlet

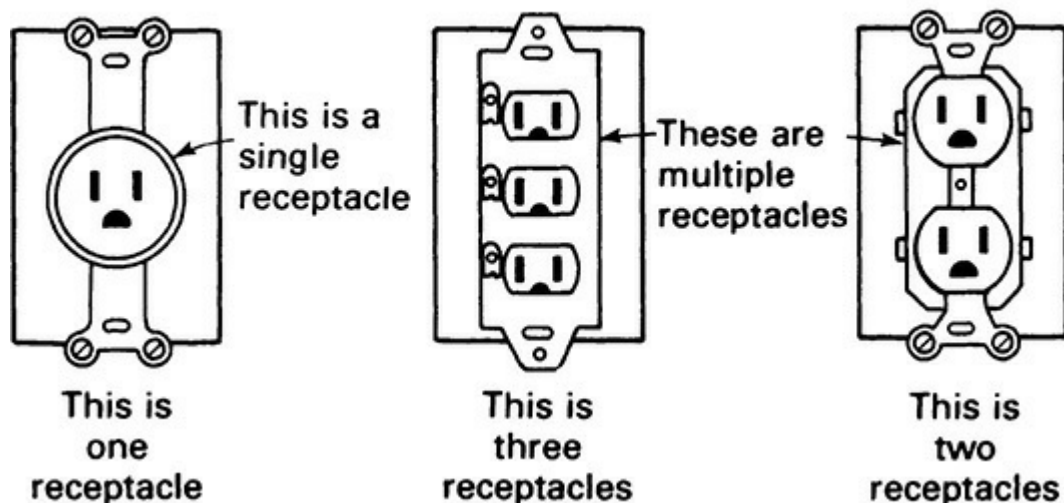

Fig. 100-27.

Only a single receptacle can be served by an individual branch circuit. See 210.21(B) and 555.19(A)(3).

The concept of a receptacle was basically unchanged for about a century of usage, but as of the 2017 **NEC**, the concept has been fundamentally expanded. Where formerly the only field attachment to a receptacle was a plug on the end of flexible cord, now the term may also be applied to a female device that receives utilization equipment equipped with a corresponding mating part. Refer to [Fig. 100-28](#) for a detailed photo of the new concept as its originators expect to apply it. The left portion shows the new version of what can now be described as a receptacle.

Fig. 100-28. A new version of a receptacle.

Instead of a plug on a cord, the device will receive the luminaire to the right, which is equipped with a mating contact device. The three contact mechanisms (ground, neutral, hot) are in that order from large to small. The equipment grounding outer ring projects further than the other two and

thereby observes the first-make, last-break principle in 406.10(D). The lever projecting from the edge of the luminaire canopy releases the pressure applied to the projecting beads on the contact arm, allowing it to drop freely and thereby disconnecting the luminaire for service.

Note that only the receptacle itself (Fig. 100-28) is listed. The mating component mounted in the luminaire canopy is a recognized component, marked as shown in Fig. 100-29 prior to inclusion in the canopy by the luminaire manufacturer. It is not field installable at present (although in principle, possibly capable of being field labeled) because the testing laboratory needs to test its load-bearing performance and electrical characteristics as part of the luminaire. This mark is issued by UL, but it is not a listing mark. The component recognition program aids efficiency. An inspector stationed in the device factory can review the conformity of the male component to established standards and, if warranted, allow the recognition mark. The component manufacturer can then sell them in quantity to many different luminaire manufacturers. And then the testing lab personnel assigned to the luminaire factory know by the mark that they don't have to investigate the mating part any more than they would have to look at a lampholder with similar recognition. They can simply evaluate the assembled luminaire in accordance with applicable product standards, in this case UL 1598, and then grant the listing if warranted.

Receptacle Outlet:

The *outlet* is the outlet box. But this definition must be carefully related to 220.12(I) for calculating receptacle loads in other than dwelling occupancies. For purposes of calculating load, 220.12(I) requires receptacle outlets to be calculated at not less than 180 for each single or for each multiple receptacle on one yoke. Because a single, duplex, or triplex receptacle is a device on a single mounting strap, the rule requires that 180 VA must be counted for each strap, whether it supports one, two, or three receptacles. On the other hand, the new multi-outlets that feature four or more receptacles permanently molded into a single piece of equipment mounted to an outlet box must be calculated at 90 VA per receptacle.

Fig. 100-29. An example of a component recognition marking. It is not an **NEC** designation, and its true meaning is often misunderstood.

Remote-Control Circuit:

The circuit that supplies energy to the operating coil of a relay, a magnetic contactor, or a magnetic motor starter is a *remote-control circuit* because that circuit controls the circuit that feeds through the contacts of the relay, contactor, or starter, as shown in Fig. 100-30.

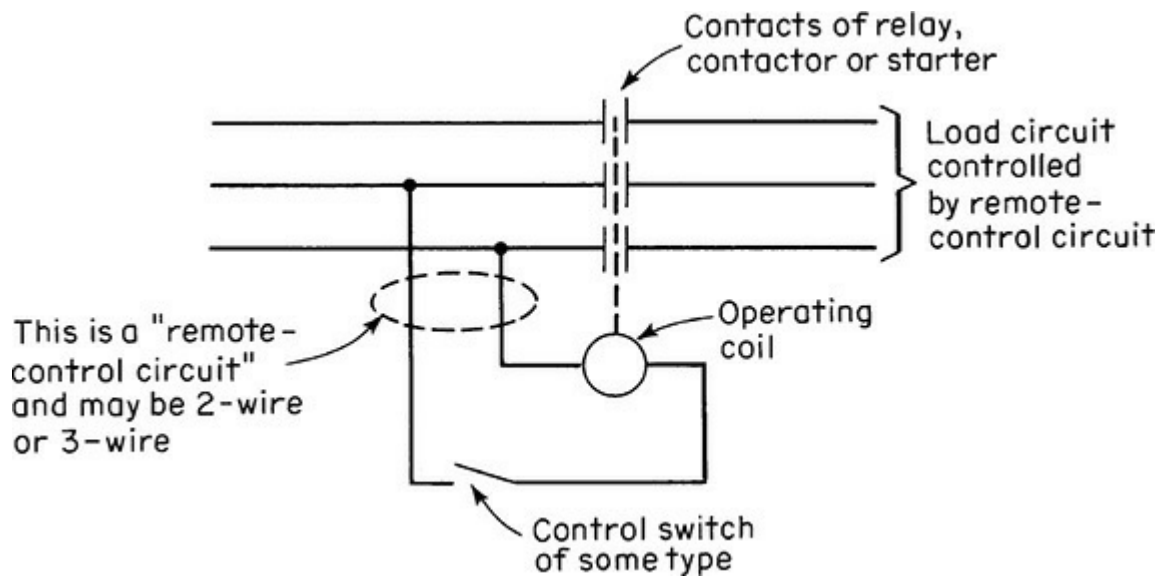

Fig. 100-30.

Note that the closely related definition of “Control Circuit” was relocated into Art. 100 from Art. 430 because it is used in a variety of **NEC** articles.

A control circuit, as shown, is any circuit that has as its load device the operating coil of a magnetic motor starter, a magnetic contactor, or a relay. Strictly speaking, it is a circuit that exercises control over one or more other circuits. And these other circuits controlled by the control circuit may themselves be control circuits, or they may be “load” circuits—carrying utilization current to a lighting, heating, power, or signal device. [Figure 100-30](#) clarifies the distinction between control circuits and load circuits.

The elements of a control circuit include all the equipment and devices concerned with the function of the circuit: conductors, raceways, contactor operating coils, source of energy supply to the circuit, overcurrent protective devices, and all switching devices that govern energization of the operating coil.

The **NEC** covers application of remote-control circuits in Art. 725 and in 430.71 through 430.75.

Separately Derived Systems:

This applies to all separate sources of power and includes transformers, generators, battery systems, fuel cells, solar panels, etc., that have no direct connection between circuit conductors of one system to those of another system; however, the definition recognizes that the derived system may share an earth or an equipment grounding connection (whether by wire or by enclosures) with other systems. Virtually, all power transformers are separately derived systems, while a backup generator, for example, may or may not be depending on whether the neutral from the generator is also switched with the phase conductors. Where the grounded (neutral) conductor is switched—such as where a four-pole transfer switch is used on a 3-phase, 4-wire generator output—then the generator is a separately derived system and must comply with the rules of 250.30.

Service:

The word *service* includes all the materials and equipment involved with the transfer of electric power from the utility distribution line to the electrical wiring system of the premises being supplied.

Only a utility can supply a service, so if a facility generates its own power, it will have no service, only one or more feeders and building disconnects. The purpose of special rules for actual services is to address the necessary transitional rules that will assure a safe transition from utility work governed by the National Electrical Safety Code (NESC) and premises wiring governed by the **NEC**. Similarly, if a building is supplied by premises wiring in any form, then the disconnect for the entrance of that wiring will be a building disconnect and not a service disconnect.

Although service layouts vary widely, depending upon the voltage and amp rating, the type of premises being served, and the type of equipment selected to do the job, every service generally consists of “service-drop” conductors (for overhead service from a utility pole line) or “service-lateral” conductors (for an underground service from either an overhead or underground utility system)—plus metering equipment, some type of switch or circuit-breaker control, overcurrent protection, and related enclosures and hardware. A typical layout of “service” for a one-family house breaks down as in [Fig. 100-31](#).

Fig. 100-31. The “service drop” terminology in this drawing is correct if the service point is at the mast (the usual case). If the service point is at the pole, then the supply drop is to be known, as of the 2011 NEC, as “overhead service conductors.”

The **NEC** does not govern where in a service layout the NEC begins and the NESC ends. This is determined by the local public authority that governs public utility activities. Although we hear a lot about deregulated utilities, this concept only applies to the generation of electric energy, not its distribution down public streets. Since only one set of line wire can run on any given street, the distribution of electric energy is what economists call a *natural monopoly*; competition is effectively impossible. In such cases, there will be regulation by public authorities. This is the case here. Part of

the regulatory process will be determining where the *service points* are allowed to be. If the service point is at the pole, then the NEC applies to the overhead service conductors as installed by the electrical contractor, with only the final connections at the street being made by utility personnel. If the service point is at the splices at the bottom of the drip loops, then a utility line crew will install the drop in accordance with the NESC and the NEC does not apply.

That part of the electrical system which directly connects to the utility-supply line is referred to as the *service entrance*. Depending upon the type of utility line serving the house, there are two basic types of service entrances—an *overhead* and an *underground* service.

The overhead service has been the most commonly used type of service. In a typical example of this type, the utility supply line is run on wood poles along the street property line or back-lot line of the building, and a cable connection is made high overhead from the utility line to a bracket installed somewhere high up on the building. This wood pole line also carries the telephone lines, and the poles are often called *telephone poles*.

The underground service is one in which the conductors that run from the utility line to the building are carried underground. Such an underground run to a building may be tapped from either an overhead utility pole line or an underground utility distribution system. Although underground utility services tapped from a pole line at the property line have been used for many years to eliminate the unsightliness of overhead wires coming to a building, the use of underground service tapped from an underground utility system has only started to gain widespread usage in residential areas over recent years. This latter technique is called URD—which stands for *underground residential distribution*.

Service Conductors—Overhead, Underground:

These are general terms that cover all the conductors on the load side of the service point used to connect the utility-supply circuit or transformer to the service equipment of the premises served. This term includes both overhead and underground service conductors, as well as “service-entrance” conductors. Although [Fig. 100-31](#) covers an ordinary one-family house, the **NEC** necessarily applies to major industrial occupancies taking power at 69 kV or even higher, and every conceivable size and type of occupancy in between. See also [Figs. 100-33](#) and [100-34](#).

Where the supply is from an underground distribution system, the underground service conductors may begin at the point of connection to the underground street mains, or at the property line, or at the terminals of the meter socket, or at the terminals of a pad-mounted transformer, again all as governed by state and local rule making around service point locations.

In every case the service conductors terminate at the service equipment, including the service disconnecting means.

Service Drop:

As the name implies, these are the conductors that “drop” from the overhead utility line and connect to the service-entrance conductors at their upper end on the building or structure supplied. See [Fig. 100-32](#). As noted in the caption to [Fig. 100-31](#), if the service point is at the utility pole, the “service drop conductors” become “overhead service conductors.”

Fig. 100-32.

The distinction between overhead (and underground) service conductors and service drop conductors (and service lateral conductors) based on service point location was new in the 2011 NEC. It upsets established terminology that goes back to the 1933 NEC. Now, only utilities will be responsible for service drops (or laterals), and only property owners will be responsible for overhead (or underground) service conductors. The rearranged terminology offers improved correlation with the “service conductors” definition, which depends on the service point location for its field application.

Service Equipment:

This is the equipment connected to the load end of service entrance conductors for the purpose of providing the principal means to control and disconnect the premises wiring from the source of utility supply. A meter socket is not service equipment in and of itself, but would be part of such equipment in the case of a combination meter-disconnect with the service disconnecting means located at the meter, all in one piece of equipment. The meter and meter socket in Fig. 100-31 is not part of the service equipment. The service disconnecting means will consist of some form of fused switch or circuit breaker because 230.91 requires the overcurrent protective device to be an integral part of the disconnecting means, or located immediately adjacent thereto. Note that any service “overcurrent device” only provides overload protection for service conductors. It cannot possibly respond to an arcing failure in progress on a service conductor located on its line side; such faults must usually burn clear, and this is why the NEC severely limits the exposure of any building to unprotected service conductors.

Service Lateral:

This is the name given to a set of underground service conductors. A service lateral serves a function similar to that of a service drop, as shown in Fig. 100-33. As in the case of a service drop, the terminology only applies on the line side of the service point. For example, if in the bottom drawing of Fig. 100-33 the service point were the transformer bushings, then the underground wiring to the house would be comprised of underground service conductors, and not a service lateral. Refer to the discussion about service drops for additional information on this concept, which was new in the 2011

Fig. 100-33.

Service Point:

Service point is the “point of connection between the facilities of the serving utility and the premises”

wiring.” All equipment on the load side of that point is subject to **NEC** rules. Any equipment on the line side is the concern of the power company and is not regulated by the Code. This definition of “service point” must be construed as establishing that “service conductors” originate at that point. The whole matter of identifying the “service conductors” is covered by this definition.

The definition of “service point” does tell where the **NEC** becomes applicable, and does pinpoint the origin of service conductors. And that is a critical task, because a corollary of that determination is identification of that equipment which is, technically, “service equipment” subject to all applicable **NEC** rules on such equipment. Any conductors between the “service point” of a particular installation and the service disconnect are identified as service conductors and subject to **NEC** rules on service conductors (Fig. 100-34).

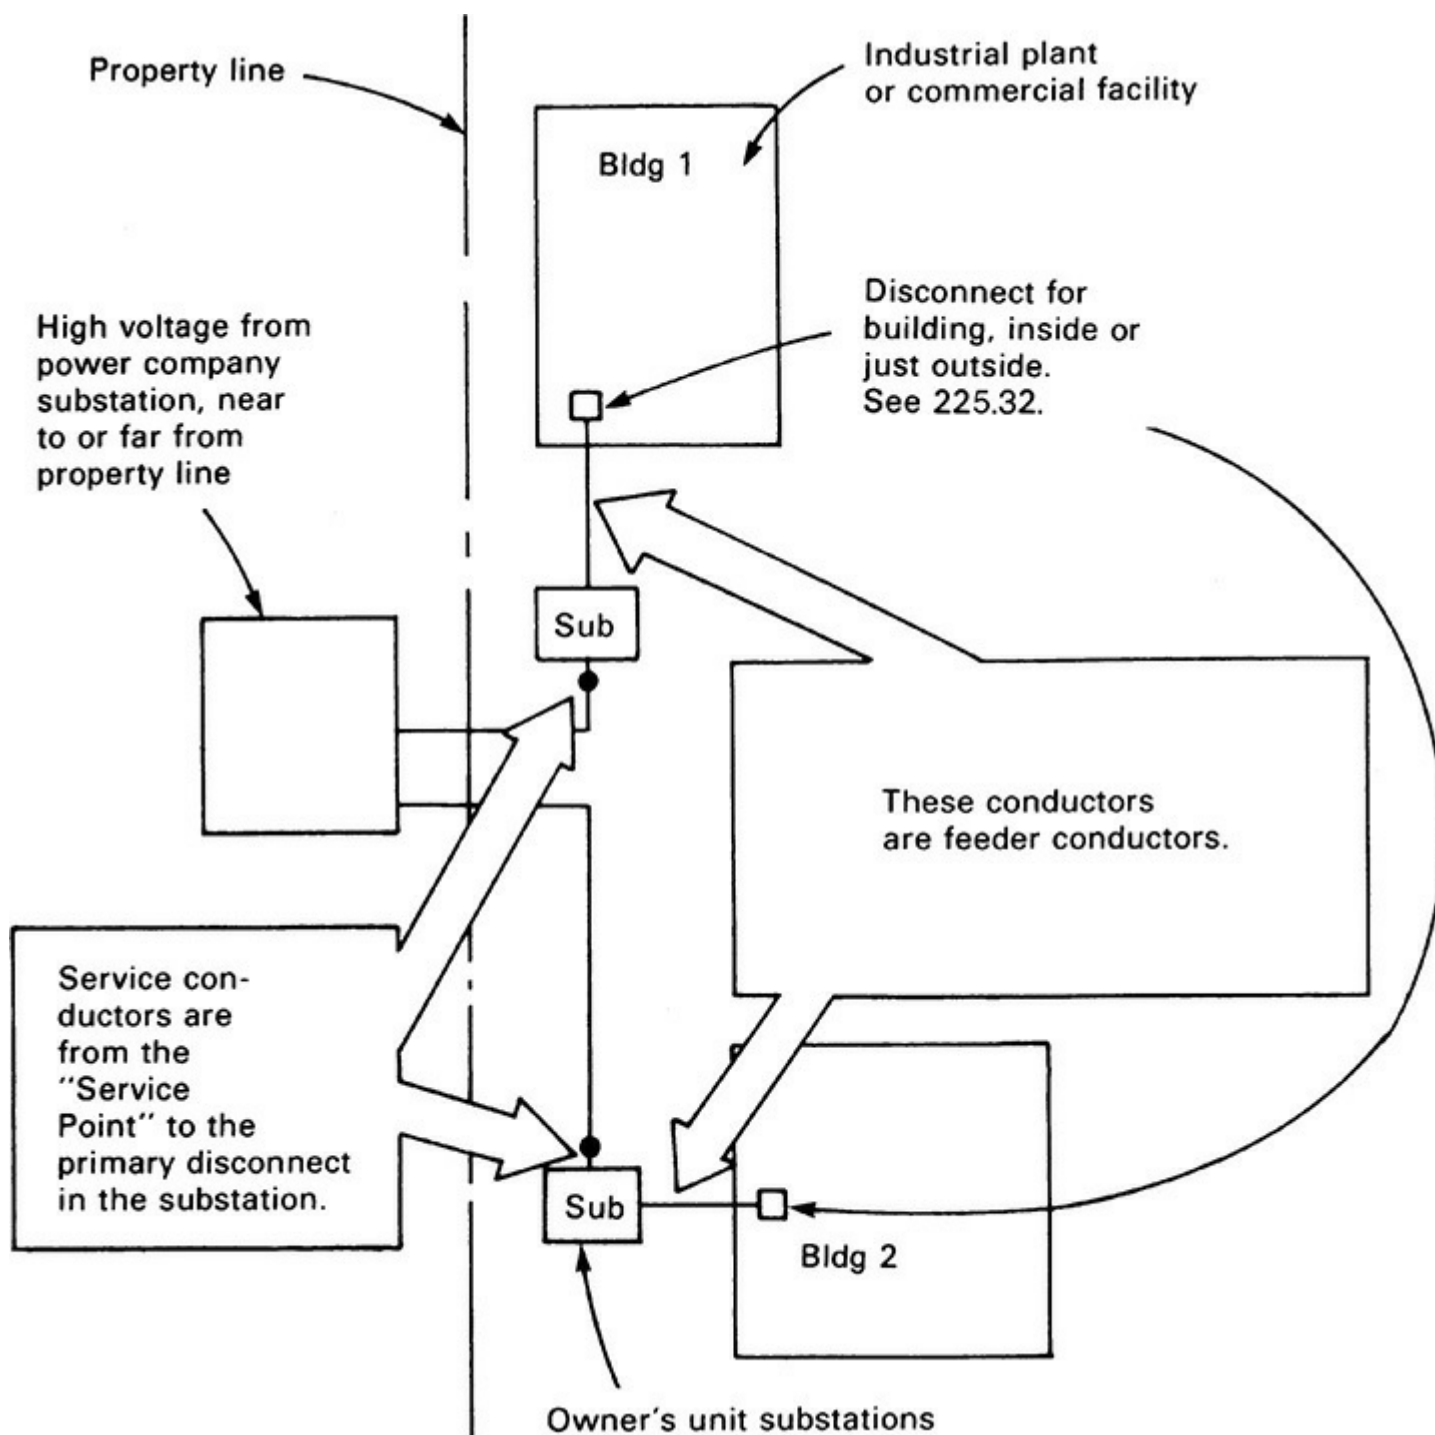

Fig. 100-34. NEC rules apply on load side of “service point”—not from property line. (230.200.)

Special Permission:

It must be carefully noted that any Code reference to *special permission* as a basis for accepting any electrical design or installation technique requires that such “permission” be in written form. Whenever the inspection authority gives “special permission” for an electrical condition that is at variance with Code rules or not covered fully by the rules, the authorization must be “written” and not simply verbal permission. This rule corresponds to the wording used in 90.4, which requires any inspector-authorized deviation from standard Code-prescribed application to be in writing.

Structure:

This definition now disallows the use of the term for equipment. The very simple wording of this definition prior to the 2017 edition, “that which is built or constructed,” led to significant controversies. Take a manufactured metering pedestal assembled in the field. That could arguably be included in the earlier definition. And, if so, then it would need a service disconnect, grounding electrode system, and the neutral and equipment grounding conductors would be required to separate from this point out. It is now clear that such equipment does not independently qualify as a structure. Another example involves multiple vehicle charging stations in a parking lot. Sec. 225.30 now has express language allowing such installations in order to countermand rejections based on the former wording of this definition. That revision is now superfluous.

Switches:

Bypass isolation switch This is “a manually operated device” for bypassing the load current around a transfer switch to permit isolating the transfer switch for maintenance or repair without shutting down the system. The second paragraph of 700.5(B) permits a “means” to be provided to bypass and isolate transfer equipment. This definition ties into that rule.

Transfer switch This is a switch for transferring load–conductor connections from one power source to another. Note that such a switch may be automatic or nonautomatic.

Switchgear:

As of the 2014 **NEC** this term replaces the former term “Metal-Enclosed Power Switchgear.” The definition is the same, but the terminology tracks current product standards and correlating changes were made throughout the NEC. A new informational note provides detailed coverage of current descriptive terminology. The note also extracts the matter of arc-resistant construction from its former location within the definition because it is explanatory in nature.

Questions often arise as to the difference between switchgear and switchboards. They are on the same continuum, but switchgear, which is exclusively metal enclosed, tends to encompass more sophisticated electronics for monitoring and control than current switchboard designs. Although modern switchboards are metal enclosed as well, they still encompass antique designs with open switches on slate backplanes, etc.

Switchgear standards (ANSI C37.20.1 and UL 1558) were developed to focus on the needs of sophisticated industrial enterprises with highly qualified on-site electrical staffing, generally responsible for electrical systems subjected to higher loading on a routine basis. Such facility personnel are also more likely to be capable of routine equipment disassembly and maintenance. For

example, switchgear will always exclusively employ draw-out breakers with serviceable arc shields, and contacts, etc. In addition, switchgear will be evaluated for a 30 cycle 3-phase short-circuit test; switchboards (under UL 891) are not subject to this test. This makes for significant differences in the internal characteristics of the support structures for the busbars, the quality of the insulation, and the strength of the enclosure. For example, a switchboard breaker enclosure might be 16 gauge; its counterpart in switchgear will be 11 gauge.

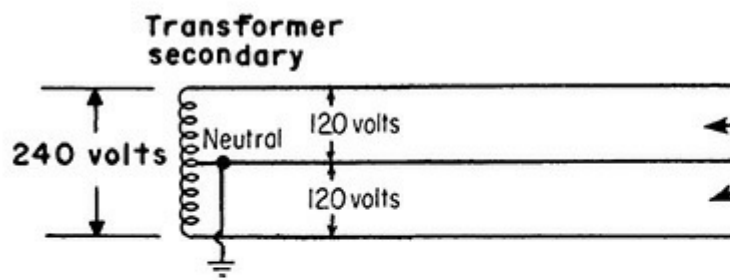

Uninterruptible Power Supply:

This was a new definition in the 2011 **NEC** of a familiar term. Of note is the limitation to alternating current applications and the explanation in the note following that a UPS can (and often does) function as a voltage regulator and power conditioner.

Voltage to Ground:

For a grounded electrical system, voltage to ground is the voltage that exists from any ungrounded circuit conductor to either the grounded circuit conductor (if one is used) or the grounded metal enclosures (conduit, boxes, panelboard cabinets, etc.) or other grounded metal, such as building steel. Examples are given in [Fig. 100-35](#).

Single-phase, 3-wire system

Voltage-to-ground is 120 volts from either ungrounded leg to the neutral conductor or to any grounded metal

3-Phase, 4-wire wye system

Voltage-to-ground is the voltage from any phase leg to the grounded neutral—277 volts, in this case

3-Phase, 4-wire delta system

Voltage-to-ground is 208 volts from phase A conductor and 120 volts from phase B or C to the grounded neutral

Fig. 100-35.

For an ungrounded electrical system, voltage-to-ground is taken to be equal to the maximum voltage that exists between any two conductors of the system. This is based on the reality that an accidental ground fault on one of the ungrounded conductors of the system places the other system conductors at a voltage aboveground that is equal to the value of the voltage between conductors. Under such a ground-fault condition, the voltage to ground is the phase-to-phase voltage between the accidentally grounded conductor and any other phase leg of the system. On, say, a 480-V, 3-phase, 3-wire ungrounded delta system, voltage to ground is, therefore, 480 V, as shown in [Fig. 100-36](#).

Ungrounded delta system at 480 volts

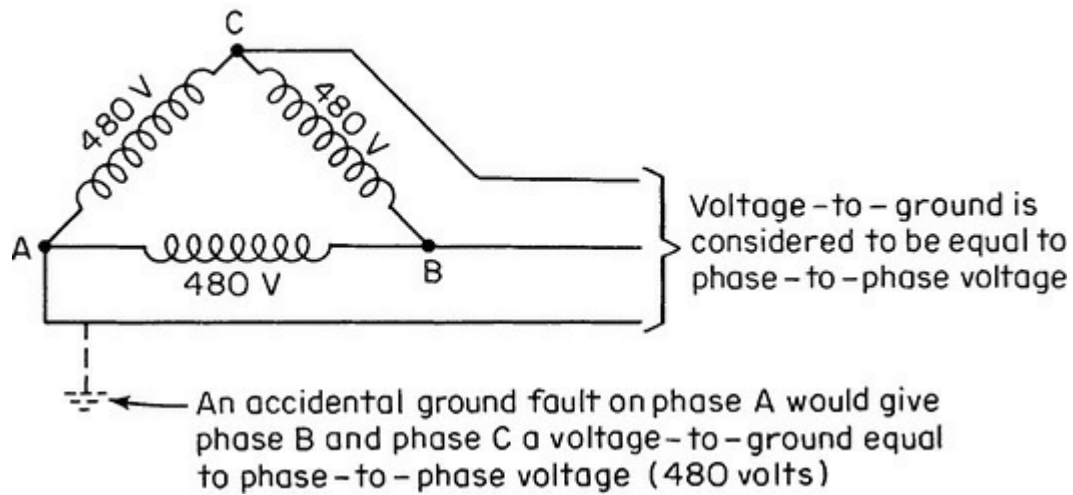

Fig. 100-36.

In many Code rules, it is critically necessary to distinguish between references to “voltage” and to “voltage to ground.” The Code also refers to “voltage between conductors,” as in 210.6(A) through (E), to make very clear how rules must be observed.

Table 100-1. New and Relocated CMP-14 Definitions in Article 100

Defined Term	Original Location
Associated Apparatus	504.2
Associated Nonincendive Field Wiring Apparatus	506.2
Combustible Dust	500.2; 506.2
Combustible Gas Detection System	500.2; 505.2
Control Drawing	500.2
Cord Connector ¹	new as of 2017 NEC
Dust-Ignitionproof ²	500.2; 506.2
Dusttight ^{3,6}	500.2; 506.2; Art. 100
Explosionproof Equipment ⁶	Art. 100; not moved
Hermetically Sealed	500.2
Intrinsically Safe Apparatus	504.2
Intrinsically Safe System	504.2
Mobile Equipment ^{4,6}	513.2
Nonincendive Circuit	500.2; 506.2
Nonincendive Component	500.2
Nonincendive Equipment	500.2; 506.2
Nonincendive Field Wiring	500.2; 506.2
Nonincendive Field Wiring Apparatus	500.2
Oil Immersion	500.2
Portable Equipment ^{4,6}	513.2
Pressurized	506.2
Process Seal ⁵	new as of 2017 NEC
Purged and Pressurized	500.2
Simple Apparatus	504.2
Unclassified Location	500.2; 505.2
Ventilated ⁶	Art. 100; not moved

¹This definition must not be confused with female cord connector bodies as used in 400.10(B) etc. Unlike customary device applications, this definition covers a type of fitting. It assists in the proper selection of fittings designed to attach cabled wiring methods to enclosures in hazardous (classified) locations.

²The informational note that follows no longer references NEMA 9 enclosures because they are no longer covered by the NEMA 250 standard. The relevant product requirements will now be the sole province of UL 1202.

³See the new Informational Note No. 1, which lists NEMA enclosure types that are considered to be dusttight. Table 110.28 includes an equivalent note, however, the note here conflicts with that note because it also includes Types 4, 4X, 6, and 6P. This will require correlation in a future cycle.

⁴Wording not reviewed by other panels; may or may not be compatible with other NEC rules.

⁵Definition based on applicable ANSI/ISA standard (12.27.01-2011).

⁶Title does not include the hazardous classification limitation.

Part II. Over 1000 Volts, Nominal

Substation:

This definition was moved from Art. 225 in the 2014 **NEC**. It covers “an assemblage of equipment,” which functions to distribute, switch, or modify the characteristics of the incoming electrical energy, or any combination of these functions. As such, they may be field engineered in more complicated cases, or arrive as a listed assembly. They may be located either indoors or outdoors, and operated with or without a medium voltage component. The majority do have a medium voltage supply, and a new Section 490.48 was created at the same time to comprehensively address this work.

ARTICLE 110. REQUIREMENTS FOR ELECTRICAL INSTALLATIONS

110.1. Scope. This article provides a variety of general regulations that govern the installation of equipment and conductors. Part I applies to installations rated 600 V or less and those rated over 600 V, unless specifically modified by another rule in Part III or IV. Part II applies only to systems rated 600 V or less, while Part III provides general rules for systems operating at over 600 V, and Part IV covers electrical systems rated over 600 V used in “tunnel installations.” Part V covers the requirements for manholes.

110.2. Approval. As indicated by this section and the companion definition given in Art. 100, all equipment used must be “acceptable to the authority having jurisdiction” (AHJ). That generally means that the local inspector is the final judge of what equipment and conductors may be used in any given application.

Review the discussion in Art. 100 on the three standards for product acceptance (approved, identified, and listed) for more information on this point.

The intent of the NEC is to place strong insistence on third-party certification of the essential safety of the equipment and component products used to assemble an electrical installation. And, many Code sections specifically require the equipment to be “listed.” But, where any piece of equipment is not required to be listed, then the local inspector is the one who determines if such equipment can be used. It should be noted that many inspectors require equipment to be “listed” if there exists a “listed” version of the type of equipment you’re using. Such action helps ensure that the equipment used is inherently safe.

The NEC is not the only controlling standard covering electrical installations. The Occupational Safety and Health Administration (OSHA) has a standard, the Electrical Design Safety Standard, that must also be satisfied. Because the **NEC** is the basis for the OSHA standard, and the NEC is more dynamic in terms of change, in the vast majority of cases, **NEC** requirements are more stringent than those of the OSHA design standard. And satisfying the **NEC** will ensure compliance with the OSHA regulations. But, while the NEC doesn’t always mandate the use of listed equipment, the OSHA standard requires that listed equipment be used to the maximum extent possible. That is, as far as OSHA is concerned, if there exists a “listed” piece of equipment of the type you are installing, then you must use the “listed” equipment instead of a nonlisted counterpart. Failure to do so is a direct violation of OSHA’s Electrical Design Safety Standard.

In addition, OSHA addresses those instances where there exists no “listed” version of the type of equipment you need. In such cases, the local inspector, plant safety personnel, the manufacturer, or other authority must perform a safety inspection. Although the OSHA standard does not provide any

guidance with respect to “what” the safety inspection must entail, it seems reasonable to assume that consideration of the points delineated in 110.3(A)(1) through (8) should serve to satisfy the intent of the OSHA requirement for a safety evaluation.

The use of custom-made equipment is also covered in OSHA rules. Every piece of custom equipment must be evaluated as essentially safe by the local inspector, plant safety personnel, the manufacturer, or other authority and documentary safety-test data of the safety evaluation should be provided to the owner on whose premises the custom equipment is installed. And it seems to be a reasonable conclusion from the whole rule itself that custom-equipment assemblies must make maximum use of “listed,” “labeled,” or “certified” components, which will serve to mitigate the enormous task of conducting the safety evaluation.

The bottom line is that if an OSHA review is a serious concern, look for listed equipment. However, this usual, overly simplistic, one-size-fits-all approach of a government bureaucracy undermines the integrity of the **NEC** process. In the 2005 **NEC** cycle, NEMA made a serious, official proposal to require all pull boxes to be listed. The panel chair put the question to CMP 9, and out of courtesy, invited the NEMA representative to make the motion, which was to accept the proposal. It was greeted with an extended dead silence, followed by an announcement by the chair that the motion failed because it did not so much as receive a second. This current author then moved to reject the proposal, on the grounds that it was excessive to require a listing, especially on pull boxes that may be made in local sheet metal shops to meet specific dimensional requirements. CMP 9 overwhelmingly followed suit, the second time during this author’s tenure on that panel that it has refused to require listings on this equipment.

The NEC process is a transparent, open process, fully subject to opportunities for public participation and comment. It is a consensus process requiring a two-thirds vote of a panel for which no interest can have more than a third of the membership, and for which the actual proportion is far lower than that. Every time some bureaucracy tries to require universal listings, it is tantamount to an attempt to make thousands of amendments throughout the **NEC**, in this case removing “approved” and “identified” and substituting “listed,” all without going through the consensus process. The OSHA rules are what they are. This author believes that such agencies would be better off staying out of the way of consensus standards development efforts by agencies that work as well as NFPA does. If OSHA has specific information that a listing is needed where it is not now specified, it should submit a proposal like anyone else. To its credit, the U.S. Consumer Product Safety Commission has been participating in this way for many years.

110.3. Examination, Identification, Installation, Use, and Listing (Product Certification) of Equipment. This section presents general rules for establishing what equipment and conductors may be used. Part (A) lists eight factors that must be evaluated in determining acceptability of equipment for Code-recognized use. It’s worth noting that these criteria may be used as a basis for the evaluation that is required, but not defined, by OSHA rules for “unlisted” equipment. Remember, as far as OSHA is concerned, use of “unlisted” equipment is only permitted in those cases where no commercially available product of the type to be used is “listed.” Where no “listed” version is available, then OSHA would permit the use of the “unlisted” piece of equipment, BUT OSHA requires a safety evaluation be performed.

Part (A)(1) states that the “suitability” of the equipment in question must be evaluated with respect to the intended use and installation location. The informational note to 110.3(A)(1) notes that, in addition to “listing” or “labeling” of a product by UL or another test lab to certify the conditions of its

use, acceptability may be “identified by a description marked on or provided with a product to identify the suitability of the product for a specific purpose, environment, or application.” This is a follow-through on the definition of the word “identified,” as given in Art. 100. The requirement for identification of a product as specifically suited to a given use is repeated at many points throughout the Code. As of the 2011 NEC, the note goes on to call attention to the fact that some equipment can only operate safely under limited conditions of use, and such constraints must be observed, all as covered in product markings, instructions, or general guide card limitations in the case of items listed within recognized categories.

As of the 2017 NEC, an informational note expressly recognizes that in addition to new equipment, reconditioned, refurbished, or remanufactured equipment can also be brought into this process. Older electrical equipment is routinely used to extend the useful life of existing equipment. Often the reconditioning process allows for safety upgrades that would not otherwise be possible.

With the exception of items **(3)** and **(8)** in 110.3(A), listing standards will generally cover the concerns listed in items **(2)** and **(4)** through **(7)**. Where “unlisted” equipment is used, these factors must be considered and adequately addressed. Item **(3)**, an important consideration for electrical inspectors to include in their examination to determine suitability of equipment for safe and effective use, is “wire-bending and connection space.” See [Fig. 110-1](#). This factor is a function of field-installation and addresses the concern for adequate gutter space to train conductors for connection at conductor terminal locations in enclosures for switches, CBs, and other control and protection equipment. This general mention of the need for sufficient conductor bending space is aimed at avoiding poor terminations and conductor damage that can result from excessively sharp conductor bends required by tight gutter spaces at terminals. Specific rules that cover this consideration are given in 312.6 on “Deflection of Conductors” at terminals or where entering or leaving cabinets or cutout boxes—covering gutter widths and wire-bending spaces. Item **(8)** is essentially a “catchall” requirement that depends on the designers and installers to use common sense and their knowledge of safe application to identify and correct any condition that may exist or develop relative to the installation they are performing.

Fig. 110-1. Equipment must be evaluated for adequate gutter space to ensure safe and effective bending of conductors at terminals. [Sec. 110.3(A)(3).]

Part **(B)** of this section is a critically important Code rule because it incorporates, as part of the NEC itself, all the application regulations and limitations published by product-testing organizations, such as UL, Factory Mutual, and ETL.

The most comprehensive collection of this information is in “UL Product Spec,” a comprehensive internet tool available to all at <http://www.ul.com/productspec>. This data is updated on a daily basis, so it is absolutely current. Product Spec offers five different ways to search including by Installation Code/Code Section; Product Type keyword; groupings of Products, Systems and Assemblies; UL Product Category Code; or Master Format number. Short YouTube videos are available to demonstrate how to use UL Product Spec at HYPERLINK “<http://www.ul.com/psvideo>” www.ul.com/psvideo. It also has some of the disadvantages of an on-line tool, most notably the complete lack of utility without an internet connection. There are other approaches still available to access this material; at least for now.

This material used to be easily available in print, in the form of color-coded reference books updated each year. Specifically, those of most relevance to electrical work were the *Electrical Construction Materials Directory* (Green Book), the *Hazardous Location Equipment Directory* (Red Book), and the *Electrical Appliance and Utilization Equipment Directory* (Orange Book). Each of these directories carried two categories of information. Every single product category carries what UL refers to as the “Guide Card” information for the category. These are based on provisions in

the product standard (also identified in the information), and in effect, they are the underlying assumptions UL, and other testing laboratories make about how the product will be used. For ease of access, every product category carries a four-letter code. These product directories also carried lists of the listees in the category as of the effective date of the publication.

Since all users constantly needed the Guide Card information and rarely needed the information about listees, UL extracted the Guide Card information from all the color-coded directories and combined it into a single book, the *Guide Information for Electrical Equipment* (White Book). This book was (and its content remains) essential to correct trade practice. Unfortunately, UL abandoned publishing the White Book with the 2014 edition, for cost reasons. Indeed, it has discontinued all of its printed directories with the sole exception of the Fire Directory. It still makes available the White Book content available electronically as a PDF; the most recent edition is the 2015-2016 version. However, UL recently announced it was seriously considering discontinuing even this effort, in favor of the strictly on-line approach. This would be a major, almost unthinkable inconvenience, and objections are being registered. As of this writing a final decision has not been made regarding the PDF version. To their credit, UL wishes it to be known that they want to hear from users, and concerns with discontinuation of the printed and/or PDF downloadable version of the white book can be directed to UL's Codes and Regulatory Services Department at ULRegulatoryServices@ul.com.

An example will illustrate just how useful, indeed essential, the information in the White Book is to ordinary electrical trade practice. The **NEC** at 430.109(F) says that “a horsepower rated attachment plug and receptacle ... shall be permitted to serve as the disconnecting means.” Suppose you would like to use this approach on a 7½ hp 460-volt 3-phase motor. Is there a ready source of information regarding such devices, since you would like to routinely connect and disconnect this motor? Yes, indeed. Looking in the White Book index, or after doing a {Ctrl}F search on “receptacles” in the electronic version, or on-line using “ProductSpec” after entering “receptacles” as a product type, yields the heading “Receptacles for Plugs and Attachment Plugs (RTRT).” The four-letter code at the end corresponds to the guide card information for this category, and once obtained, greatly simplifies information retrieval.

The guide card information on this product category runs to almost two full pages of small print, and remember, every word of it is effectively incorporated by reference into the NEC and is enforceable as such, by 110.3(B). In this case, you will see a table with 50 different NEMA receptacle configurations arranged by amperes, then voltage, then number of phases, then number of poles, then number of wires, then the NEMA configuration designation, and finally, the horsepower rating. In this case, we are looking for a 30 ampere, 3-phase, 3-pole, 4-wire grounding receptacle, and the one listed (NEMA L16-30) has a 10 hp rating. That combination of a locking 30 ampere 3P 4W grounding plug and receptacle combination will meet the 430.109(F) requirement nicely.

Part (C), new as of the 2017 **NEC**, addresses equipment that is not evaluated in accordance with the North America electrical safety system. European procedures allow for self-certification as evidenced by the (CE) mark. This is a one-time self-certification mark. It is not a listing mark. Repeated studies have decisively proven that substantial safety defects are frequently in evidence when equipment so evaluated is submitted for listing to the applicable product standards, that work in concert with the **NEC** and that are included in Annex A in the NEC. The informational note that follows addresses the OSHA program to qualify electrical testing laboratories as having suitable testing protocols and follow-up testing to assure suitability for application in accordance with NEC requirements.

110.4. Voltages. In all electrical systems there is a normal, predictable spread of voltage values over the impedances of the system equipment. It has been a common practice to assign these basic levels to each nominal system voltage. The highest value of voltage is that at the service entrance or transformer secondary, such as 480Y/277 V. Then considering voltage drop due to impedance in the circuit conductors and equipment, at midsystem the actual voltage would be 460Y/265 V, and finally a “utilization” voltage would be 440Y/254 V. Variations in “nominal” voltages have come about because of (1) differences in utility-supply voltages throughout the country, and (2) varying transformer secondary voltages produced by different and often uncontrolled voltage drops in primary feeders. Note that a system drop from 480 to 440 V is over 8 percent and significantly exceeds the recommendation in the second informational note that follows 215.2(A). This degree of variation inside a facility would be very unusual; however, utility distribution practice does vary, particularly when their distribution systems are under stress such as under summer air-conditioning loads.

110.6. Conductor Sizes. In this country, the American Wire Gauge (AWG) is the standard for copper wire and for aluminum wire used for electrical conductors. The American Wire Gauge is the same as the Brown & Sharpe (B & S) gauge. The largest gauge size is 4/0 AWG; above this size the sizes of wires and cables are stated in thousands of circular mils (kcmil). The circular mil is a unit used for measuring the cross-sectional area of the conductor, or the area of the end of a wire that has been cut square across. One circular mil (commonly abbreviated cmil) is the area of a circle 1/1000 in. in diameter. The area of a circle 1 in. in diameter is 1,000,000 cmil; also, the area of a circle of this size is 0.7854 sq in.

To convert square inches to circular mils, multiply the square inches by 1,273,200.

To convert circular mils to square inches, divide the circular mils by 1,273,200 or multiply the circular mils by 0.7854 and divide by 1,000,000.

In interior wiring the gauge sizes 14, 12, and 10 are frequently solid wire; 8 AWG and larger conductors in raceways are required to be stranded if pulled into a raceway, although in practice this is the usual configuration anyway, even in cable assemblies. [See 310.106(C).]

A cable (if not larger than 1,000,000 cmil) will have one of the following numbers of strands: 7, 19, 37, or 61. In order to make a cable of any standard size, in nearly every case the individual strands cannot be any regular gauge number but must be some special odd size. For example, a Class B stranded 2/0 AWG cable must have a total cross-sectional area of 133,100 cmil and is made up of 19 strands. No. 12 AWG has an area of 6530 cmil and 11 AWG, an area of 8234 cmil; therefore, each strand must be a special size between Nos. 12 and 11.

110.7. Wiring Integrity. This general rule requires that the integrity of the conductor insulation must be maintained. This can be accomplished by observing conduit fill limitations as well as proper pulling techniques. However, basic knowledge of insulation-resistance testing is important.

Measurements of insulation resistance can best be made with a megohmmeter insulation tester. As measured with such an instrument, insulation resistance is the resistance to the flow of direct current (usually at 500 or 1000 V for systems of 600 V or less) through or over the surface of the insulation in electrical equipment. The results are in ohms or megohms, but where the insulation has not been damaged, insulation-resistance readings should be in the megohm range.

110.8. Wiring Methods. All Code-recognized wiring methods are covered in [Chap. 3](#) of the NEC.

110.9. Interrupting Rating. Interrupting rating of electrical equipment is divided into two

categories: current at fault levels and current at operating levels.

Equipment intended to clear fault currents must have interrupting rating equal to the maximum fault current that the circuit is capable of delivering at the line (not the load) terminals of the equipment. See Fig. 110-2. The internal impedance of the equipment itself may not be factored in to use the equipment at a point where the available fault current on its line side is greater than the rated, marked interrupting capacity of the equipment.

All short-circuit protective devices. . .

. . . must have an interrupting rating at least equal to the maximum fault current that the circuit could deliver into a short circuit on the *line side* of the device.

NOTE: That means that the fault current "available" at the line terminals of all fuses and circuit breakers *must be known* in order to assure that the device has a rating sufficient for the level of fault current.

Fig. 110-2. (Sec. 110.9.)

If overcurrent devices with a specific AIR (ampere interrupting rating) are inserted at a point on a wiring system where the available short-circuit current exceeds the AIR of the device, a resultant downstream solid short circuit between conductors or between one ungrounded conductor and ground (in grounded systems) could cause serious damage to life and property. Since each electrical installation is different, the selection of overcurrent devices with a proper AIR is not always a simple task. To begin with, the amount of available short-circuit current at the service equipment must be known. Such short-circuit current depends upon the capacity rating of the utility primary supply to the building, transformer impedances, and service conductor impedances. Most utilities will provide this information. But, be aware that 110.9 essentially implies such calculations be performed for all electrical systems, and 110.10 mandates consideration of the available fault current at every point in the system where an overcurrent protective device is applied.

Downstream from the service equipment, AIRs of overcurrent devices generally will be reduced to lower values than those at the service, depending on lengths and sizes of feeders, line impedances, and other factors. However, large motors and capacitors, while in operation, will feed additional current into a fault, and this must be considered when calculating short-circuit currents.

Manufacturers of overcurrent devices have excellent literature on figuring short-circuit currents, including graphs, charts, and one-line-diagram layout sheets to simplify the selection of proper overcurrent devices.

In the last paragraph, the Code recognizes that equipment intended only for control of load or

operating currents, such as contactors and unfused switches, must be rated for the current to be interrupted, but does not have to be rated to interrupt available fault current, as shown in [Fig. 110-3](#).

All switches, contactors, starters, relays. . .

. . . must have an interrupting rating at least equal to “the current that must be interrupted” — which could be full-load current or, in the case of isolating or disconnect switches, some lesser value of operating current (such as transformer magnetizing current).

Fig. 110-3. (Sec. 110.9.)

110.10. Circuit Impedance, Short-Circuit Current Ratings, and Other

Characteristics. This section requires that all equipment be rated to withstand the level of fault current that is let through by the circuit protective device in the time it takes to operate—without “extensive damage” to any of the electrical components of the circuit as illustrated in [Fig. 110-4](#).

Fig. 110-4. (Sec. 110.10.)

The phrase “the component short-circuit current ratings” was added to this rule a few editions back. The intent of this addition is to require all circuit components that are subjected to ground faults or short-circuit faults to be capable of withstanding the thermal and magnetic stresses produced within them from the time a fault occurs until the circuit protective device (fuse or CB) opens to clear the fault, without extensive damage to the components.

The Code-making panel (CMP) responsible for Art. 110 has indicated that this section is not intended to establish a quantifiable amount of damage that is permissible under conditions of short circuit. The general requirement presented here is just that, a general rule. Specifics, regarding what damage is or is not acceptable under fault conditions, are established by the product test standard. For example, as stipulated in UL 508, Industrial Control Equipment, which covers combination motor starters, the permissible damage for a Type E (the so-called self-protected) motor starter is different from the requirements for other types of motor starters. The Type E unit must satisfy a more rigorous performance criterion than the others. Therefore, it is the UL Standard, not 110.10, that requires a more rigorous performance criterion for the Type E starter than is required for the other types of listed motor starters. The last sentence helps clarify that the prevention of “extensive damage” can be achieved by applying listed devices within their listed ratings. That is to say, the **NEC** does not intend to regulate product safety. Such regulation is the function of the NEMA/UL Product Standards. Any product that satisfies the controlling standard, and is applied in accordance with its ratings, is acceptable to the **NEC** and will satisfy the intent of this general rule.

110.11. Deteriorating Agents. Equipment must be “identified” for use in the presence of specific deteriorating agents, as shown on the typical nameplate in [Fig. 110-5](#). In addition, equipment not normally suitable for use in wet locations must be protected from permanent damage while

exposed to outdoor conditions during construction. The NEC has long stated that a dry location may be temporarily wet during building construction; this provision does not contradict that principle, but requires appropriate care during the construction process.

“Identified”— This kind of marking on a product makes it “recognizable as suitable for the specific purpose” as indicated on the labels.

Fig. 110-5.

110.12. Mechanical Execution of Work. This statement has been the source of many conflicts because opinions differ as to what is a “neat and workmanlike manner.”

The Code places the responsibility for determining what is acceptable and how it is applied in the particular jurisdiction on the authority having jurisdiction. This basis in most areas is the result of:

1. Competent knowledge and experience of installation methods.
2. What has been the established practice by the qualified journeymen in the particular area.
3. What has been taught in the trade schools having certified electrical training courses for apprentices and journeymen.

Examples that generally would not be considered as “neat and workmanlike” include nonmetallic cables installed with kinks or twists; unsightly exposed runs; wiring improperly trained in enclosures; slack in cables between supports; flattened conduit bends; or improvised fittings, straps, or supports. See [Fig. 110-6](#).

Fig. 110-6. Irregular stapling of BX to bottoms of joists and ragged drilling of joists add up to an unsightly installation that does not appear “workmanlike.” (Sec. 110.12.)

It has long been required in specific Code rules that unused openings in boxes and cabinets be closed by a plug or cap and such rules were presented in what was then Art. 370, now Art. 314, and Art. 373, now Art. 312. The requirement, now given in part (A) for such plugging of open holes is also a general rule to provide fire-resistive integrity of all equipment—boxes, raceways, auxiliary gutters, cabinets, equipment cases, or housings (Fig. 110-7). This rule does not extend to mounting holes in the back of boxes, etc. Not specifically mentioned, but presumably still permitted, would be weep holes drilled in outdoor enclosures. This is far from clear in the current language. When this rule was part of Arts. 312 and 314, the Code-making panel with jurisdiction (CMP 9) specifically adjusted the wording so weep holes could be drilled in boxes. Now a different panel (CMP 1) has jurisdiction, and it refused to correct the problem in the 2011 cycle. In the 2014 **NEC**, CMP 9 inserted express permission (in 314.15) to add such drainage holes not over 1/4-inch in diameter, provided they were approved. That applies to conduit bodies and boxes, and probably addresses the majority of the problems. Trapped condensation that accumulates in sealed boxes can do great damage over time.

Fig. 110-7. Unused openings in *any* electrical enclosure must be plugged or capped. Any punched knockout that will not be used *must* be closed, as at arrow.

Part **(B)** presents a requirement for current-carrying parts—buswork, terminals, etc.—that is similar to the rule of 250.12. Both rules effectively prohibit conductive surfaces from being rendered nonconductive due to the introduction of paint, lacquer, or other substances. It should be noted that this rule is not intended to prohibit the use of “cleaners.” Use of cleaning agents is recognized, but only those agents that do not contaminate conductive surfaces or deteriorate nonmetallic structures within the enclosure, as some spray lubricants are capable of doing. Be certain that any type of cleaner used for maintenance purposes is suitable for the specific application.

This section also indicates that defective equipment may not be used. Although wording prohibiting the use of damaged or otherwise defective equipment may seem superfluous, apparently many installers were using or reusing damaged equipment. At complete odds with common sense, such practice puts those who use and maintain the system at risk and is expressly forbidden. And although not specifically mentioned, any equipment that is damaged during the construction phase should be considered as covered by the rule of 110.12(B) and should be replaced.

110.14. Electrical Connections. Proper electrical connections at terminals and splices are absolutely essential to ensure a safe installation. Improper connections are the cause of most failures of wiring devices, equipment burndowns, and electrically oriented fires. Remember, field installation of electrical equipment and conductors boils down to the interconnection of manufactured components. The circuit breakers, conductors, cables, raceway systems, switchboards, MCCs, panelboards, locknuts, bushings—everything—only need be connected together. With that in mind it can be easily understood *why* the most critical concern for any designer and installer should be the actual interconnection of the various system components—especially terminations of electrical

conductors and bus. Although failure to properly terminate conductors is presently the primary cause of system failure throughout the country, it can easily be overcome by attention to, and compliance with, the rules of this section as well as applicable listing and installation instructions.

Terminals and splicing connectors must be “identified” for the material of the conductor or conductors used with them. Where in previous NEC editions this rule called for conductor terminal and splicing devices to be “suitable” for the material of the conductor (i.e., for aluminum or copper), the wording now requires that terminal and splicing devices must be “identified” for use with the material of the conductor. And devices that combine copper and aluminum conductors in direct contact with each other must also be “identified for the purpose and conditions of use.”

The **NEC** definition of identified does not specifically require that products be marked to designate specific application suitability, as noted in the discussion in Art. 100 on the topic of “Identified.” However, the general information from the UL directory quoted in the discussion of 110.3 does say that terminations are generally suitable for copper wire only, and where aluminum is suitable there will be a marking. In addition, the installation instructions furnished with the equipment will clearly indicate whether aluminum terminations are permitted, and how they are to be made and torqued.

In general, pressure-type wire splicing lugs or connectors bear no marking if suitable for only copper wire. If suitable for copper, copper-clad aluminum, and/or aluminum, they are marked “AL-CU”; and if suitable for aluminum only, they are marked “AL.” Devices listed by Underwriters Laboratories Inc. indicate the range or combination of wire sizes for which such devices have been listed. Terminals of 15- and 20-A receptacles not marked “CO/ALR” are for use with copper and copper-clad aluminum conductors only. Terminals marked “CO/ALR” are for use with aluminum, copper, and copper-clad aluminum conductors.

The vast majority of distribution equipment has always come from the manufacturer with mechanical set-screw-type lugs for connecting circuit conductors to the equipment terminals. Lugs on such equipment are commonly marked “AL-CU” or “CU-AL,” indicating that the set-screw terminal is suitable for use with either copper or aluminum conductors. But, such marking on the lug itself is not sufficient evidence of suitability for use with aluminum conductors. UL requires that equipment with terminals that are found to be suitable for use with either copper or aluminum conductors must be marked to indicate such use on the label or wiring diagram of the equipment—completely independent of a marking like “AL-CU” on the lugs themselves. A typical safety switch, for instance, would have lugs marked “AL-CU,” but also must have a notation on the label or nameplate of the switch that reads like this: “Lugs suitable for copper or aluminum conductors.”

UL-listed equipment must be used in the condition as supplied by the manufacturer—in accordance with **NEC** rules and any instructions covered in the UL listing in the Guide Card information for the product category—as required by the NEC’s 110.3(B). Unauthorized alteration or modification of equipment in the field is not covered by the UL listing and can lead to very dangerous conditions. For this reason, any arbitrary or unspecified changing of terminal lugs on equipment is not acceptable unless such field modification is recognized by UL and spelled out very carefully in the manufacturers’ literature and on the label of the equipment itself.

For instance, UL-listed authorization for field changing of terminals on a safety switch might be described in manufacturers’ catalog data and on the switch label itself. It is obvious that field replacement of set-screw lugs with compression-type lugs can be a risky matter if great care is not taken to assure that the size, mounting holes, bolts, and other characteristics of the compression lug

line up with and are fully compatible for replacement of the lug that is removed. Careless or makeshift changing of lugs in the field has produced overheating, burning, and failures. To prevent junk-box assembly of replacement lugs, UL requires that any authorized field replacement data must indicate the specific lug to be used and also must indicate the tool to be used in making the crimps. Any crimp connection of a lug should always be done with the tool specified by the lug manufacturer. Otherwise, there is no assurance that the type of crimp produces a sound connection of the lug to the conductor.

The 2011 **NEC** inserted a second paragraph, located as part of the parent text of 110.14 so it applies to both terminals and splices, covering fine-stranded conductors. This equipment must be specifically identified for the class of stranding if the stranding is more fine than that described in a new Table 10 in [Chap. 9](#).

Effective with the 2002 edition of the UL White Book, the Guide Card information on this topic, under the heading “Wire Connectors and Soldering Lugs (ZMVV)” has limited the applicability of conventional splicing and terminating methods to stranding no finer than Class B for aluminum and Class C concentric for copper. The same guide card information specified that “wire connectors additionally rated for use with other Class conductors, such as Class M, are marked with the additional class designation and number of strands.” The 2008 **NEC** incorporated this concept in 690.31(F), and it arrived in [Chap. 1](#) for the first time in the next cycle. This concept has been fully enforceable under 110.3(B) since 2002, but has seldom been applied in the field.

One major reason for this has been the relative lack of availability of mechanical solutions for this work. Most available terminations employ some form of crimping with a hydraulically actuated tool. This type of tooling is a significant expense, especially for small shops. Electricians have been making these terminations for a very long time and putting up with occasional failures as a result. Section 410.62(C)(1) recognizes numerous applications of flexible cord (generally Class M) connected to building wire at outlets. Has anyone ever observed a twist-on wire connector marked with the class and number of strands? The overwhelming majority of motor leads are Class H or Class I stranding. Has anyone ever seen a split-bolt connector marked with a stranding classification? For that matter, although plugs and cord bodies are obviously designed to terminate flexible cord, the stranding class and conductor count has not generally been included with these items either.

Nevertheless, this topic will now receive a great deal of attention. [Chapter 9](#), Table 10, in concert with this new paragraph, effectively incorporates the UL limitations in the NEC. This process of making an arcane guide card limitation general knowledge by placing it in black-letter Code text has a long pedigree. A relevant example is the concept of limiting the temperature exposure of electrical equipment from terminated conductors, which was fully enforceable under UL guide card limitations for decades, and yet remained largely unknown before 110.14(C) first appeared in the 1993 **NEC**.

The new paragraph does not require a stranding count; however, the guide card limits still ask for this. At this writing it is not clear if UL plans to withdraw this aspect of the requirement. The strand count was specifically stripped out of the rule at the very end of the **NEC** process because of concerns about practicality, so this creates some pressure on UL to follow suit. Regardless, the need for a specific listing evaluation by class of stranding will apply. Fortunately, mechanical solutions to this are beginning to appear from major vendors with broad market penetration. Figure 110-8 shows such connectors and the caption provides additional background on available configurations.

Fig. 110-8. These connectors are listed for a wide variety of finely stranded conductors, including Classes H, I, K, M, and DLO for diesel locomotive use. This vendor has over 50 different configurations with two to six ports and running from 14 AWG up to 350 kcmil, making them suitable for motors up to 200 hp and many other applications. A closely related product line from the same manufacturer covers from 6 AWG up to 750 kcmil. Such terminations routinely involve the use of ferrules to contain the strands, but these do not require them and are therefore reusable without acquiring replacement ferrules. The bearing screw includes a pivoting, nonturning pressure plate that does not cut strands as it tightens. (Courtesy of IlSCO.)

Part (A) prohibits the use of more than one conductor in a terminal (see [Fig. 110-9](#)) unless the terminal is identified for the purpose (meaning generally recognizable as suitable for the purpose by appropriate markings or instructions).

**WATCH
OUT!**

Fig. 110-9. [Sec. 110.14(A).]

Use of the word “identified” in the last sentence of 110.14(A) could be interpreted to require that terminals suited to use with two or more conductors must somehow be marked. This is a frequent example of where installers confuse “identified” with “marked” as covered in the discussion of the definition of “identified.” For a long time terminals suited to and acceptable for use with aluminum conductors have been marked “AL-CU” or “CU-AL” right on the terminal. Twist-on or crimp-type splicing devices are “identified” both for use with aluminum wires and for the number and sizes of wires permitted in a single terminal—with the identification marked on the box in which the devices are packaged or marked on an enclosed sheet.

For set-screw and compression-type lugs used on equipment or for splicing or tapping-off, suitability for use with two or more conductors in a single barrel of a lug could be marked on the lug in the same way that such lugs are marked with the range of sizes of a single conductor that may be used (e.g., “No. 2 to No. 2/0.”). But the intent of the Code rule is that any single-barrel lug used with two or more conductors must be tested for such use (such as in accordance with UL 486B standard), and some indication must be made by the manufacturer that the lug is properly suited and rated for the number and sizes of conductors to be inserted into a single barrel. Again, the best and most effective way to identify a lug for such use is with marking right on the lug, as is done for “AL-CU.” But the second sentence of 110.3(A)(1) also allows such identification to be “provided with” a product, such as on the box or on an instruction sheet. See [Fig. 110-10](#).

Fig. 110-10. A *terminal* with more than one conductor terminated in a single barrel (hole) of the lug (at arrows) must be “identified” (marked, listed, or otherwise tested and certified as suitable for such use).

Section 110.14(B) covers splice connectors and similar devices used to connect fixture wires to branch-circuit conductors and to splice circuit wires in junction boxes and other enclosures. Much valuable application information on such devices is given in the UL Electrical Construction Materials Directory, under the heading of “Wire Connectors and Soldering Lugs.” The new last sentence of 110.14(B) states that connectors or splices used with directly buried conductors must be listed for the application.

This wording makes the use of listed connectors and splice kits mandatory where used directly buried. As indicated by the submitter of this proposal for a change, such equipment *is* listed, *is* commercially available, and *should* be used.

Part (C) of 110.14 reiterates the UL rules regarding temperature limitations of terminations, which are made mandatory by 110.3(B). It is worth noting that the information given by UL in the guide card information for “Electrical Equipment for Use in Ordinary Locations” is more detailed. The informational note following this section is intended to indicate that if information in a general or specific UL rule permits or requires different ratings and/or sizes, the UL rule must be followed.

The last sentence indicates acceptability of 90°C-rated wire where applied in accordance with the temperature limitations of the termination.

90°C-insulated conductors may be used in virtually any application that 60°C- or 75°C-rated conductors may be used and in some that the lower-rated conductors cannot. But the ampacity of the 90°C-rated conductor must never be taken to be more than that permitted in the column that corresponds with the temperature rating of the terminations to which the conductor will be connected. And that applies to both ends of the conductor. For example, consider a 6 AWG THHN copper conductor, which has a Table 310.16 ampacity of 55 A in the 60°C column. But, if the 6 AWG is supplied from a CB with, say, a 60/75°C-rating, it may be considered to be a 65-A wire, provided the equipment end is also rated 60/75°C or 75°C. But, if the equipment *at either end of the wire* is rated at 60°C, or unmarked and therefore rated that way by default, the 6 AWG THHN copper conductor may carry no more than the 60°C-ampacity (55 A) shown in Table 310.16 for a 6-AWG copper wire. The wording in parts (C)(1)(a)(3) and (C)(1)(b)(2) is intended to indicate as much (Fig. 110-11). Note also that most motors go directly to the 75°C ratings regardless of wire size, per (C)(1)(a)(4).

Sec. 110.14(C)

Although this conductor can safely carry 55 A, because the equipment terminations are rated for 60°C, the No. 8 must carry no more than the current shown in the 60°C column in Table 310.16 for a No. 8 copper conductor, i.e., 40 A.

Fig. 110-11. 90°C-insulated conductors may be used even where derating is not required, provided they are taken as having an ampacity not greater than the ampacity shown in the column from Table 310.15(B)(16) that corresponds to the temperature rating of the terminations—at both ends—to which the conductors will be connected.

Part (D) calls attention to the fact that manufacturers are marking equipment, terminations, packing cartons, and/or catalog sheets with specific values of required tightening torques (pound-inches or pound-feet). Although that puts the installer to the task of finding out appropriate torque values, virtually all manufacturers are presently publishing “recommended” values in their catalogs and spec sheets. In the case of connector and lug manufacturers, such values are even printed on the boxes in which the devices are sold. In 110.3(B), the NEC requires that all listed equipment be installed as indicated by the listing instructions that are issued with the product. In virtually all cases, where a mechanical type terminating device is used, the manufacturer will indicate a prescribed torque value. That is the value that was used during product testing. In order for one to be certain that the installed equipment will operate as it did during product certification testing, the equipment must be used in the

same manner it was during testing. And that includes torquing the terminating devices to the values prescribed in the manufacturer's installation instructions. Failure to torque every terminal to the manufacturer-prescribed value is a clear and direct violation of this Code section.

Torque is what produces the amount of tightness of the screw or bolt in its threaded hole; that is, torque is the measure of the twisting movement that produces rotations around an axis. Such turning tightness is measured in terms of the force applied to the handle of the device that is rotating the screw or bolt and the distance from the axis of rotation to the point where the force is applied to the handle of the wrench or screwdriver:

$$\begin{aligned}\text{Torque (lb ft)} &= \text{force (lb)} \times \text{distance (ft)} \\ \text{Torque (lb in.)} &= \text{force (lb)} \times \text{distance (in.)}\end{aligned}$$

Because there are 12 in. in a foot, a torque of "1 lb-ft" is equal to "12 lb-in." Any value of "pound-feet" is converted to "pound-inches" by multiplying the value of "pound-feet" by 12. To convert from "pound-inches" to "pound-feet," the value of "pound-inches" is divided by 12.

Note: The expressions "pound-feet" and "pound-inches" are preferred to "foot-pounds" or "inch-pounds," although the expressions are used interchangeably. When the unit leads with the distance (such as foot-pounds), it is supposed to be referring to a unit of energy in classical physics, where energy is defined as the product of applied force and the distance over which that force acted.

Torque wrenches and torque screwdrivers are designed, calibrated, and marked to show the torque (or turning force) being exerted at any position of the turning screw or bolt. [Fig. 110-12](#) shows typical torque tools and their application. And they do require periodic calibration. See also the additional coverage in this book at Annex I at the end of the code book. This annex presents default torque specifications based on the size and type of screw supplied with the equipment, and can be used in the event that specifications on or with the equipment are unavailable.

Fig. 110-12. Readily available torque tools are (at top, L–R): torque screwdriver, beam-type torque wrench, and ratchet-type torque wrench. These tools afford ready compliance with the implied requirement of the informational note in the Code rule. Sec. 110.14(D).

110.15. High-Leg Marking. Here the Code mandates a specific “color-coding” for the “high leg” in a 4-wire delta system. These systems, used in certain areas, create two 120-V “legs” by center-tapping one of the secondary windings of a 240-V delta-wound transformer. That is, by grounding the center point of one winding, the phase-to-phase voltage remains 240 V, 3-phase, and the voltage between phase A and the grounded conductor, and between phase C and the grounded conductor will be 120 V, single phase. BUT the difference of potential between phase B and the grounded conductor will be 208 V, single-phase. The fact that phase B is at 208 V, with respect to the grounded center-tapped conductor, while phases A and C are at 120 V, is the reason that this type of distribution system is known as a “high-leg” delta system.

As indicated, this rule requires color-coding of the “high leg” (i.e., phase B—the one that’s at 208 V to the grounded conductor) or other “effective means” to identify the “high leg.” This “identification” must be provided at any point in the system where “a connection is made” and the high leg is run with the other circuit conductors. That would include enclosures where the high leg is itself not connected but merely “present” within the enclosure, and would exclude enclosures where the grounded conductor is not present, such as where the three phase legs supply a motor load. Although the wording used in this section would permit identifying the high leg by tagging with numbers or letters, or other “effective means,” where color-coding is used, the high leg must be colored orange. Use of other colors to identify the high leg would seem to be a violation of the wording used here.

110.16. Arc-Flash Hazard Warning. This section calls for a field marking of electrical equipment such as switchboards, panelboards, motor control centers, meter socket enclosures, and industrial control panels—provided by the installer at the time of installation—that indicates that protection against arc-flash hazards is required when maintaining such equipment. Frequently, the hazards encountered will be generic to the equipment and the 2014 NEC also allows for, but does not require, factory applied markings to meet this rule. The marking is intended to alert maintenance personnel of the need for protective gear when working on the equipment while it is energized. Such marking must be on the exterior of covers and doors that provide access to energized live parts to satisfy the requirement for the warning to be “clearly visible” “before examination, etc.” Refer to NFPA 70E[®] for detailed information on selecting personal protective equipment (PPE) that is appropriate for the degree of arc-flash exposure involved. The rule applies to equipment in “other than dwelling units” so it would not apply to a household service panel or an apartment panel within the apartment. However, it does apply to service equipment and distribution panels for multifamily housing that are in common areas outside any dwelling unit. Typical equipment for single dwelling units is not exposed to the incident energy levels that other equipment may see. Effective with the 2017 NEC, in (B), large-capacity (1200 amps. or more) non-residential services must include actual numerical values of specific site parameters (voltage, available fault, and clearing time under those conditions) on the label, together with the “date the label was applied.” In the case of a pre-applied label by the manufacturer, this should be interpreted as the date the required calculations were made. These numbers allow arc-flash hazard calculations to be done easily. One aspect of the specific wording will require interpretation. The literal text (“in other than dwelling units”) raises the

question as to whether a large apartment building service is included. Very few individual dwelling services are of such a size. Where the service supplies a building of multiple occupancy, the power is not confined to any dwelling unit, and therefore the rule may apply. It certainly would never be a violation to provide this labeling on an apartment building service. The NEC also allows, as covered in Informational Note No. 3, arc-flash labeling as detailed in **NFPA 70E** to substitute for this labeling. This makes sense because the intent of the labeling is to allow for appropriate PPE selections.

Note that the fault current calculation does suffer from the same problem of inevitable inaccuracy based on utility changes over time as the value developed in 110.24. Refer to the discussion in that section for more information.

110.18. Arcing Parts. Complete enclosures are always preferable, but where this is not practicable, all combustible material must be kept well away from the equipment.

110.21. Marking. The marking required in 110.21(A) should be done in a manner that will allow inspectors to examine such marking without removing the equipment from a permanently installed position. It should be noted that the last sentence in 110.21 requires electrical equipment to have a marking durable enough to withstand the environment involved (such as equipment designed for wet or corrosive locations). Effective with the 2017 NEC, this section also includes express requirements regarding reconditioned equipment. A marking must identify the responsible entity for the work along with the date of reconditioning. This will establish the beginning of a paper trail through which the inspector can determine the qualifications of the reconditioning party.

Part (B) was new in the 2014 NEC and addresses how hazard markings applied in the field should be placed and formatted. This change is even more important than it might first appear, because many sections all across the Code now point to these rules as being applicable to the labels being created in accordance with those diverse sections. The actual code text is quite vague (“adequately warn ... using effective words and/or colors and/or symbols”) but the informational note is anything but vague. By pointing to the ANSI Z535.4 standard, an inspectional authority can apply the detailed requirements of that standard. For example, there are three hazard commands:

DANGER (a hazardous condition that if not avoided will result in death or serious injury); label to use red, white, and black

WARNING (a hazardous condition that if not avoided could result in death or serious injury); label to use black, white, and orange

CAUTION (a hazardous condition that if not avoided might result in minor or moderate injury); label to use black, white, and yellow

The new subsection also requires that the label be permanently affixed to its target and have sufficient durability to withstand applicable environmental factors. In addition, the label must not be handwritten, with an exception for a portion of a label that may have variable information or that is otherwise subject to change. In such cases handwriting, which must be legible, is permitted. The information presented here is necessarily incomplete; the Z535.4 standard (developed by NEMA) goes on to address font sizes, colors, placement locations, wording choices, acceptable symbols and appropriate wording, as well as tactics to provide durability under various adverse operating conditions.

110.22. Identification of Disconnecting Means. As shown in [Fig. 110-13](#), it is a mandatory Code rule that all disconnect devices (switches or CBs) for load devices and for circuits

be clearly and permanently marked to show the purposes of the disconnects. This is a “must” and, under OSHA, it applies to all existing electrical systems, no matter how old, and also to all new, modernized, expanded, or altered electrical systems. This requirement for marking has been widely neglected in electrical systems in the past. Panelboard circuit directories must be fully and clearly filled out. And all such marking on equipment must be in painted lettering or other substantial identification.

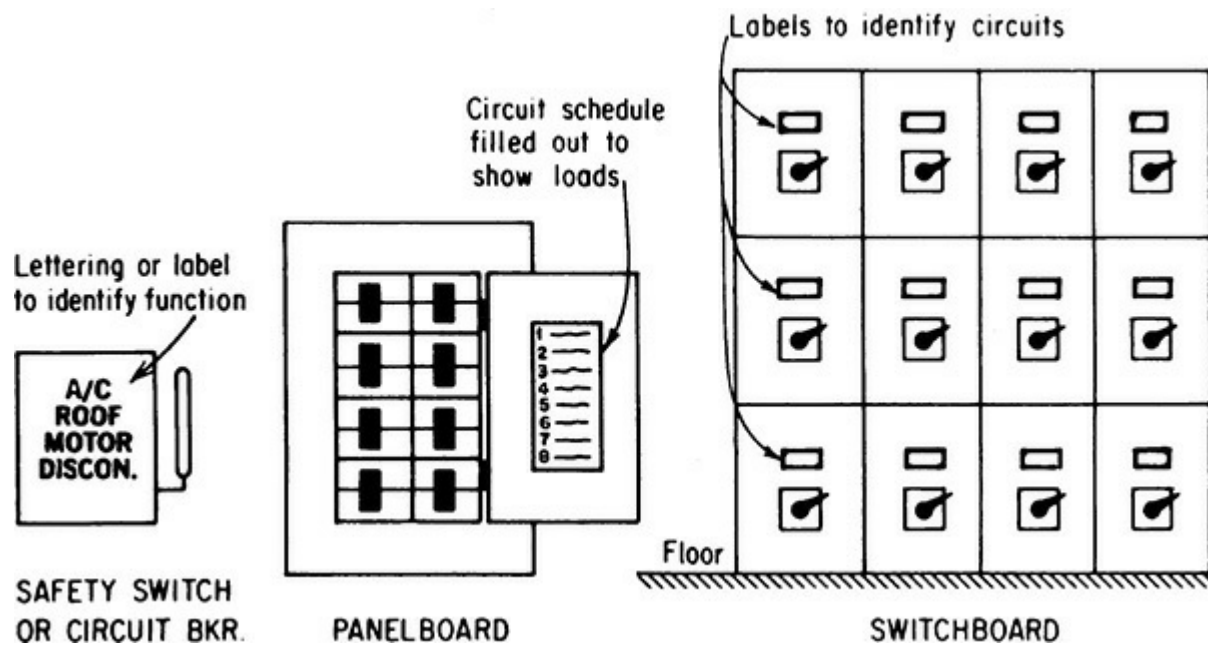

Fig. 110-13. All circuits and disconnects must be identified. OSHA regulations make NEC Sec. 110.22 mandatory and retroactive for existing installations and for all new, expanded, or modernized systems—applying to switches as well as circuit breakers. (Sec. 110.22.)

This rule now appears as 110.22(A) because the section has been divided into three lettered paragraphs. Effective identification of all disconnect devices is a critically important safety matter. When a switch or CB has to be opened to de-energize a circuit quickly—as when a threat of injury to personnel dictates—it is absolutely necessary to identify quickly and positively the disconnect for the circuit or equipment that constitutes the hazard to a person or property. Painted labeling or embossed identification plates affixed to enclosures would comply with the requirement that disconnects be “legibly marked” and that the “marking shall be of sufficient durability.” Paste-on paper labels or marking with crayon or chalk could be rejected as not complying with the intent of this rule. Ideally, marking should tell exactly what piece of equipment is controlled by a disconnect (switch or CB) and should tell where the controlled equipment is located and how it may be identified. [Figure 110-14](#) shows a case of this kind of identification as used in an industrial facility where all equipment is marked in two languages because personnel speak different languages. And that is an old installation, attesting to the long-standing recognition of this safety feature.

Fig. 110-14. Identification of disconnect switch and pushbutton stations is “legibly marked” in both English and French—and is of “sufficient durability to withstand the environment”—as required by the **Code** rule. (Sec. 110.22.)

The rule of 110.22 has long required that every disconnect be marked to indicate exactly what it controls. And that marking must be legible and sufficiently durable to withstand the environment to which it will be exposed. And, the rule of 408.4 requires that any modifications also be reflected in the circuit directory of panelboards. While most are aware of the requirement in 110.22, it seems as if very few pay any attention to this part of the rule of 408.4.

It should be noted that the marking of disconnects is one of the few requirements that is made retroactive by OSHA. That is, regardless of when the disconnect was installed, or when a modification was performed, the purpose of every disconnect must be marked at the disconnect. If your facility or your customer’s facility does not have such markings for each and every disconnect, every effort should be made to ensure that a program to provide such markings is initiated and completed. Failure to do so could result in heavy fines should you be subject to an inspection by OSHA (Fig. 110-14).

The second paragraph, 110.22(B), covers the field marking requirements for series combinations of circuit breakers or fused switches used in an “engineered series combination” with downstream devices that do not have an interrupting rating equal to the available short-circuit current but are dependent for safe operation on upstream protection that is rated for the short-circuit current; enclosure(s) for such “series rated” protective devices must be marked in the field “Caution—Engineered Series Combination System Rated _____ Amperes. Identified Replacement Components Required.”

Note that this paragraph as well as the one following it specifically cite the new (2014 **NEC**)

110.21(B) for the required field marking.

This provision correlates with the new procedure in 240.86(A) that allows, under strict engineering supervision and only in existing installations, the use of upstream overcurrent protective devices with a let-through current under fault conditions that does not exceed the interrupting rating of a downstream overcurrent device. This allows for adapting existing installations to increases in available fault current resulting from changes in the infrastructure of the serving utility or other factors. The engineer must be able to certify that the lower-rated downstream device will not begin to open or melt during the operating period of the upstream device, or the downstream device may be subjected to the full available fault in excess of its rating, instead of merely the let-through current. This requires a very sophisticated evaluation, and will be completely defeated if the wrong replacement component is selected.

The third paragraph, 110.22(C), says that where circuit breakers or fused switches are used in a “tested series combination” with downstream devices that do not have an interrupting rating equal to the available short-circuit current but are dependent for safe operation on upstream protection that is rated for the short-circuit current, enclosure(s) for such “series rated” protective devices must be marked in the field “Caution—Series Combination System Rated _____ Amperes. Identified Replacement Components Required.”

Such equipment is typically employed in multimeter distribution equipment for multiple-occupancy buildings—especially residential installations—with equipment containing a main service protective device that has a short-circuit interrupting rating of some value (e.g., 65,000 A) that is connected in series with feeder and branch-circuit protective devices of considerably lower short-circuit interrupting ratings (say 22,000 or 10,000 A). Because all of the protective devices are physically very close together, the feeder and branch-circuit devices do not have to have a rated interrupting capability equal to the available short-circuit current at their points of installation. Although such application is a literal violation of NEC 110.9, which calls for all protective devices to be rated for the short-circuit current available at their supply terminals, “series rated” equipment takes advantage of the ability of the protective devices to operate in series (or in cascade as it is sometimes called) with a fault current interruption on, say, a branch circuit being shared by the three series protective devices—the main, feeder, and branch circuit. Such operation can enable a properly rated main protective device to protect downstream protective devices that are not rated for the available fault. When manufacturers combine such series protective devices in available distribution equipment, they do so on the basis of careful testing to assure that all of the protective devices can operate without damage to themselves. Then UL tests such equipment to verify its safe and effective operation and will list such equipment as a “Series Rated System.”

Because UL listing is based on use of specific models of protective devices to assure safe application, it is critically important that all maintenance on such equipment be based on the specific equipment. For that reason, this Code rule demands that the enclosure(s) for all such equipment be provided with “readily visible” markings to alert all personnel to the critical condition that must always be maintained to ensure safety. Thus, all series-rated equipment enclosure(s) must be marked.

Note that the enhanced requirements for series-rated systems only apply where the series rating is required to satisfy 110.9. For example, on a 22-kA available fault current system at the service disconnect, if it can be shown that there is sufficient static impedance in the length of feeder between the service and a downstream panel so that the available fault current at that panel is only 10 kA, then no series connection listing is involved and this marking requirement does not apply. This is true even

though the downstream panel is still in series with the service protective device. Series-connected listings are an economical way to avoid a fully rated system, but they are not required when the conditions in the field are such that a downstream overcurrent device could not be subjected to a fault current in excess of its rating, and therefore comply with 110.9 without any upstream assistance. Since a very little impedance goes a long way in reducing an otherwise very high available fault current, this is a very frequent practical result. Many engineers take this into account when they position downstream equipment.

110.24. Available Fault Current. This rule was new in the 2011 **NEC** and requires a field marking of the maximum available fault current to be placed on service equipment in other than dwelling units. As in the case of the arc-flash warning in 110.16, the preposition “in” means that the label would be required for a service in a common area for multifamily housing. An exception waives the rule in industrial occupancies with qualified maintenance and supervision.

The rule further requires that this label be updated when modifications occur that change the available fault current. As in the case of the original label, the applicable date when the calculation was performed must be included.

There are serious issues with such a label, beginning with the fact that such a label, if applied, will tend to be believed. Utilities routinely change their distribution patterns without advising property owners of potential changes in fault current availability. This section is in the general part of Art. 110 and therefore also literally applies to medium-voltage installations; routine utility switching operations on medium-voltage networks make the available fault particularly volatile. Frequently, when a utility does provide a fault current number, it does so over a disclaimer that the calculation is only good as of the date on the letter. If the fault current increases, the label is worse than useless if it is relied upon to select additional overcurrent devices.

Although utilities will always make fault current assumptions known to customers on request, they do not inform them prospectively and cannot be expected to know where such labels have been applied and update them. And by far the single most likely modification that would affect a 110.9 calculation would be utility activities on their system. We are left with a label that likely will not be updated, and that would be hazardous if erroneous and acted upon. The 2017 **NEC** additionally requires that the fault current calculation be documented and made available to interested parties; however that does not address the concerns raised here.

Section 110.9 addresses bolted short-circuit available current, and it must be properly applied. A failure, however, normally only occurs on start-up of a new installation. For example, a parallel makeup on a large feeder, if the wires are crossed, will produce such a fault. This is not a failure that will occur after the commencement of occupancy, where the normal failure mode is about ground faults. This is why documented bolted short-circuit failures are vanishingly rare in occupied buildings, and why utilities see little gain in publishing changes to their required fault duty levels.

There is an additional issue with this label, involving incident energy calculations for personal protective equipment (PPE) to address arc-flash hazards. The number on this label should not be used for this work, but preliminary field discussions indicate that is how it will frequently be applied.

For just this reason the 2014 **NEC** placed an informational note at this location describing its intended application and differentiating it from *NFPA 70E* that addresses workplace safety requirements.

110.25 Lockable Disconnecting Means. For some time, section after section in the **NEC** has been devoting considerable real estate to what constitutes an acceptable disconnecting means,

particularly when the disconnect is supposed to be lockable. Now a universal rule appears in Art. 110, which will apply throughout the Code, and in almost 50 locations this verbiage has been withdrawn in favor of a reference to this rule. These disconnecting means must lock open, and the lockable portion must be permanently installed so as to remain in place whether or not a padlock is in place. Other arrangements are too easily defeated, because they can usually be removed with the padlock still closed. Note that special conditions do arise. For example, 490.46 covers medium-voltage circuit breakers, and in addition to referencing this section, that section also integrates instances where a drawout mechanism is relied upon in this context.

II 1000 Volts, Nominal, or Less

110.26. Spaces about Electric Equipment. Although the upper voltage parameter throughout most of the code has been raised from 600 to 1000 V largely to accommodate higher dc voltages from PV applications, the 600-V limit did not change in this article. The basic rule of 110.26 calls for “sufficient access and working space” to be provided in all cases to permit ready and safe operation and maintenance of electrical equipment. This rule applies to receptacles and all electrical equipment. However, the specific work space dimensions and other rules that are in the lettered paragraphs following only apply under the conditions set forth in those paragraphs. For example, a hydromassage bathtub motor and receptacle that has no access door provided is in violation of this section (as well as some prescriptive criteria in Art. 680). However, the full panoply of required work space widths and depths does not apply because such equipment does not need to be worked hot.

The wording of 110.26(A) calls for compliance with parts **(A)(1)**, **(2)**, and **(3)**. Those three subparts define the work space zone needed at electrical equipment. These rules are slightly modified and expanded upon by parts **(B)**, **(C)**, **(D)**, and **(E)**. Part **(F)** has nothing whatever to do with work space and covers the dedicated wiring space above (and below) certain pieces of equipment.

As indicated by 110.26(A)(1), the dimensions [shown in Table 110.26(A)] of working space in the direction of access to live electrical parts for equipment operating at 1000 V or less—where live parts are exposed—or to the equipment enclosure—in the usual case where the live parts are enclosed—must be carefully observed. The minimum clearance is 3 ft. The minimum of 3 ft was adopted for Code Table 110.26(A)(1) to make all electrical equipment—panelboards, switches, breakers, starters, etc.—subject to the same 3-ft (914-mm) minimum to increase the level of safety and assure consistent, uniform spacing where anyone might be exposed to the hazard of working on any kind of live equipment. Application of Code Table 110.26(A)(1) to the three “conditions” described in the note below Table 110.26(A)(1) is shown in the sketches making up this handbook’s Table 110-1. The 2017 **NEC** added a line to the table for 601–1000 volts. This made no change in **NEC** requirements, because the required spacings agree with Table 110.34(A), which formerly applied. This rearrangement is part of the gradual inclusion of this subject matter in rules that formerly went only up to 600 volts. [Figure 110-15](#) shows a typical example of Condition 3.

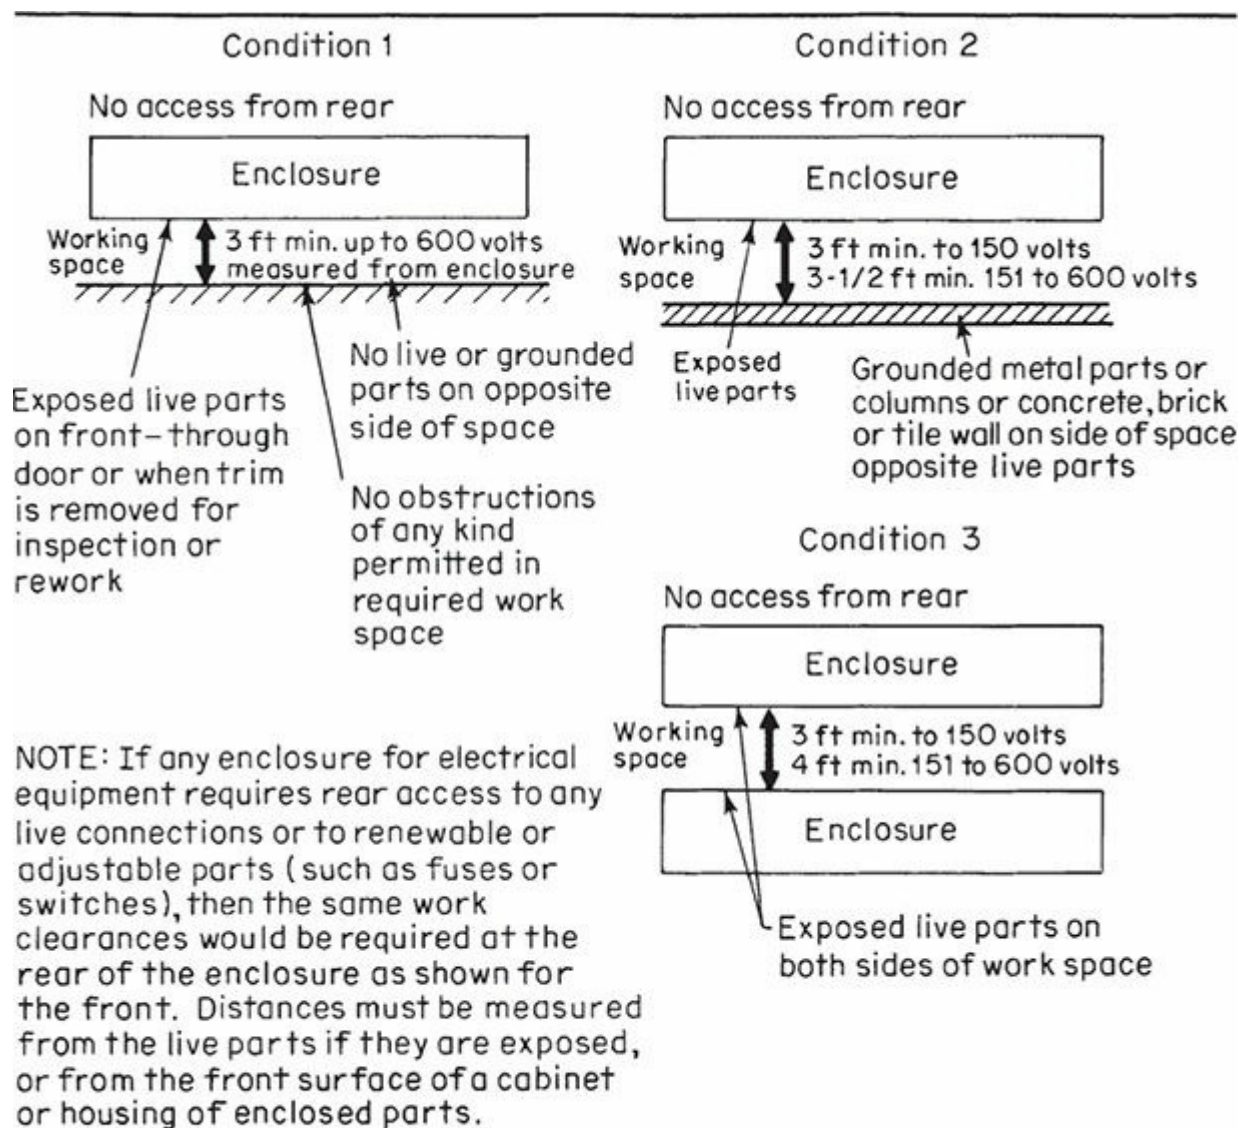

Fig. 110-15. Condition 3 in Code Table 110.26(A) for the rule covered by Sec. 110.26(A) applies to the case of face-to-face enclosures, as shown here where two switchboards face each other. The distance indicated must be at least 3 or 4 ft depending on the voltage of enclosed parts. [Sec. 110.26(A).]

Table 110-1. Clearance Needed in Direction of Access to Live Parts in Enclosures for Switchboards, Panelboards, Switches, CBs, or Other Electrical Equipment—Plan Views [110.26(A)]

For applications above 600 volts but not exceeding 1000 volts, Condition 1 clearances (3 ft) are unchanged, but Condition 2 clearances increase to 4 ft and Condition 3 clearances increase to 5 ft.

According to 110.26(A)(1)(a), a “minimum” depth of work space behind equipment rated 1000 V, and less, must be provided where access is needed when deenergized. The past few editions of the **NEC** have required a minimum depth of work space behind equipment rated over 600 V where access was required only when the equipment was deenergized. The 2002 **NEC** strengthened these requirements by changing the references from “deenergized parts” to “nonelectrical parts,” concluding that merely shutting off power to such equipment was not sufficient. An example of such access would be periodic replacement of an air filter (Fig. 110-16).

110.26(A)(1)(a)

Fig. 110-16. Where access is needed, but only when the equipment is deenergized, the work space need only be 30 in. deep. This addition to part (a) in Sec. 110.26(A) applies *only* to those cases where access is needed only to service *nonelectrical parts*. As always, if access is needed at the rear for “examination, adjustment, servicing, or maintenance” when the equipment is energized, the depth, as well as the other aspects of work space must satisfy the basic rule. And, if there is never a need to gain access to the rear of the equipment, there is no minimum depth required by the Code, but careful attention should be paid to any clearances required by the equipment manufacturer.

Part (1)(b) to 110.26(A) allows working clearance of less than the distances given in Table 110.26(A) for live parts that are operating at not over 30 V RMS, 42 V peak, or 60 V dc. The last phrase recognizes the inherent safety of low-voltage circuits like the Class 2 and Class 3 control and power-limited circuits covered by Art. 725, as well as certain other low-voltage systems recognized in [Chaps. 7 and 8](#). This exception allows less than the 3-ft minimum spacing of Table 110.26(A) for live parts of low-voltage communication, control, or power-limited circuits. BUT, only where “special permission” is granted. Remember, any such “special permission” must be in writing.

Part (1)(c) to 110.26(A) permits smaller work space when replacing equipment at existing facilities, provided procedures are established to ensure safety. This allowance responds to widespread misinterpretation of these rules at the time 480- and 600-V motor control centers were being installed in industrial occupancies with Condition 2 dimensioned aisles. Many engineers considered this to be a 3½-ft clearance because when staff would be working one side hot the other side would be closed, and therefore present a grounded and not energized surface. This was never the intent of the rule, because often both sides are worked hot at the same time. The **NEC** has been reworded to preclude this misinterpretation from continuing.

However, when it came time to upgrade such existing nonconforming installations, facilities were in a quandary because now the room and the conduits were in place. The solution was to provide limited relief for existing applications that allows Condition 2, but only if qualified personnel are involved and there are written procedures in place that preclude working both sides of the aisle hot.

In part (A)(2) of 110.26, the Code mandates a minimum width for the required clear work space. For all equipment, the work space must be 762 mm (30 in.) or the width of the equipment, whichever is greater. Note that there is no requirement to center the equipment in the clear space, only the requirement to provide the space, which may even begin right at one edge of the equipment and then

extend beyond the equipment on the other side.

And, as required by the second sentence of Sec. 110.26(A)(2), clear work space in front of any enclosure for electrical equipment must be deep enough to allow doors, hinged panels, or covers on the enclosure to be opened to an angle of at least 90°. Any door or cover on a panelboard or cabinet that is obstructed from opening to at least a 90° position makes it difficult for any personnel to install, maintain, or inspect the equipment in the enclosure safely. Full opening provides safer access to the enclosure and minimizes potential hazards (Fig. 110-15). Although this rule seems to be related to “depth” of work space, it is covered in 110.26(A)(2), “Width of Working Space.” (See Fig. 110-17.)

Fig. 110-17. Working space required in front of electrical equipment for side-to-side clearance and door opening. [Sec. 110.26(A).]

Part (A)(3) covers the minimum headroom, which must extend from the floor or work platform to 6½ ft (2 m) or (if higher) the height of the equipment. The rule applies to any equipment covered in 110.26(A), and generally includes service equipment, switchboards, panelboards, and motor control centers. The first exception permits “service equipment or panelboards, in existing dwelling units, that do not exceed 200 A” to be installed with less than 6½ ft of headroom—such as in crawl spaces under single-family houses. But this exception applies only in existing “dwelling units” that meet the definition of that phrase. In any space other than an existing dwelling unit, all indoor service equipment, switchboards, panelboards, or control centers must have headroom at the equipment that is at least 6½ ft high, but never less than the height of the equipment.

Some details on headroom are shown in the bottom portion of Fig. 110-20. But, in that sketch, it should be noted that the 2.0-m (6½-ft) headroom must be available for the entire length of the work space. There must be a 2.0-m (6½-ft) clearance from the floor up to the bottom of the light fixture or to any other overhead obstruction—and not simply to the ceiling or bottom of the joists. Note that this rule now incorporates the provisions in former 110.26(E), which has been deleted.

The wording here does permit a limited intrusion into the required work space. Equipment associated with the electrical installation, such as wireways, and pull boxes, may protrude into the work space, but not more than 150 mm (6 in.) beyond the front of the electrical equipment that requires the dedicated space. This intrusion is permitted either below or above the equipment in question. It is also permitted for even the items specified in 110.26(E) (service equipment, panelboards, distribution boards, and motor control centers) because all 110.26(E) does is to establish the extent of the vertical dimension. The rule in this location, and no other, determines the

extent to which the required work space may be intruded upon. Note that this allowance does not permit large transformers or other equipment that extend further into the work space. The second exception, covering electric meters, allows a further intrusion over and above the 6-in. allowance for general electrical equipment. The meter socket that supports the meter, however, is subject to the normal 6-in. intrusion limitation.

The rules in 424.66(B) regarding work space above suspended ceilings were moved to 110.26(A) in the 2017 NEC as a new (4). In the process, the rules now apply to equipment generally, not just duct heaters, and parallel rules were inaugurated for crawl spaces as well. Fig. 110-18 shows a typical example above a suspended ceiling. Note that the metric dimensions are unrounded soft conversions. This is obviously an inappropriate use of soft conversions. Clearly, a couple millimeters is of no consequence here and, ironically, soft conversions were being inserted while the Code-making panel, elsewhere in Article 110, was busily and correctly changing soft conversions to hard conversions.

Fig. 110-18. Example of typical cramped working space above suspended ceilings.

The minimum opening to the space has been chosen to match a typical square lay-in tile clear opening between the T-bar edges. The minimum width follows the usual rules, being that of the equipment and not less than 30 in., and also such that the enclosure doors open not less than 90°. The front space must also meet the usual depth requirement as given in Table 110.26(A)(1). The final set of rules, in (d), will undoubtedly require some discussion with the inspector, for several reasons. First, the “maximum” height is specified, beginning with the required height to install the equipment. It would seem the appropriate word would be “minimum.” Obviously, there should be no code objection to a ceiling cavity (or, for that matter, a crawl space height) of any height that happens to be greater than that necessary for the equipment to function. In effect, this provision should be read, as common sense would indicate, as a simple recognition that the maximum space available in such installations is an acceptable working space height.

Another issue that will likely initiate discussion relates to the allowance for “a horizontal ceiling structural member” in this space. The original text in 2014 **NEC** 424.66(B)(4) specifically mentioned T-bars; the meaning here is less clear because crawl spaces are also covered. Crawl spaces generally have ceilings comprised of horizontal ceiling structural members that support the floor immediately above. The fact that the sentence also includes “access panel,” in wording joined by the coordinating conjunction “or,” suggests the provision only applies to suspended ceilings but

the inspector will need to decide.

There is at least one more issue. This wording remained in Art. 424 through the input period, only coming over completely in the comment period. The Code-making panel responsible for Art. 424 (remember, applied only to ceilings) also accepted additional wording in the input period mandating that the working space be unobstructed to the floor. This is crucial to a safe work environment. Often suspended ceiling cavities extend over fixed partition walls that only extend up to the suspended ceiling. If the equipment access panel is located above one of those partitions, it will be impossible to position a stepladder below the working space. The electrician working on the equipment will then be forced to lean, often to a hazardous extent, to the side of the ladder, defeating the objective of the requirement. The wording to address this issue was inexplicably lost when the requirement was relocated.

Part **(A)** also includes, as of the 2017 **NEC**, item (5) which is essentially a mirror image of 110.34(B) from the standpoint of lower voltage equipment. The exception was not duplicated because the paragraph, as written in this location, ends up with the same requirements as the original section.

Part **(B)** in 110.26 presents a very important requirement regarding the use of work space. The three-dimensional area identified by parts **(A)(1)**, **(A)(2)**, and **(A)(3)** of 110.26 must not only be provided but must be maintained! That is, such space must be viewed and treated as an “exclusion zone.” There may be no other things in the work space—not even on a “temporary” basis.

The second sentence of 110.26(B) addresses maintenance situations on equipment located in “passageways or general open space.” The concern here is for unqualified personnel, coming into the proximity of and potentially in contact with live electrical parts. Where equipment located in areas accessible to the general population of a building or facility is opened to perform maintenance or repair, the work space area must be cordoned off to keep unqualified persons from approaching the live parts. Failure to do so clearly constitutes a violation of the NEC.

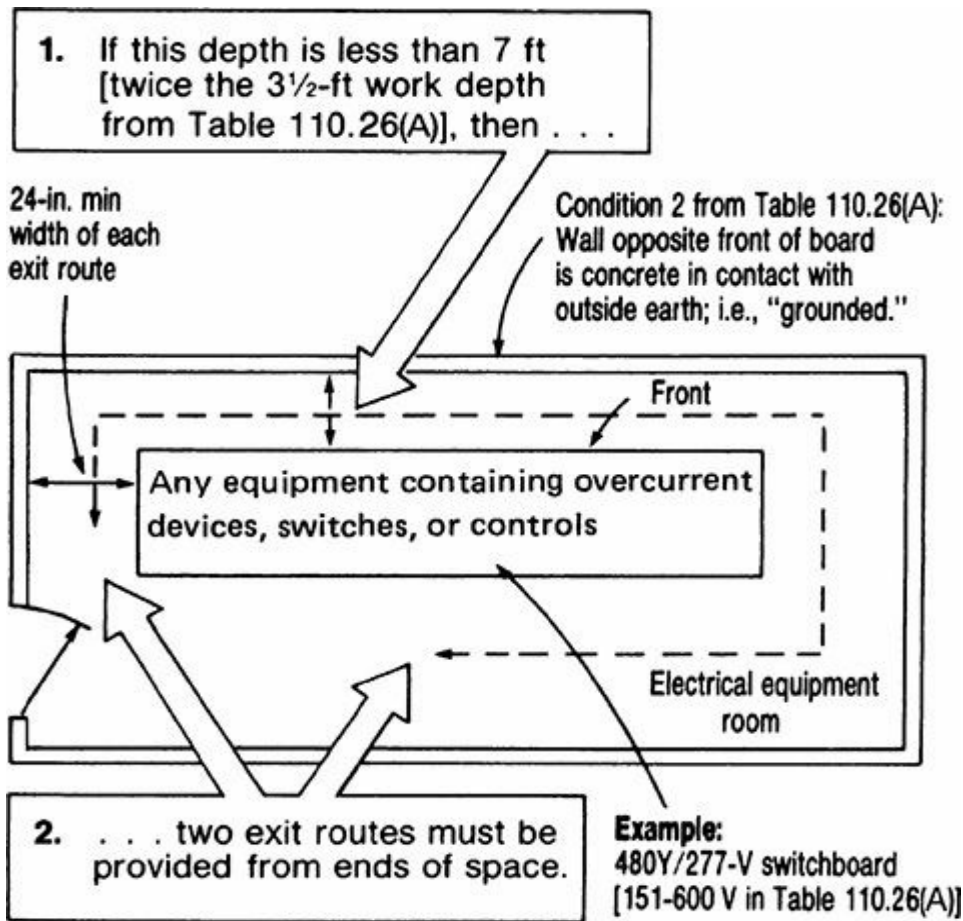

In 110.26(C), “Entrance to Working Space,” the Code regulates the necessary entrance/exit to the work space. In part **(A)**, a general statement calls for at least one entrance, of sufficient size, be provided to allow the work space to be entered/exited. Although the wording used here—“of sufficient area”—does not clearly define the dimensions needed to ensure compliance, it seems safe to assume that compliance with the dimensions spelled out in 110.26(C)(2) [i.e., 610 mm (24 in.) wide × 2.0 m (6½ ft) high] would be acceptable to the vast majority of electrical inspectors, if not all electrical inspectors.

As an added safety measure, to prevent personnel from being trapped in the working space around burning or arcing electrical equipment, the rule of 110.26(C)(2) requires *two* “entrances” or directions of access to the working space around any equipment enclosure that contains “overcurrent devices, switching devices, or control devices,” where such equipment is rated 1200 A or more, and which is also larger than 1.8 m (6 ft) wide; both conditions must be met before the enhanced access rules in this provision apply. This rule covers all types of equipment. That is, 110.26(C)(2) requires *two* “entrances” or directions of access to the working space around switchboards, motor-control centers, distribution centers, panelboard lineups, UPS cubicles, rectifier modules, substations, power conditioners, and any other equipment that is rated 1200 A or more.

At each end of the working space at such equipment, an entranceway or access route at least 610 mm (24 in.) wide and at least 2.0 m (6½ ft) high must be provided. Because personnel have been trapped in work spaces by fire between them and the only route of exit from the space, rigid enforcement of this rule is likely. Certainly, design engineers should make two paths of exit a

standard requirement in their drawings and specs. Although the rule does not require two doors into an electrical equipment room, it may be necessary to use two doors in order to obtain the required two entrances to the required work space—especially where the switchboard or control panel is in tight quarters and does not afford a 24-in.-wide path of exit at each end of the work space.

In [Fig. 110-19](#), sketch “A” shows compliance with the Code rule—providing two areas for entering or leaving the defined dimensions of the work space. In that sketch, placing the switchboard with its front to the larger area of the room and/or other layouts would also satisfy the intent of the rule. It is only necessary to have an assured means of exit from the defined work space. If the space in front of the equipment is deeper than the required depth of work space, then a person could simply move back out of the work space at any point along the length of the equipment. That is confirmed by the wording in 110.26(C)(2)(a). A similar idea is behind the objective of part (b) to 110.26(C)(2), which recognizes that where the space in front of equipment is twice the minimum depth of working space required by Table 110.26(A) for the voltage of the equipment and the conditions described, it is not necessary to have an entrance at each end of the space ([Fig. 110-20](#)). In such cases, a worker can move directly back out of the working space to avoid fire. For any case where the depth of space is not twice the depth value given in Table 110.26(A) for working space, an entranceway or access route at least 24 in. wide must be provided at each end of the working space in front of the equipment.

(A) Complies

(B) Violation

Fig. 110-19. There must be two paths out of the work space required in front of any equipment containing fuses, circuit breakers, motor starters, switches, and/or any other control or protective devices, where the equipment is rated 1200 A or more and is more than 1.8 m (6 ft) wide. [Sec. 110.26(C).]

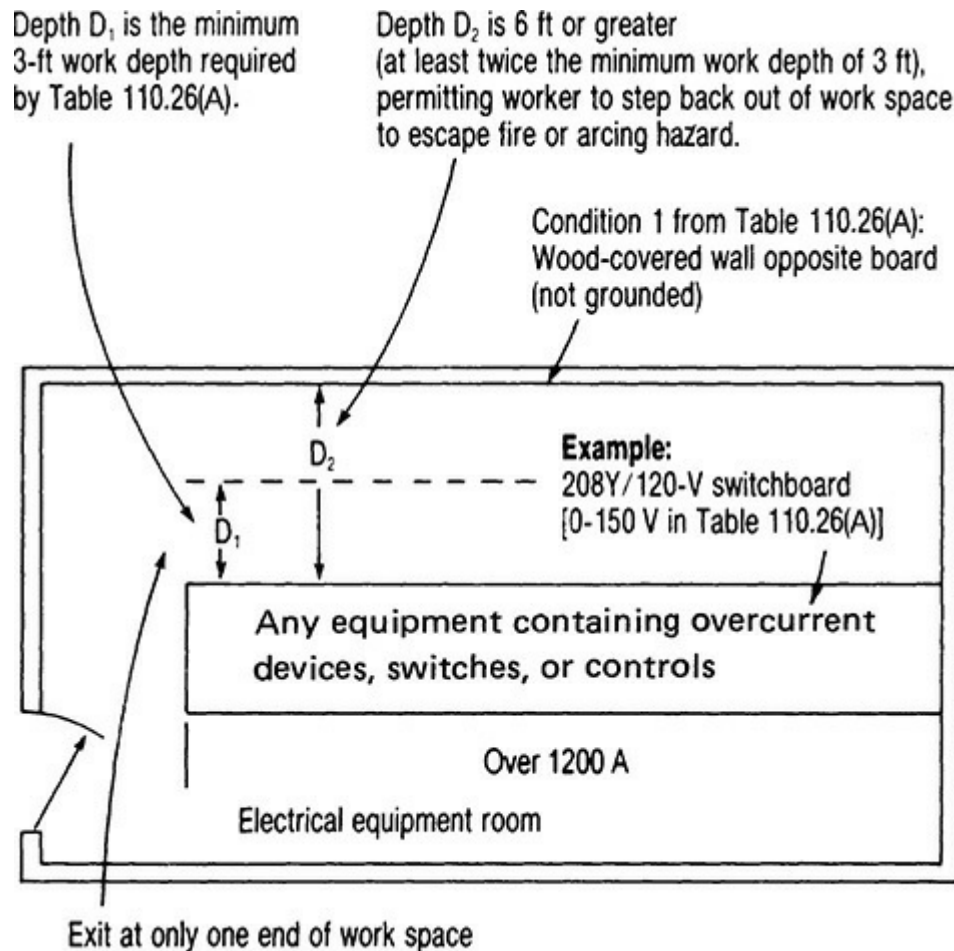

Fig. 110-20. This satisfies Sec. 110.26(C)(2)(b).

Sketch “B” in Fig. 110-19 shows the layout that must be avoided. With sufficient space available in the room, layout of any equipment rated 1200 A or more and over 1.8 m (6 ft) wide with only one exit route from the required work space would be a clear violation of the rule. As shown in sketch “B,” a door at the right end of the working space would eliminate the violation. *But*, if the depth D in sketch “B” is equal to or greater than twice the minimum required depth of working space from Table 110.26(A) for the voltage and “conditions” of installation, then a door at the right is not needed and the layout would not be a violation.

The last sentence in 110.26(C)(2)(b) states that when the defined work space in front of an electrical switchboard or other equipment has an entranceway at only one end of the space, the edge of the entrance nearest the equipment must be at least 3, 3½, or 4 ft (900 mm, 1.0 m, or 1.2 m) away from the equipment—as designated in Table 110.26(A) for the voltage and conditions of installation of the particular equipment. This Code requirement requires careful determination in satisfying the precise wording of the rule. Figure 110-21 shows a few of the many possible applications that would be subject to the rule.

Even though D_2 , the depth of work space, is double the minimum depth D_1 required by Table 110.26(A) . . .

VIOLATION!

. . . an arcing burndown here will block the single entrance to the work space, preventing escape of personnel.

Depth D_1 is the minimum 3-ft work depth required by Table 110.26(A).

Depth D_2 is 6 ft or greater (at least twice the minimum work depth of 3 ft) permitting worker to step back out of work space to escape fire or arcing hazard.

Condition 1 from Table 110.26(A): wood-covered wall opposite board (not grounded)

Work space has double the depth from Table 110.26(A); one entrance is acceptable.

COMPLIES:

Any equipment containing overcurrent devices, switches, or controls

. . . because the nearest edge of the entrance is at least 3 ft [Table 110.26(A)] away from the equipment.

Edge of entrance nearest to each switchboard or panel is at least 3 ft (0-150 V) or 4 ft (151-600 V) from enclosure

Fig. 110-21. Arcing burndown must not block route of exit. [Sec. 110.26(C).] Note that the spacings increase for voltages above 600.

The third numbered paragraph in 110.26(C) puts forth an additional requirement for installations where doors are used as a means of access. Here the NEC mandates that any such door be provided with special hardware to facilitate exit where a maintenance person has lost the use of his or her hands, as could be the case in a fire. The Code calls for the “personnel” doors to open in the direction of egress, which of course is “out” of the spaces. Additionally, such doors must be fitted with listed panic hardware. The open-out and the panic-hardware rules now apply to all egress doors within 25 ft of the work space area. The issue is making sure that an injured electrician who has been burned and cannot use his hands to turn a knob can get far enough away from the burndown to seek help, without unduly burdening the rest of the facility with special hardware requirements. The NEC is unclear as to how the 25 ft is to be measured, whether in a straight line on a plan view or by proceeding through a reasonably assumed route of travel, but the route of travel would seem to be more closely related to the motivation for the requirement.

This requirement applies only to large equipment rated 800 A or more, where it is assumed that the risks are greater just as it is assumed that enhanced egress rules are appropriate. Although not required for other than “Large Equipment” work space access, recommending and providing such a means of egress is not a Code violation and could be viewed as an added safety feature.

Note that, as in the past, this parameter is an equal or exceed number, which differs from the enhanced egress rule that uses a measurement that must be exceeded in order to trigger the requirement. However, the 2014 **NEC** is the first time that the trigger numbers differ, with the larger number applicable to the enhanced egress requirements only.

110.26(D) requires lighting of work space at “service equipment, switchboards, panelboards, or motor control centers installed indoors.” The basic rule is shown in [Fig. 110-22](#).

Some type of lighting must be provided for any defined work space around switchboards, panelboards, motor control centers, and service equipment unless adjacent fixture(s) light the area.

Any service equipment, switchboard, panelboard, or motor control center installed indoors in other than a "dwelling unit"

Elevation

If the space on this side of a switchboard is a work space covered by Section 110.26(A)...

...as well as the space on this side, then a lighting unit here, over only one of the work spaces, would not be adequate. Another light would be required for the work space on the other side of the equipment, unless a single fixture provides adequate illumination.

Plan

Illumination required . . . but no dedicated fixture is required; an adjacent fixture may satisfy this rule.

... BUT only in an existing one-family house, an existing apartment unit of an apartment house or other existing "dwelling unit."

Fig. 110-22. Electrical equipment requires lighting and 6½-ft headroom at *all* work spaces around certain equipment. [Secs. 110.26(D) and 110.26(A)(3).]

The second to last sentence in 110.26(D) points out the Code-making panel's intent. That is, if an adjacent fixture provides adequate illumination, another fixture is not required. In dwelling units where the identified equipment is located in a habitable room, a switched receptacle outlet, as permitted by 210.70(A)(1) Exception No. 1, would also satisfy the requirement for illumination given here. And, lastly, control of the required lighting outlet at electrical equipment by automatic means, only, is prohibited. But, the use of automatic control along with a manual override would meet the spirit and the letter of this rule.

It should be noted that although lighting is required for safety of personnel in work spaces, nothing specific is said about the kind of lighting (incandescent, fluorescent, mercury-vapor), no minimum footcandle level is set, and such details as the position and mounting of lighting equipment are omitted. All that is left to the designer and/or installer, with the inspector the final judge of acceptability.

110.26(E). Dedicated Equipment Space. Pipes, ducts, etc., must be kept out of the way of circuits from panelboards and switchboards. This rule is aimed at ensuring clean, unobstructed space for proper installation of switchboards and panelboards, along with the connecting wiring methods used with such equipment.

The wording of this rule has created much confusion among electrical people as to its intent and

correct application in everyday electrical work. And, it seems that one can develop a complete understanding of this rule only by repeated readings. On first reading, there are certain observations about the rule that can be made clearly and without question:

1. Although the rule is aimed at eliminating the undesirable effects of water or other liquids running down onto electrical equipment and entering and contacting live parts—which should always be avoided both indoors and outdoors—the wording of the first sentence limits the requirement to switchboards, switchgear, panelboards, and to motor control centers. Individual switches and CBs and all other equipment are not subject to the rule—although the same concern for protection against liquid penetrations ought to be applied to all such other equipment. The reason for this is rooted in the history of the requirement and not technical merit. The rule originated in what is now Art. 408 under the control of a different Code-making panel, and in that location the other types of equipment were not within the scope of that article. The material was relocated by order of the Correlating Committee, but the wording here still is focused on the old applications.
2. The designated electrical equipment covered by the rule (switchboards, panelboards, etc.) does not have to be installed in rooms dedicated exclusively to such equipment, although it may be. This rule applies only to the area above the equipment, for the width and depth of the equipment.

Part **(E)(1)(a)** (for indoor installations) of this rule very clearly defines the “zones” for electrical equipment to include any open space above the equipment up to 1.8 m (6 ft) above the top of the gear, or the structural ceiling, whichever is lower. In any case, the dedicated clear space above switchboards, panelboards, distribution panels, and motor control centers extends to the structural ceiling if it is less than 1.8 m (6 ft) above the equipment. And, where the structural ceiling is higher than 1.8 m (6 ft) above the equipment, this rule permits water piping, sanitary drain lines, and similar piping for liquids to be located above switchboards, etc., if such piping is at least 1.8 m (6 ft) above the equipment. The permission for switchboards and panelboards to be installed below liquid piping that is located more than 6 ft above the equipment must be carefully considered, even though containment systems, etc., are required to prevent damage from dripping or leaking liquids. The object is to keep foreign piping (chilled-water pipes, steam pipes, cold-water pipes, and other piping) from passing directly over electrical equipment and thereby eliminate even the possibility of water leaking from the piping and overflowing the drain onto the equipment ([Fig. 110-23](#)). This rule completely prohibits any intrusion on the dedicated area, up to 6 ft above the equipment. And, where piping, etc., is to be run over the 6-ft minimum dedicated area, it must be provided with some means to prevent any discharge or condensation from coming into contact with the equipment below.

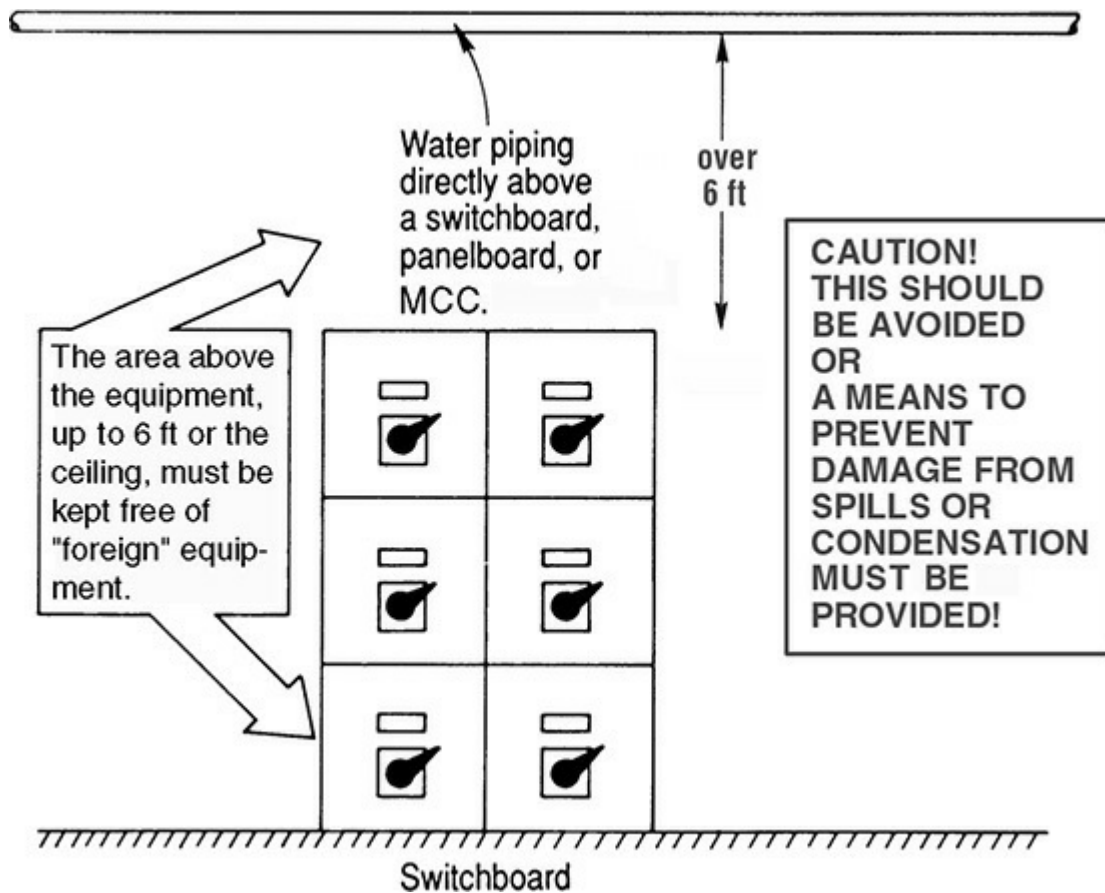

Fig. 110-23. Water pipes and other “foreign” piping must not be located less than 6 ft above switchboard. [Sec. 110.26(E).]

The exception recognizes that suspended ceiling systems with removable tiles may occupy the dedicated space above switchboards, etc.

110.26(E)(1)(b) identifies the area where “foreign systems” are permitted to be installed. As one would imagine, this zone begins at a distance of 6 ft above the top of the electrical equipment and extends to the structural ceiling. As indicated, protection against damage due to leaking of the foreign piping systems must be provided.

Note carefully: It is not a requirement of this rule that “foreign” piping, ducts, etc., must always be excluded from the entire area above electrical equipment. Although the rules require that the “foreign” piping, ducts, etc., must be kept out of the “space” dedicated to the electrical equipment, the rule, literally, permits such “foreign” piping, ducts, etc., to be installed *above* the dedicated space, above the equipment. BUT, protection must be provided in the form of drain gutters or containment systems of some sort to prevent damage to the electrical equipment, below. However, it is much wiser to eliminate any foreign piping—even sprinkler piping used for fire suppression—from the area above electrical equipment. Where such installation is not possible, then take great care to ensure an adequate system of protection for the electrical equipment. (See [Fig. 110-23](#).)

As covered in part (E)(1)(c), sprinkler piping, which is intended to provide fire suppression in the event of electrical ignition or arcing fault, would not be foreign to the electrical equipment and would not be objectionable to the Code rule. Another confirmation of Code acceptance of sprinkler protection for electrical equipment (which means sprinkler piping within electrical equipment and even directly over electrical equipment) is very specifically verified by 450.47, which states, “Any pipe or duct system foreign to the electrical installation shall not enter or pass through a transformer vault. Piping or other facilities provided for vault fire protection or for transformer cooling shall not

be considered foreign to the electrical installation.” BUT, the wording here only permits installation of sprinkler piping above the dedicated space “where the piping complies with this section.” That means the sprinkler piping would have to be at least 6 ft above the equipment to comply with 110.26(E)(1)(a) *and* be provided with the “protection”—a gutter or containment system—required by 110.26(E)(1)(b). As long as the containment system only falls below the sprinkler pipe and not underneath the sprinkler head, the sprinkler will still be able to perform its function. In other words, route the sprinkler piping in such a manner that it is offset and not directly over the equipment, or at the least, make sure that the suppression system is arranged so the sprinkler head is not directly over the electrical equipment, allowing it to discharge on a fire in the gear from either the front or sides or both. Layouts of piping can be made to assure effective fire suppression by water from the sprinkler heads when needed, without exposing equipment to shorts and ground faults that can be caused by accidental water leaks from the piping. That will prevent any conflict with the rule given here and provide for the desired fire suppression.

Part **(2)** of this rule covers outdoor installations. The first portion covers the required enclosure types, reiterates the normal work space requirement, and requires protection against accidental vehicular contact. This portion continues unchanged from the previous five Code cycles. The second portion is new as of the 2014 **NEC**. It takes the dedicated electrical space concept for indoor installations and makes it applicable, essentially unchanged, to outdoor work. The idea is to reserve a 6-ft zone above the equipment (and down to grade) that is not to be invaded by foreign systems. As of the 2017 **NEC**, a misplaced exception [to (b) instead of (c)] permits structural overhangs and roof extensions into this area.

The final lettered paragraph, 110.26(F), used to be the last sentence of 110.26. It makes clear that the use of a locked door or enclosure is acceptable, where the key or combination is available to “qualified personnel” (e.g., the house electrician or serving contractor’s journeyman). Under such conditions, a lock does not inhibit the ready accessibility contemplated in the definition of that term.

110.27. Guarding of Live Parts. Part **(A)** of this rule generally requires that “live parts” (i.e., energized parts of equipment) be “guarded” to prevent accidental contact. It applies to all systems operating at 50 V or more. This is typically accomplished through the use of manufacturer-provided enclosures. However, where live parts are not enclosed with a suitable enclosure, the alternate methods described in parts **(A)(1)** through **(A)(4)** can be employed to satisfy this requirement.

Part **(B)** of 110.27 addresses an additional concern for protection of electrical equipment. After the 1968 NEC, old Sec. 110.17(a)(3), accepting guardrails as suitable for guarding live parts, was deleted. It was felt that a guardrail is not proper or adequate protection in areas accessible to other than qualified persons. However, where electrical equipment is exposed to physical damage—such as where installed alongside a driveway, or a loading dock, or other locations subjected to vehicular traffic—the use of guardrails is clearly acceptable and required by this rule. Failure to protect equipment against contact by vehicles is a violation of this section.

Live parts of equipment should in general be protected from accidental contact by complete enclosure (i.e., the equipment should be “dead-front”). Such construction is not practicable in some large control panels, and in such cases the apparatus should be isolated or guarded as required by these rules.

The **NEC** also recognizes guarding through elevation at a height of at least 8 ft above the floor.

The 2014 **NEC** has fine-tuned this requirement in order to correlate with NESC requirements, and increased this height requirement for voltages over 300 and up to 600 by 6 in. (to 8½ ft). The 2017 **NEC** went a slight step further, adding a third height limit of 8 ft 7 in. (1 in. higher than the next lower height) above the floor for 600-1000 volts. In addition, all the voltages covered in (4) are now clarified as voltages between ungrounded conductors.

110.28. Enclosure Types. This section and table cover selection criteria on types of enclosures. The second paragraph of this section makes the selection criteria set forth in the table mandatory. The material has been relocated from 430.91 because it does not just cover motor control centers but has general applicability for all installations. This section gives selection data, with characteristics tabulated, for application of the various NEMA types of motor controller enclosures for use in specific nonhazardous locations operating at 600 V and below. Note that this table is relocated into Part II (1000 Volts Nominal, or Less) from Part I (General) because it does not apply to medium-voltage equipment.

III. Over 1000 V, Nominal

110.30. General. Figure 110-24 notes that high-voltage switches and circuit breakers must be marked to indicate the circuit or equipment controlled. This requirement arises because 110.30 says that high-voltage equipment must comply with preceding sections in Part I of Art. 110. Therefore, the rule of 110.22 calling for marking of all disconnecting means must be observed for high-voltage equipment as well as for equipment rated up to 1000 V.

Fig. 110-24. High-voltage switches and breakers must be properly marked to indicate their function. (Sec. 110.30.)

The second sentence states clearly, and emphatically, that the rules given in Part II of Art. 110 apply only to equipment on the load side of the service. That is, only high-voltage equipment installed on the load side of the “service point” is covered. In no case shall these rules be applied to high-voltage equipment that is owned and operated by the utility.

110.31. Enclosure for Electrical Installations. The last sentence of the first paragraph

indicates that there may be instances where additional precautions or special design would be necessary, due to the specifics related to the application. Always check the manufacturer's installation instructions and appropriate UL data to ensure that the enclosure meets the specific hazard encountered.

Table 110.31 provides minimum clearance requirements between the required fencing to live parts.

Section 110.31(A) repeats key construction requirements from the basic rules in Part III of Art. 450 for transformer vaults and makes them applicable to comparable rooms without transformers, but with other medium-voltage equipment. It is presently unclear, however, when such a vault requirement would be triggered by a medium-voltage installation. The opening text simply applies the requirement when the vault is "required or specified." For the 2011 **NEC**, additional text was imported from Art. 450, including the allowance for a fire-rating reduction to 1 h if an automatic fire suppression system is installed.

Section 110.31(B) covers enclosed areas or rooms in interior locations. [Figure 110-25](#) illustrates the rules that cover installation of high-voltage equipment indoors in places accessible to unqualified persons in part **(B)(1)**. Installation must be in a locked vault or locked area, or equipment must be metal-enclosed and locked. The Code is quite clear that a lock and key is the only acceptable means to provide positive control [110.34(C)]. The basic concern is related to unqualified persons coming into proximity or contact with high voltage. This rule states what is considered as adequate to provide the desired exclusion of other than "qualified personnel."

Fig. 110-25. NEC rules on high-voltage equipment installations in buildings accessible to electrically unqualified persons. [Sec. 110.31(A).]

For equipment that is not enclosed, as described in 110.31(C), another enclosure—or, more accurately, a barrier—must be constructed around the entire area where unenclosed high-voltage equipment is "accessible" to other than qualified persons. Such fencing must be no lower than 7 ft in

total height. This may be 7 ft of fencing, or a 6-ft fence supplemented by at least three strands of barbed wire, or the “equivalent.”

Part **(B)(1)** also calls for “appropriate caution signs” for all enclosures, boxes, or “similar associated equipment.” This is a field marking that must be provided by the installer. For any equipment, rooms, or enclosures where the voltage exceeds 600 V, permanent and conspicuous warning signs reading “DANGER—HIGH VOLTAGE, KEEP OUT” must always be provided. It is a safety measure that alerts unfamiliar or unqualified persons who may, for some reason, attempt to gain access to a locked, high-voltage area. Note that Sec. 110.31(B)(1) does not require locking indoor metal-enclosed equipment that is accessible to unqualified persons, but such equipment is required to be marked with “WARNING” signs [see 110.34(C)].

And, the last sentence of part **(A)(1)** requires that manufacturers design their equipment to ensure that unqualified persons can’t come into contact with live parts of the high-voltage equipment.

Part **(B)(2)** applies to areas accessible only to qualified persons. In such areas, no guarding or enclosing of the live high-voltage parts is called for. The rule simply requires compliance with the rules given in 110.34, 110.36, and 490.24. In 110.34, the Code covers clear “working space” and the methods of “guarding” for systems rated over 600 V. Section 110.36 describes the acceptable wiring methods and 490.24 covers internal spacings in medium-voltage equipment that are field wired, and fabricated. Note that the spacings in Table 490.24 do not apply to internal spacings on equipment “designed, manufactured, and tested in accordance with accepted national standards.”

In 110.31(C)(1), the Code requires compliance with the rules for equipment rated over 1000 V, given in all parts of Art. 225. And, **(C)(2)** requires compliance with 110.34, 110.36, and 490.24 where outdoor high-voltage equipment is accessible only to qualified persons.

110.31(D) essentially specifies that outdoor installations with exposed live parts must not provide access to unqualified persons.

For equipment rated over 600 V, nominal, 110.31 requires that access be limited to qualified persons only, by installing such equipment within a “vault, room, closet, or in an area that is surrounded” by a fence, etc., with locks on the doors. In part **(D)** of Sec. 110.31, the Code identifies additional methods for preventing unauthorized access to metal-enclosed equipment where it is *not* installed in a locked room or in a locked, fenced-in area.

110.31(D) provides a variety of precautions that are needed where high-voltage equipment, installed outdoors, is accessible to unqualified persons. For example, the design of openings in the equipment enclosure, such as for ventilation, must be such that they deflect inserted “foreign objects” from energized parts. Also, “guards” must be provided where the equipment is subject to damage by cars, trucks, and so forth. Enclosed equipment must be equipped with nuts and bolts that are not “readily removed.” In addition, elevation may be used to prevent access [110.34(E)], or equipment may be enclosed by a wall, screen, or fence under lock and key, as shown in [Fig. 110-26](#). Where the bottom of high-voltage equipment is *not* mounted at least 8 ft above the floor or grade, the equipment enclosures must be kept locked. And covers on junction boxes, pull boxes, and so forth, must be secured using a lock, bolt, or nut.

Fig. 110-26. High-voltage equipment enclosed by a wall, screen, or fence at least 7 ft (2.13 m) high with a lockable door or gate is considered as accessible only to qualified persons. [Sec. 110.31(B).]

That sentence in 110.31(D) recognizes a difference in safety concern between high-voltage equipment accessible to “unqualified persons”—who may not be qualified as electrical personnel but are adults who have the ability to recognize warning signs and the good sense to stay out of electrical enclosures—and “the general public,” which includes children who cannot read and/or are not wary enough to stay out of unlocked enclosures ([Fig. 110-27](#)).

Fig. 110-27. *Metal-enclosed* high-voltage equipment accessible to the general public—such as pad-mount transformers or switchgear units installed outdoors or in indoor areas where the general public is not excluded—must have doors or hinged covers locked (arrow) if the bottom of the enclosure is less than 8 ft (2.5 m) above the ground or above the floor.

The rationale submitted with the proposal that led to this change in the Code rule noted:

Where metal-enclosed equipment rated above 600 V is accessible to the general public and located at an elevation less than 8 ft, the doors should be kept locked to prevent children and others who may be unaware of the contents of such enclosures from opening the doors.

However, in a controlled environment where the equipment is marked with appropriate caution signs as required elsewhere in the **NEC**, and only knowledgeable people have access to the equipment, the requirement to lock the doors on all metal-enclosed equipment rated above 600 V and located less than 8 ft (2.5 m) above the floor does not contribute to safety and may place a burden on the safe operation of systems by delaying access to the equipment.

For equipment rated over 600 V, 110.31(D) has required that the equipment cover or door be locked unless the enclosure is mounted with its bottom at least 8 ft off the ground. In that way, access to the general public is restricted and controlled. In addition, the bolts or screws used to secure a cover or door may serve to satisfy the rule of Sec. 110.31(D), provided the enclosure is used only as a pull, splice, or junction box. Where accessible to the general public, an enclosure used for any other purpose must have its cover locked unless it is mounted with its bottom at least 8 ft (2.5 m) above the floor ([Fig. 110-28](#)).

Fig. 110-28. Access by the general public to any metal enclosure containing circuits or equipment rated over 600 V, nominal, must be prevented. The wording recognizes the bolts or screws on the covers of boxes used as pull, splice, and junction boxes as satisfying the requirement for preventing access. And, additional wording in this rule recognizes that covers weighing over 100 lb are inherently secured and do not require bolts or screws for the cover or door. *Remember*, the permission given in the basic rule is for pull, splice, and junction boxes, *only*.

In the last two sentences of 110.31(D), “bolted or screwed-on” covers, as well as in-ground box covers over 100 lb (45.4 kg) are recognized as preventing access to the general public. The last sentence recognizes that there is no need to secure the cover on an in-ground box that weighs at least 100 lb. This correlates with the rule of 314.72(E), which states that covers weighing 100 lb (45.4 kg) satisfy the basic requirement for securing covers given in this section.

110.32. Work Space about Equipment. Figures 110-29 and 110-30 point out the basic Code rule of 110.32 relating to working space around electrical equipment.

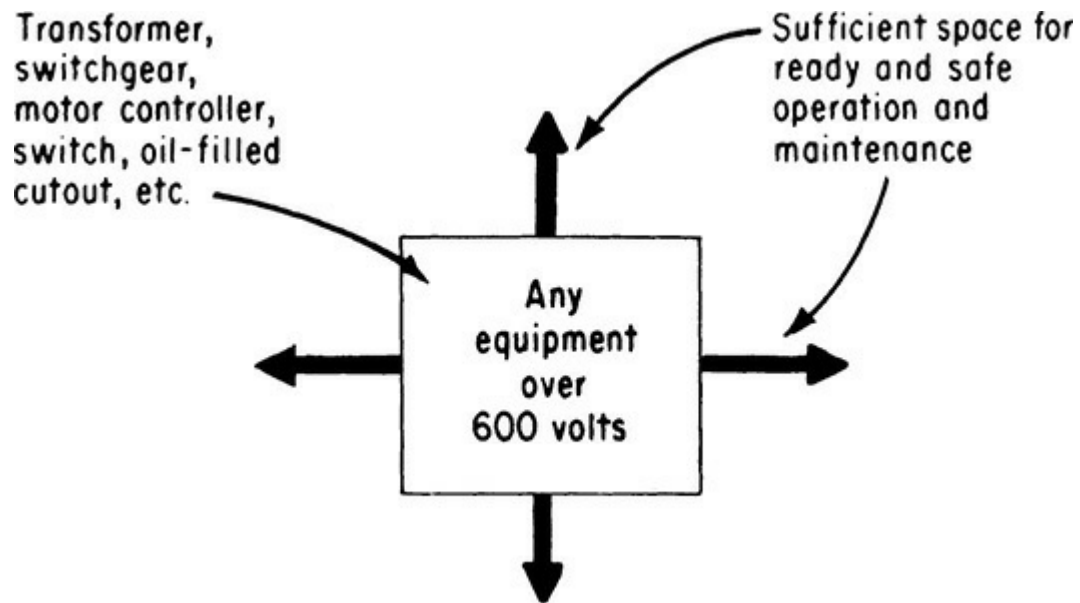

Fig. 110-29. This is the general rule for work space around any high-voltage equipment. (Sec. 110.32.)

Fig. 110-30. Sufficient headroom and adequate lighting are essential to safe operation, maintenance, and repair of high-voltage equipment. (Sec. 110.32.)

Figure 110-31 shows required side-to-side working space for adequate elbow room in front of high-voltage equipment.

Fig. 110-31. Working space in front of equipment must be at least 3 ft (900 mm) wide, measured parallel to front surface of the enclosure. (Sec. 110.32.)

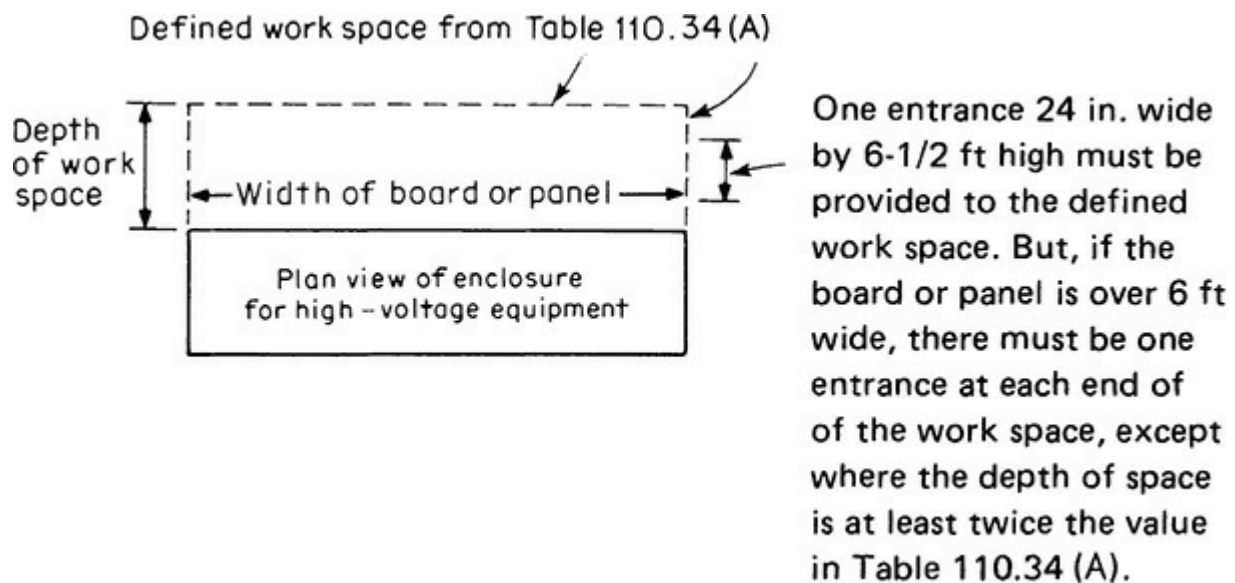

Fig. 110-32. Access to required work space around high-voltage equipment must be ensured. (Sec. 110.33.)

110.33. Entrance to Enclosures and Access to Working Space. Entrances and access to working space around high-voltage equipment must comply with the rules shown in Fig. 110-32. Section 110.33(A)(1) says that if the depth of space in front of a switchboard is at least twice the minimum required depth of working space from Table 110.34(A), any person in the working space would be capable of moving back out of the working space to escape any fire, arcing, or other hazardous condition. In such cases there is no need for a path of exit at either end or at both ends of the working space. But where the depth of space is not equal to twice the minimum required depth of working space, there must be an exit path at each end of the working space in front of switchgear or control equipment enclosures that are wider than 6 ft (1.8 m). And what applies to the front of a switchboard also applies to working space at the rear of the board if rear access is required to work on energized parts.

The wording of 110.33(A)(1)(b) specifies minimum clearance distance between high-voltage equipment and edge of entranceway to the defined work space in front of the equipment, where only one access route is provided. Based on Table 110.34(A)—which gives minimum depths of clear working space in front of equipment operating at over 600 V—the rule in this section presents the same type of requirement described by 110.26(C)(2). Based on the particular voltage and the conditions of installation of the high-voltage switchgear, control panel, or other equipment enclosure, the nearest edge of an entranceway must be a prescribed distance from the equipment enclosure. Refer to the sketches given for 110.26(C).

Section 110.33(A) concludes with paragraph (3) on personnel doors, how they must open and what hardware is required for them. This rule is identical to the comparable rule for large equipment in 110.26(C)(3), and raises the same issues. Refer to that discussion for more information. Section 110.33(B) requires permanent provisions for access in the form of ladders or stairways to the required work space about medium-voltage equipment on balconies, rooftops, attics, platforms, etc.

110.34. Work Space and Guarding. Application of Code Table 110.34(A) to working space around high-voltage equipment is made in the same way, as shown for Code Table 110.26(A)—except that the depths are greater to provide more room because of the higher voltages.

As shown in Fig. 110-33, a 30-in. (762-mm)-deep work space is required behind enclosed high-

voltage equipment that requires rear access to “deenergized” parts. Section 110.34(A)(1) notes that working space is not required behind dead-front equipment when there are no fuses, switches, other parts, or connections requiring rear access. But the rule adds that if rear access is necessary to permit work on “nonelectrical” parts of the enclosed assembly, the work space must be at least 30 in. (762 mm) deep. This is intended to prohibit cases where switchgear requiring rear access is installed too close to a wall behind it, and personnel have to work in cramped quarters to reach taps, splices, and terminations. However, it must be noted that this applies only where “nonelectrical” parts are accessible from the back of the equipment. If energized parts are accessible, then Condition 2 of 110.34(A) would exist, and the depth of working space would have to be anywhere from 4 to 10 ft (1.2 to 3.0 m) depending upon the voltage [see Table 110.34(A)].

Fig. 110-33. Space for safe work on nonelectrical parts. [Sec. 110.34(A).] An example would be an intake air filter.

Section 110.34(B) covers the common occurrence of medium-voltage equipment or transformer rooms with exposed live parts, and what that means for 600 V and lower equipment that may be in the same room. In such cases the medium-voltage equipment must be separated by a screen, fence, or other partition. However, this separation rule does not apply to lower voltage equipment that is only serving the room where the medium-voltage equipment is located. For example, a snap switch and a luminaire in the room would not provoke the separation rule.

Section 110.34(C) requires that the entrances to all buildings, rooms, or enclosures containing live parts or exposed conductors operating in excess of 600 V be kept locked, except where such entrances are under the observation of a qualified attendant at all times. The last paragraph in this section requires use of warning signs to deter unauthorized personnel. The rule of 110.34(D) on lighting of high-voltage work space is shown in [Fig. 110-30](#). Note that the rule calls for “adequate illumination,” but does not specify a footcandle level or any other characteristics.

Figure 110-34 shows how “elevation” may be used to protect high-voltage live parts from unauthorized persons.

Fig. 110-34. Elevation may be used to isolate unguarded live parts from unqualified persons. [Sec. 110.34(E).]

110.34(F). Protection of Service Equipment, Metal-Enclosed Power Switchgear, and Industrial Control Assemblies. The basic rule of the first sentence in this section excludes “pipes or ducts foreign to the electrical installation” from the “vicinity of the service equipment, metal-enclosed power switchgear, or industrial control assemblies.” Then, addressing the case where foreign piping is unavoidably close to the designated electrical equipment, the next sentence calls for “protection” (such as a hood or shield above such equipment) to prevent damage to the equipment by “leaks or breaks in such foreign systems.”

Piping for supplying a fire protection medium for the electrical equipment is not considered to be “foreign” and may be installed at the high-voltage gear. The reason given for that sentence was to prevent the first sentence from being “interpreted to mean that no sprinklers should be installed.” Fire suppression at such locations may use water sprinklers or protection systems of dry chemicals and/or gases specifically designed to extinguish fires in the equipment without jeopardizing the equipment. Water is sometimes found to be objectionable; leaks in piping or malfunction of a sprinkler head could reduce the switchgear integrity by exposing it to a flashover and thereby initiate a fire.

110.40. Temperature Limitations at Terminations. Terminations for equipment supplied by conductors rated over 2000 V must carry not more than the 90°C ampacity values given in Tables 310.60(C)(67) through 310.60(C)(86), unless the conductors and equipment to which the conductors are connected are “identified” for the 105°C ampacity.

The proposal to include this section pointed out that the ampacity values given in tables for conductors rated above 2000 V were all 90°C-rated values. And, with the increased attention that has been focused on the coordination between conductor ampacity and temperature limitations of the equipment, some question had been raised regarding the use of the 90°C ampacity values in Tables 310.60(C)(67) through 310.60(C)(86) with equipment intended to be supplied by conductors rated over 2000 V. The rule of 110.40 allows the conductors covered in Tables 310.60(C)(67) through 310.60(C)(86) to carry the full 90°C ampacity and be connected virtually without concern for the equipment terminations, unless otherwise marked to indicate that such application is *not* permitted.

This rule was accepted based, in part, on information provided in the proposal regarding American National Standards Institute (ANSI) acceptance of the use of such conductors at their full 90°C ampacity, where tested for such operation. The Code-making panel (CMP) added the qualifying statement “unless otherwise identified” to indicate that such application is permitted where equipment has been so tested. In fact, the wording accepted actually assumes that equipment intended to be supplied by conductors rated over 2000 V—i.e., the conductors covered by Tables 310.60(C)(67) through 310.60(C)(86)—is tested at the full 90°C ampacity. But, if the equipment is otherwise “identified,” it must be used as indicated by the manufacturer. It should be noted that although the rule is contained in Part III of Art. 110, which covers equipment rated over 600 V, because the tables mentioned cover conductors rated over 2000 V, it only applies to the terminations on equipment intended to be supplied by conductors rated over 2000 V. The terminations on all other equipment supplied by conductors rated from 601 to 2000 V must be coordinated with the ampacity value corresponding to the temperature rating of the terminations ([Fig. 110-35](#)).

Wording of 110.40 indicates terminations in such equipment **may be assumed** to be suitable for carrying the 90°C ampacity shown in Tables 310.60(C)(67) through 310.60(C)(86). If the terminations are not suited for connection to conductors at their full 90°C ampacity, the equipment must be marked by the manufacturer. **Remember, this only applies to conductors and equipment rated over 2000 V.**

Fig. 110-35. When derating with conductors rated over 2000 V, the temperature rating of the terminations may be assumed to be 90°C unless otherwise marked.

110.41. Inspections and Tests. Acceptance testing is of equal, perhaps even greater importance for indoor applications as for outdoor installations. This section, new as of the 2017 **NEC**, creates a basis for the inspector to request and then review such testing. The inspiration for this section came from Part III (medium voltage) of Article 225, primarily 225.56. Its location here makes it a likely point of reference for future **NEC** requirements.

Part IV of Art. 110 covers high-voltage—600 V or more—installations in tunnels. Given that mines and surface mining equipment are not regulated by the **NEC**, the types of tunnels covered here are those used for trains, cars, irrigation, or whatever—but NOT for mines. Installation of all high-voltage power and distribution equipment, as well as the tunneling equipment identified here, must be protected and installed in accordance with 110.51 through 110.59.

V. Manholes and Other Electric Enclosures Intended for Personnel Entry, All Voltages

110.70. General. The rules in this part apply unless an industrial occupancy demonstrates appropriate engineering supervision that supports design differences; those differences being subject to documentation and review by the inspector. The **NEC** requires that manholes must be designed under engineering supervision and that they must withstand the loading likely to be imposed.

110.72. Cabling Work Space. A clear work space must be provided not less than 3 ft (900 mm) wide where cables run on both sides, and 2½ ft (750 mm) wide if the cables are on only one side, with vertical headroom not less than 6 ft (1.8 m) unless the opening is within 1 ft (300 mm) of the adjacent interior side wall of the manhole. If the only wiring in the manhole is power-limited fire alarm or signaling circuits, or optical-fiber cabling, then one of the work space dimensions can drop to 2 ft (600 mm) if the other horizontal clear work space is increased so the sum of both dimensions is

not less than 6 ft (1.8 m).

110.73. Equipment Work Space. If the manhole includes equipment with live parts that will require work while energized, then the normal NEC work space rules apply. The headroom rises to 6½ ft (2.0 m), and there must be clear work space at least 3 ft deep and 30 in. (762 mm) wide (wider if the equipment is wider). The depth rises to 3½ ft or 1.1 m over 150 V to ground, and then goes up to 4 ft (1.2 m) for up to 2.5 kV, 5 ft (1.5 m) for up to 9 kV, 6 ft for up to 25 kV, and deeper for higher voltages, as covered in Table 110.34(A).

110.74. Conductor Installation. Essentially, manholes are pull boxes that are large enough for personnel to enter, and therefore they need to be sized to accommodate the installed conductors without violating the rules that normally apply to sizing pull boxes, as covered for comparable applications in Art. 314. For medium-voltage applications, where the same conductor passes straight through the manhole (e.g., entering the south wall and leaving the north wall) the minimum distance is 48 times the largest shielded cable diameter (32 times the largest unshielded cable diameter). If a conductor enters one side of a manhole and then makes a right-angle turn, the dimension drops to 36 times (24 times for unshielded conductors), but it is measured in both directions, and it is increased by the sum of the outside diameters of all other cable entries on the same wall. If there are multiple rows or columns of duct openings in any direction, use the row or column that gives you the largest sizing calculation and ignore all other cable entries.

110.75. Access to Manholes. The NEC requires access to be at least 26 × 22 in. (650 × 550 mm) if rectangular, otherwise at least 26 in. (650 mm) in diameter. This allows for a ladder to rest against the edge of the opening; if the manhole has a fixed ladder permanently mounted, then the diameter can be reduced to 24 in. (600 mm). A similar reduction is permitted if the only wiring in the manhole is power-limited fire alarm or signaling circuits, or optical-fiber cabling. The access opening must not be directly over electrical equipment or conductors, but if this is not practicable, the manhole must be fitted with a protective barrier or a fixed ladder. The cover, if rectangular, must be restrained so it cannot fall into the manhole. Covers must “prominently” identify the manhole’s function by wording (e.g., “ELECTRIC”) or a logo, and they must weigh at least 100 lb (45 kg); if not, then they must be secure so a tool will be required for access.

Chapter Two

ARTICLE 200. USE AND IDENTIFICATION OF GROUNDED CONDUCTORS

200.2. General. Generally, all grounded conductors used in premises wiring systems must be identified as described in 200.6. This section used to require grounded conductors unless exempted, and a laundry list of such exemptions was included. It turned out that that list was not all inclusive, and furthermore 250.24 and 250.30(A) adequately cover instances where a grounded conductor should be required. Therefore, the entire content of this paragraph was deleted in favor of a parent sentence introducing lettered paragraphs (A) and (B), which remain in effect.

Grounded conductors must have the same insulation voltage rating as the ungrounded conductors in all circuits rated up to 1000 V—which means in all the commonly used 240/120-, 208/120-, and 480/277-V circuits. To correlate with 250.184 on minimum voltage rating of insulation on grounded neutrals of high-voltage systems, 250.184 and 200.2 state that where an insulated, solidly grounded neutral conductor is used with any circuit rated over 1000 V—such as in 4160/2400- or 13,200/7600-V solidly grounded neutral circuits—the neutral conductor does not have to have insulation rated for either phase-to-phase or phase-to-neutral voltage, but must have insulation rated for at least 600 V. See 250.184. (Of course, a bare, solidly grounded neutral conductor may be used in such circuits that constitute service-entrance conductors, are direct-buried portions of feeders, or are installed overhead, outdoors—as specified in Sec. 250.184. But when an insulated neutral is used, the previously noted rule on 600-V rating applies.) Both 250.184 and 200.2(A) represent exceptions to 310.2(A) requiring conductors to be insulated.

Part (B) of this section is new as of the 2008 **NEC**. The continuity of a grounded circuit conductor must not depend on connections to enclosures, raceways, or cable armor. This problem frequently arises in service panelboards with multiple busbars. [Figure 200-1](#) shows an example of the problem, and how to correct it. The **NEC** Committee has spent considerable effort in recent years, trying to assure that normal circuit current is confined to recognized conductors, and does not pass over raceways and enclosures that were never designed to be current-carrying conductors.

Fig. 200-1. *Violation!* The feeder neutral has been terminated on the equipment grounding bus in this service panelboard. The neutral current must flow over the enclosure in order to reach the service neutral, thereby making the continuity of the grounded conductor depend on the enclosure. The feeder neutral must be reterminated on the neutral busbar above.

200.3. Connection to Grounded System. Here the Code prohibits “connection” of a grounded conductor in a premises wiring system to any supply system—the utility feed or generator—that does not also have a grounded conductor. The second sentence clarifies that the “connection” referred to here is a direct connection. Supply of grounded conductor through a transformer is acceptable, even if the supply system does not contain a grounded conductor.

200.4. Neutral Conductor. Part (A) of this section, new as of the 2011 **NEC**, prohibits using an oversize neutral conductor in association with plural ungrounded conductors on the same line or phase leg, or in association with plural multiwire branch circuits, unless the Code specifically allows the practice. For these purposes a multiwire branch circuit is considered a single circuit and is not addressed here. Section 215.4 allows the practice for up to two sets of 4-wire feeders and up to three sets of 3-wire feeders, and Sec. 225.7 allows the practice for lighting branch circuits installed outdoors.

Part (B) of this section is new as of the 2014 **NEC** and significantly broadened the requirement formerly of 210.4(D) for grouping multiwire circuit conductors with their associated neutrals in the originating panelboards. Now all circuits with grounded conductors, whether two-wire or more, must

have the conductors grouped within any enclosure. Wire markers are also allowed on the grounded conductors that specify the corresponding circuit(s) in lieu of a cable tie or other grouping mechanism. There are two exceptions. The first waives the rule if the grouping is obvious due to a wiring entry unique to the circuit, such as a raceway entry with a single circuit or a cable entry through a single cable connector. The second, in effect, waives the requirement in instances where the conductors are in a box or conduit body and are so short that it would violate 300.14 if someone attempted to make a splice or termination.

200.6. Means of Identifying Grounded Conductors. The basic rule in part (A), covering 6 AWG and smaller wires, generally requires, as covered in the first four list items, that any grounded neutral conductor or other circuit conductor that is operated intentionally grounded must have a white (or gray) outer finish for the entire length of the conductor, or a conductor with three white stripes encircling other than green insulation is also permitted, or colored threads in white or gray insulation, if the conductor is 6 AWG size or smaller. See Fig. 200-2.

Fig. 200-2. Generally any grounded circuit conductor that is No. 6 size or smaller must have a continuous white or gray outer finish. [Sec. 200.6(A).]

Note that there is no language in Art. 200 to exempt dc circuits from its provisions. One of the global changes throughout the **NEC** commencing with the 2014 edition is the introduction of a color code for dc circuits, with red for positive and black for negative. However, if either a positive or negative dc conductor is operated as a grounded circuit conductor, then its color must become either white or gray, or meet one of the other identification provisions of this section.

Exempted by parts (A)(5) through (A)(8) from the requirement of 200.6 for a white, gray, or three white (or gray) striped neutral are mineral-insulated, metal-sheathed cable; single conductors used as the grounded conductor in photovoltaic systems provided the conductor's insulation is rated for outdoor use and is "sunlight resistant"; fixture wires as covered by 402.8; and neutrals of aerial cable—which may have a raised ridge on the exterior of the neutral to identify them.

The rule of 200.6(B) requires any grounded conductor larger than No. 6 to either comply with the usual identification rules, or to be marked with white or gray identification (such as white tape) encircling the conductor at all terminations at the time of installation. This is the usual approach in the field, since colored insulation is seldom available as a stock item on larger conductors. See [Fig. 200-3](#).

Fig. 200-3. Conductors of colors other than white or gray—in sizes larger than No. 6—may be used as grounded neutrals or grounded phase legs if marked white at all terminations—such as by white tape on the grounded feeder neutrals, at left. [Other color tapes are used on other circuit conductors to identify the three phases as A, B, and C—as required by 210.5(C) for branch circuits and 215.12(C) for feeders.] [Sec. 200.6(B).]

In the rule of part (D), color coding must distinguish between grounded circuit conductors where branch circuits and/or feeders of different systems are in the same raceway or enclosure. This rule ensures that differentiation between grounded circuit conductors of different wiring systems in the same raceway or other enclosure is provided for feeder circuits as well as branch circuits. (See [Fig. 200-4](#).) Because gray is now permitted as a color choice for grounded conductors, identifying two systems in an enclosure is easily done with white wire for one system and gray for the other. You can also use white or gray wire with a stripe, which would become a requirement if there are three or more systems in a common enclosure, although such wires are usually only available on special order and with a very large minimum length. Whatever method of identification is chosen, it must be posted on the panelboard or other circuit source, or otherwise documented in a readily available manner.

Refer to the discussion at 210.5(C) for more information on this point.

Fig. 200-4. Grounded circuit conductors must have color identification and must be distinguishable by system wherever they enter a cable assembly, common raceway, or other common enclosure. [Sec. 200.6(D).]

For approximately 75 years (beginning with 1923), the **NEC** described the customary identification rule in terms of “white or natural gray” coloring. This originally referred to the color of latex insulation and the unbleached muslin put over it. It wasn’t exactly either white or gray, but installers knew what it was. It was never intended to be the controlled color gray, and conductors manufactured in this way have not been produced for many decades. In fact, the controlled color gray could always have been used, and occasionally was used as an ungrounded conductor. However, with the advent of 480Y/277-V systems, the controlled color gray was increasingly used as an identified conductor based on an improper interpretation of the old terminology “natural gray.” The 2002 **NEC** ratified what had become the convention, dropped the term “natural gray” completely, and recognized the controlled color gray as a permitted color for identified conductors for the first time. However, since gray wires were permitted, at least theoretically, for use as ungrounded conductors, the **NEC** advises caution when working with gray wires on existing systems.

The basic rules of 200.6(A) and (B) require the use of continuous white or gray or three continuous white (or gray) stripes running the entire length of an insulated grounded conductor (such as grounded neutral). But the Code permits the use of a conductor of other colors (black, purple, yellow, etc.) for a grounded conductor in a multiconductor cable under certain conditions (see [Fig.](#)

200-5):

NOTE: This permission applies to No. 6 and smaller conductors—as well as to conductors larger than No. 6. Qualified maintenance and supervision must be demonstrated.

Fig. 200-5. [Sec. 200.6(E).]

1. That such a conductor is used only where qualified persons supervise and do service or maintenance on the cable—such as in industrial and mining applications.
2. That every grounded conductor of color other than white or gray will be effectively and permanently identified at all terminations by distinctive white marking or other effective means applied at the time of installation.

This permission for such use of grounded conductors in multiconductor cable allows the practice in those industrial facilities where multiconductor cables are commonly used—although the rule does not limit the use to industrial occupancies. Be aware that this permission *does not apply to conductors in a raceway*, regardless of the degree of supervision. In a raceway, it is assumed that there is no good reason why a conductor with the wrong color insulation cannot be replaced with one having the appropriate color insulation if its function changes. See also Sec. 200.7 and [Fig. 200-6](#).

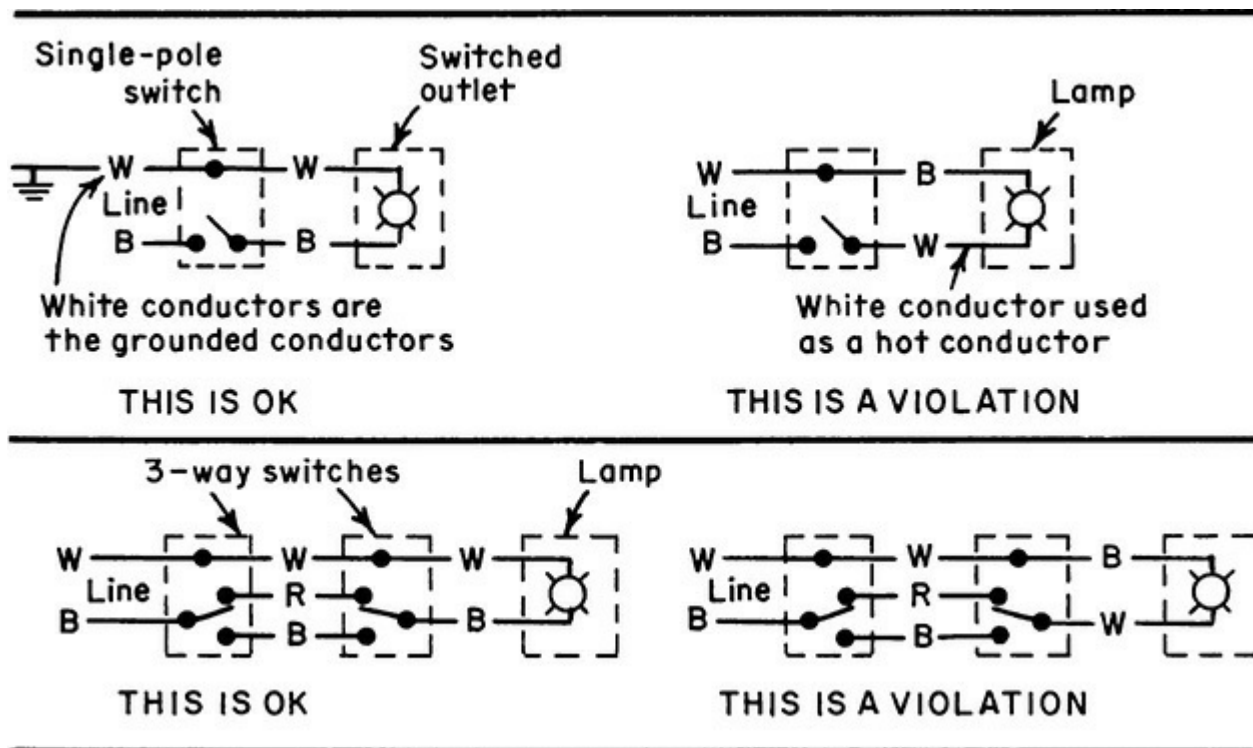

Fig. 200-6. A white- or gray-colored conductor must normally be used only as a grounded conductor (the grounded circuit neutral or grounded phase leg of a delta system). (Sec. 200.7.)

200.7. Use of Insulation of a White or Gray Color or Three Continuous White (or Gray) Stripes. The previous section covered how to identify grounded conductors, the usual, but not the only approach being white or gray color coding. This section has the reciprocal function of covering how the colors white and gray are to be limited in their allowable uses. It is a subtle difference, but taking these sections together definitively covers white/gray usage in the **NEC**.

The basic rule here limits conductors with outer covering colored white or gray or with three continuous white (or gray) stripes on other colors to use only as grounded conductors (i.e., as grounded neutral or grounded phase or line conductors [see Fig. 200-6]). In addition, those conductors reidentified at the time of installation as “grounded” conductors (usually the neutral of a grounded system) must actually be grounded conductors. [200.7(A).]

Figure 200-7 shows a white-colored conductor used for an ungrounded phase conductor of a feeder to a panelboard. As shown in the left side of the panel bottom gutter, the white conductor has black tape wrapped around its end for a length of a few inches. The Code used to permit a white conductor to be used for an ungrounded (a hot phase leg) conductor if the white is “permanently reidentified”—such as by wrapping with black or other color tape—to indicate clearly and effectively that the conductor is ungrounded. However, the permission given for such application of white or gray, or even the three white stripes on conductors of other colors, has been eliminated for other than cable assemblies, multiconductor flexible cord, and for circuits “of less than 50 V.”

Fig. 200-7. *Violation!* White conductor in lower left of panel gutter is used as an ungrounded phase conductor of a feeder, with black tape wrapped around the conductor end to “reidentify” the conductor as *not* a grounded conductor. Although such practice was previously permitted, the **NEC** no longer recognizes it. (Sec. 200.7.)

Part (B) of 200.7 covers the use of conductors whose insulation is white, gray, or has three continuous white (or gray) stripes for circuits operating at 50 V, or less. Circuit conductors in such systems that have an insulation coloring or configuration reserved for “grounded” conductors are not required to be grounded unless required by 250.20, which identifies those systems that must be operated with a grounded conductor. If the low-voltage system in question is supplied from a transformer whose primary supply voltage is over 150 V to ground; or if the supply transformer’s primary conductors are not grounded; or where the low-voltage system is run overhead outdoors, 250.20(A) would mandate grounding of one of the circuit conductors. And therefore, reidentifying a conductor with an overall outer covering or insulation that is one of the colors or configurations reserved for grounded conductors, as an ungrounded conductor, is prohibited.

Part (C)(1) indicates conditions under which a white conductor in a cable (such as BX or nonmetallic-sheathed cable) may be used for an ungrounded (hot-leg) conductor. When used as described, the white conductor is acceptable even though it is not a grounded conductor, provided it is reidentified (such as by painting or taping). [Figure 200-8](#) shows examples of correct and incorrect hookups of switch loops where the hot supply is run first to the switched outlet, then to switches.

LEGEND: "W" is the white grounded neutral conductor
 "B" is the black (or other color) ungrounded hot conductor
 "R" is the red ungrounded hot conductor
 In all cases, "white" conductor must be reidentified as an *ungrounded* conductor!!

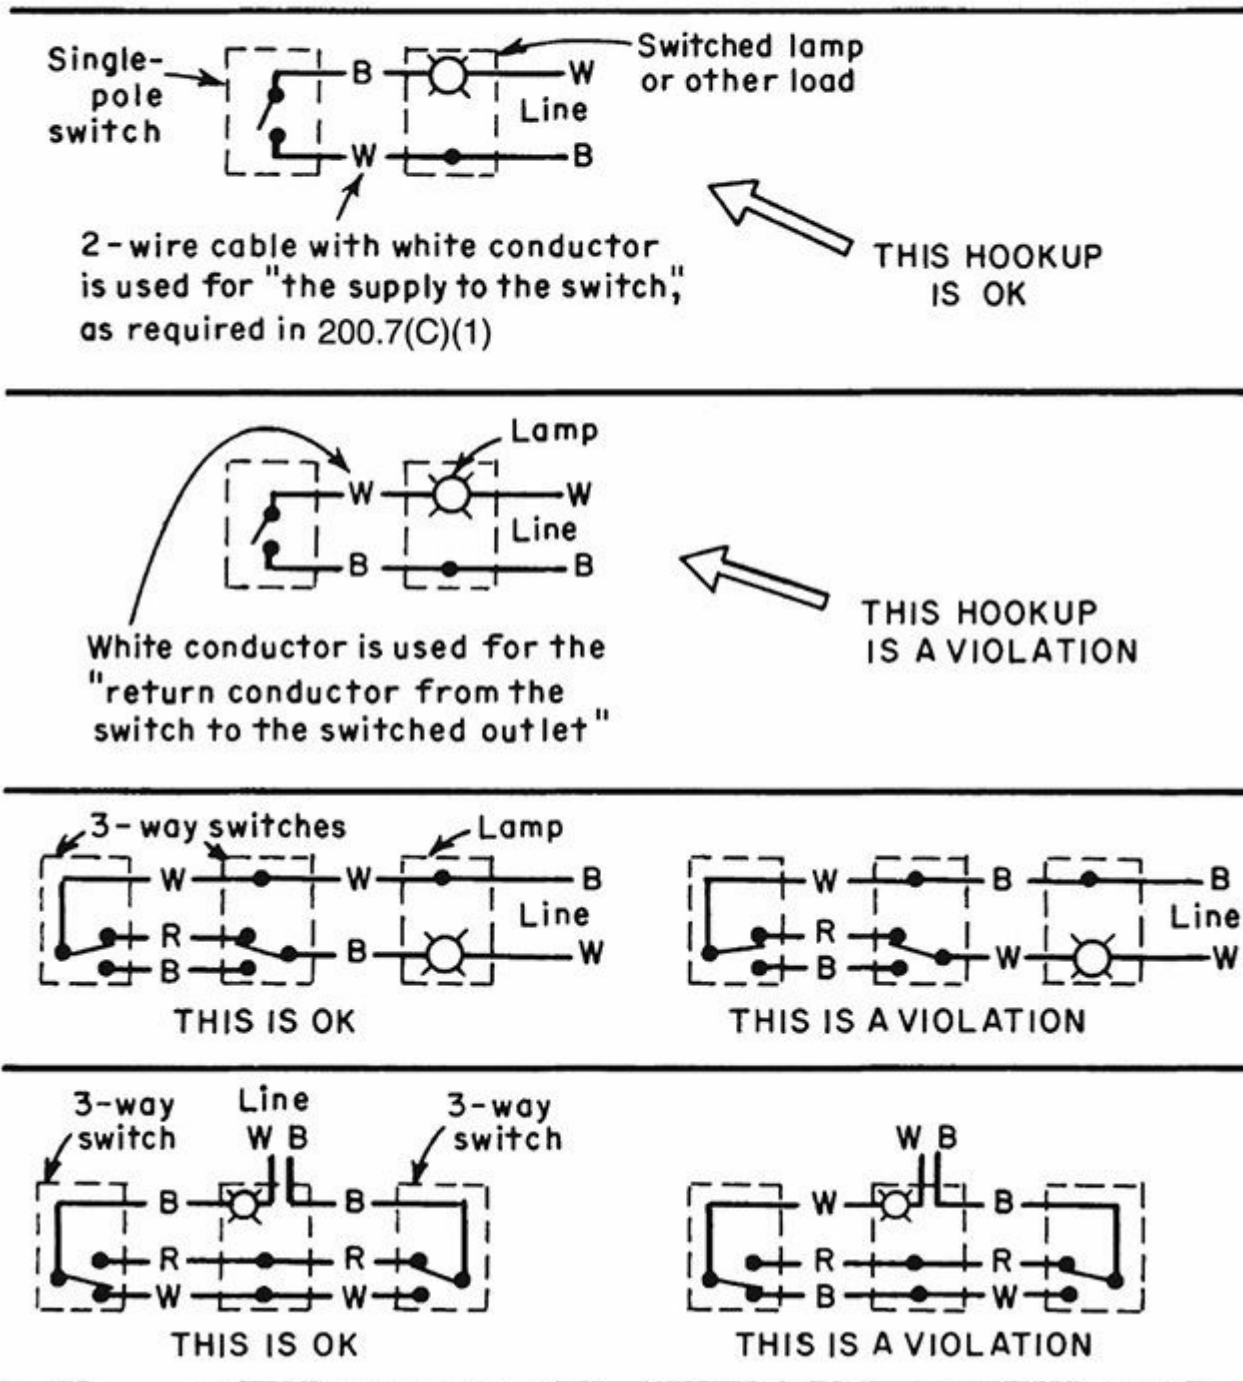

Fig. 200-8. For switch loops from load outlets with hot supply to the load outlet, white conductor in cable must be the "supply to the switch." Also, the white conductors must be reidentified at the time of installation. [Sec. 200.7(C)(1).]

The former unrestricted allowance to use the white wire in a cable assembly as the supply side of a switch leg, something every apprentice learns in the first year, is still in the Code but now the white wire must be reidentified at terminations and other places where it is "visible and accessible." Although the original substantiation for this change was questionable, the requirement has taken on increased importance given the likely steady increase in actual grounded white wire connections to

switches with electronic components, as anticipated by 404.2(C).

200.7(C)(2) covers flexible cords for connecting any equipment recognized by 400.10 for cord-and-plug connection to a receptacle outlet.

200.10. Identification of Terminals. Part (B) permits a grounded terminal on a receptacle to be identified by the word “white” or the letter “W” marked on the receptacle as an alternative to the use of terminal parts (screw, etc.) that are “substantially white in color.”

Marking of the word “white” or the letter “W” provides the required identification of the neutral terminal on receptacles that require white-colored plating on all terminals of a receptacle for purposes of corrosion resistance or for connection of aluminum conductors. Obviously, if all terminals are white colored, color no longer serves to identify or distinguish the neutral as it does if the hot-conductor terminals are brass colored. And as the rule is worded, the marking “white” or the letter “W” may be used to identify the neutral terminal on receptacles that have all brass-colored terminal screws. See [Fig. 200-9](#).

If all screw terminals (for both hot and neutral wires) on both sides of the device body are the same color—either white-colored plating or brass-colored—the neutral terminals may be identified as such by the word “white” marked adjacent to the terminals.

Fig. 200-9.

Subpart (2) of part (B) permits a push-in-type wire terminal to be identified as the neutral (grounded) conductor terminal either by marking the word “white” or the letter “W” on the receptacle body adjacent to the conductor entrance hole or by coloring the entrance hole white—as with a white-painted ring around the edge of the hole.

The rule of part (C) is shown in [Fig. 200-10](#).

SCREW-SHELL LAMPHOLDERS are wired so that ungrounded conductor is connected to center terminal to reduce shock hazard. The identified (grounded) conductor is connected to the screw-shell.

Fig. 200-10. Screw-shell sockets must have the grounded wire (the neutral) connected to the screw-shell part. [Sec. 200.10(C).]

Part (E) of Sec. 200.10 requires that the grounded conductor terminal of appliances be identified—to provide proper connection of field-installed wiring (either fixed wiring connection or attachment of a cord set).

The rule applies to “appliances that have a single-pole switch or a single-pole overcurrent device in the line or any line-connected screw-shell lampholder” and requires simply that some “means” (instead of “marking”) be provided to identify the neutral. As a result, use of white color instead of marking is clearly recognized for such neutral terminals of appliances.

200.11. Polarity of Connections. This rule makes failure to observe the proper polarity when terminating conductors a Code violation. Installers are required to ensure that each and every grounded conductor is connected to the termination specifically identified as the neutral point of connection. Any connection either of grounded conductors to “other” termination points, or the connection of an ungrounded conductor to an identified “grounded” conductor connection point, is clearly and specifically prohibited.

ARTICLE 210. BRANCH CIRCUITS

210.1. Scope. Article 210 covers all branch circuits other than those “specific-purpose branch circuits” such as those that supply only motor loads, which are covered in Art. 430. This section makes clear that the article covers branch circuits supplying lighting and/or appliance loads as well as branch circuits supplying any combination of those loads plus motor loads or motor-operated appliances, unless the branch circuit is one identified in Table 210.2, “Specific-Purpose Branch Circuits.” Where motors or motor-operated appliances are connected to branch circuits supplying lighting and/or appliance loads, the rules of both Arts. 210 and 430 apply. Article 430 alone applies to branch circuits that supply only motor loads.

210.3. Other Articles for Specific-Purpose Branch Circuits. This rule provides correlation with specific branch-circuiting requirements in other articles. There are a number of

“specific-purpose” circuits identified in this rule that must be laid-out and installed in compliance with the specific requirements of those rules shown. However, all the rules of Art. 210 continue to apply, except to the extent modified by the other provisions.

210.4. Multiwire Branch Circuits. A “branch circuit,” as covered by Art. 210, may be a 2-wire circuit or may be a “multiwire” branch circuit. A “multiwire” branch circuit consists of two or more ungrounded conductors having a potential difference between them and an identified grounded conductor having equal potential difference between it and each of the ungrounded conductors and which is connected to the neutral conductor of the system. Thus, a 3-wire circuit consisting of two opposite-polarity ungrounded conductors and a neutral derived from a 3-wire, single-phase system or a 4-wire circuit consisting of three different phase conductors and a neutral of a 3-phase, 4-wire system is a single multiwire branch circuit. This is only one circuit, even though it involves two or three single-pole protective devices in the panelboard (Fig. 210-1). This is important, because other sections of the Code refer to conditions involving “one branch circuit” or “the single branch circuit.” (See 250.32 Exception and 410.64(C).)

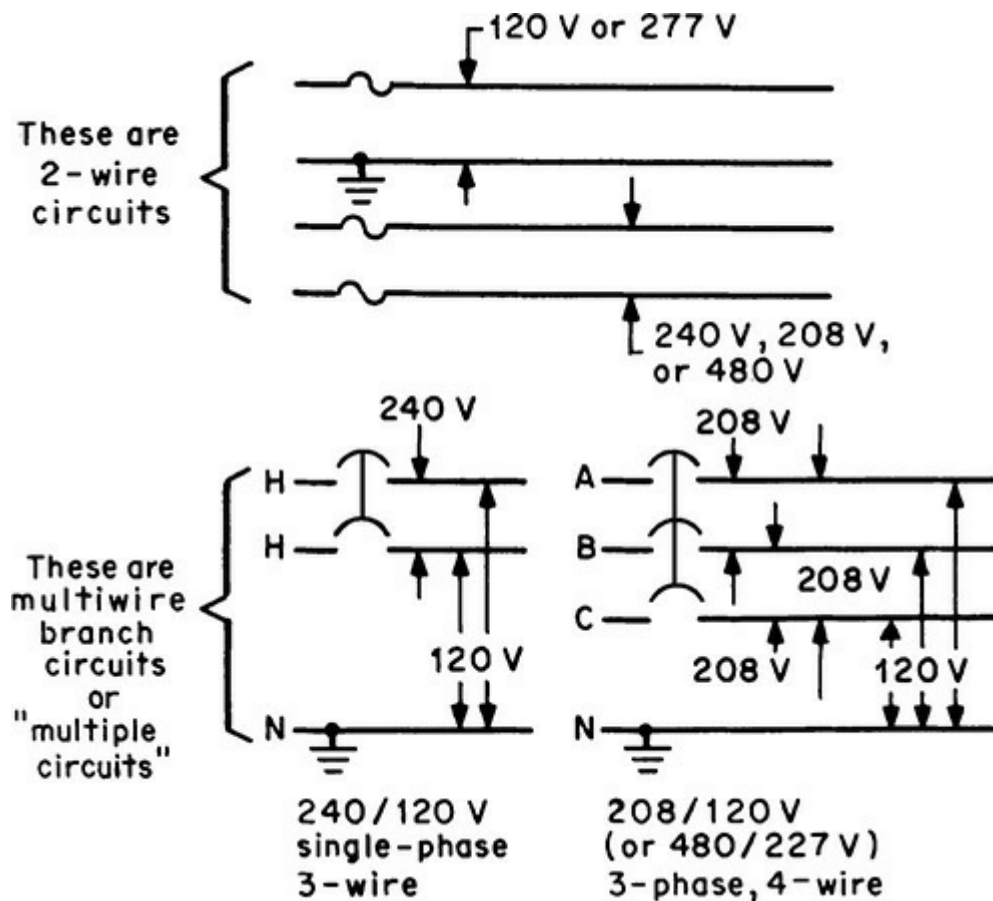

Fig. 210-1. Branch circuits may be 2-wire or multiwire type. (Sec. 210.4.)

The wording of part (A) of this section makes clear that a multiwire branch circuit may be considered to be either “a single circuit” or “multiple circuits.” This coordinates with other Code rules that refer to multiwire circuits as well as rules that call for two or more circuits. For instance, 210.11(C)(1) requires that at least two 20-A small appliance branch circuits be provided for receptacle outlets in those areas specified in 210.52(B)—that is, the kitchen, dining room, pantry, and breakfast room of a dwelling unit. The wording of this rule recognizes that a single 3-wire, single-phase 240/120-V circuit run to the receptacles in those rooms is equivalent to two 120-V circuits and

satisfies the rule of 210.11(C)(1).

In addition, a “multiwire” branch circuit is considered to be a single circuit of multiple-wire makeup. That will satisfy the rule in 410.64(C), which recognizes that a multiwire circuit is a single circuit when run through end-to-end connected lighting fixtures that are used as a raceway for the circuit conductors. Only one principal circuit—either a 2-wire circuit or a multiwire (3- or 4-wire) circuit—may be run through fixtures connected in a line.

The first informational note following part (A) of 210.4 warns of the potential for “neutral overload” where line-to-neutral nonlinear loads are supplied. This results from the additive harmonics that will be carried by the neutral in multiwire branch circuits. In some cases, where the load to be supplied consists of, or is expected to consist of, so-called nonlinear loads that are connected line-to-neutral, it may be necessary to use an oversized neutral (up to two sizes larger), or each phase conductor could be run with an individual full-size neutral. Either way, a derating of 80 percent would be required for the number of conductors [see 310.15(B)(5)(c)].

The second informational note calls attention to 300.13(B), which requires maintaining the continuity of the grounded neutral wire in a multiwire branch circuit by pigtail the neutral to the neutral terminal of a receptacle. Exception No. 2 of 210.4(C) and 300.13(B) are both aimed at the same safety objective—to prevent damage to electrical equipment that can result when two loads of unequal impedances are series-connected from hot leg to hot leg as a result of opening the neutral of an energized multiwire branch circuit or are series-connected from hot leg to neutral. 300.13(B) prohibits dependency upon device terminals (such as internally connected screw terminals of duplex receptacles) for the splicing of neutral conductors in multiwire (3- or 4-wire) circuits. Grounded neutral wires must not depend on device connection (such as the break-off tab between duplex-receptacle screw terminals) for continuity. White wires can be spliced together, with a pigtail to the neutral terminal on the receptacle. If the receptacle is removed, the neutral will not be opened.

This rule is intended to prevent the establishment of unbalanced voltages should a neutral conductor be opened first when a receptacle or similar device is replaced on energized circuits. In such cases, the line-to-neutral connections downstream from this point (farther from the point of supply) could result in a considerably higher-than-normal voltage on one part of a multiwire circuit and damage equipment, because of the “open” neutral, if the downstream line-to-neutral loads are appreciably unbalanced. Refer to the description given in 300.13 of this book.

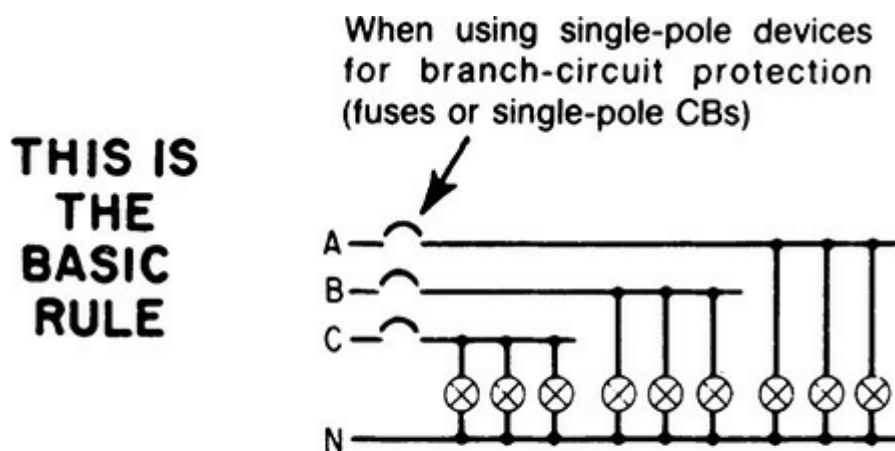

Part (B) of this section requires a “means” to simultaneously disconnect all ungrounded conductors of a multiwire branch circuit “at the point where the branch circuit originates.” Although at one time this was a dwelling-unit provision for split-wired receptacles, and then it applied in all occupancies to multiple devices on one yoke, *it now applies to all multiwire circuits serving any loads in all occupancies*. There is a long and unfortunate history of unqualified persons creating havoc when working on multiwire circuits without protecting against the consequences of open neutrals and of voltage backfeeding into an outlet from a different leg than the one thought to be at issue. Now a common disconnecting means will be in an obvious and prominent location when the branch circuit is being disconnected.

A multipole circuit breaker (CB) certainly complies with this rule, as would a multipole fused switch. Single-pole CBs connected together with identified handle ties definitely qualify due to clarifying language in 240.15(B), as now cross-referenced in an informational note. Remember that handle ties are for operation by hand; they are not rated to automatically open the companion breaker if only one leg trips. Even less clear is a multipole switch located immediately adjacent to the panel

where the circuit originates. This would be the only practical option on an existing fusible panelboard with no internal switching.

The objective is to assure that when someone goes to deenergize an ungrounded conductor of some equipment being maintained or replaced, that person will open all the conductors and thereby preclude line voltage from appearing on the load-side neutral conductor through loads connected on another leg of the circuit. In other words, this rule serves a maintenance function. If the purpose were electrical, even fuses in a multipole fused switch, would have been disallowed because they are inherently single-pole devices and if one opens, the others still provide power to the other legs. In this regard, note that the wording here differs from the requirement in 210.4(C) Exception No. 2, which serves an electrical function and clearly does require a multipole CB for other reasons. On this basis a good case can be made for the multipole switch adjacent to the panel, but this is certainly subject to local interpretation.

The basic rule of part (C) addresses the need for personnel safety. To help minimize the possibility of shock or electrocution during maintenance or repair, this section states that multiwire branch circuits (such as 240/120-V, 3-wire, single-phase and 3-phase, 4-wire circuits at 208/120 or 480/277 V) may be used only with loads connected from a hot or phase leg to the neutral conductor (Fig. 210-2). However, while generally prohibited, where additional measures are taken to protect personnel, the two exceptions to this rule permit supplying “other than line-to-neutral loads” from multiwire branch circuits. The two exceptions to that rule are shown in Fig. 210-3.

... multiwire branch circuits shall supply only line-to-neutral connected loads.

Fig. 210-2. With single-pole protection only line-to-neutral loads may be fed. (Sec. 210.4.)

Exception No. 1 permits use of single-pole protective devices for an individual circuit to “only one utilization equipment”—in which the load may be connected line-to-line as well as line-to-neutral. “Utilization equipment,” as defined in Art. 100, is “equipment which utilizes electric energy for electronic, electromechanical, chemical, heating, lighting, or similar purposes.” The definition of “appliance,” in Art. 100, notes that an *appliance* is “utilization equipment, generally other than industrial, that is normally built in standardized sizes or types and is installed or connected as a unit to perform one or more functions such as washing clothes, air conditioning, food mixing, deep frying, and so forth.” Because of those definitions, the wording of Exception No. 1 opens its application to commercial and industrial equipment as well as residential. It should be noted that 210.4(B) applies

in these cases, and therefore means must still be provided, such as handle ties, to provide for simultaneous opening of a set of single-pole breakers installed for this equipment.

Exception No. 2 permits a multiwire branch-circuit to supply line-to-line connected loads, but only when it is protected by a multipole CB. The intent of Exception No. 2 is that line-to-line connected loads may be used (other than in Exception No. 1) only where the poles of the circuit protective device operate together, or simultaneously. A multipole CB satisfies the rule, but a fused multipole switch would not comply because the hot circuit conductors are not “opened simultaneously by the branch-circuit overcurrent device.” This rule requiring a multipole CB for any circuit that supplies line-to-line connected loads as well as line-to-neutral loads was put in the Code to prevent equipment loss under the conditions shown in Fig. 210-4. Use of a 2-pole CB in the sketch would cause opening of both hot legs on any fault and prevent the condition shown.

Ex. No. 1 A multiwire branch circuit may supply a single utilization equipment with line-to-line and line-to-neutral voltage using single-pole switching devices in branch-circuit protection.

Ex. No. 2 If a multipole CB is used, loads may be connected line-to-line and/or line-to-neutral.

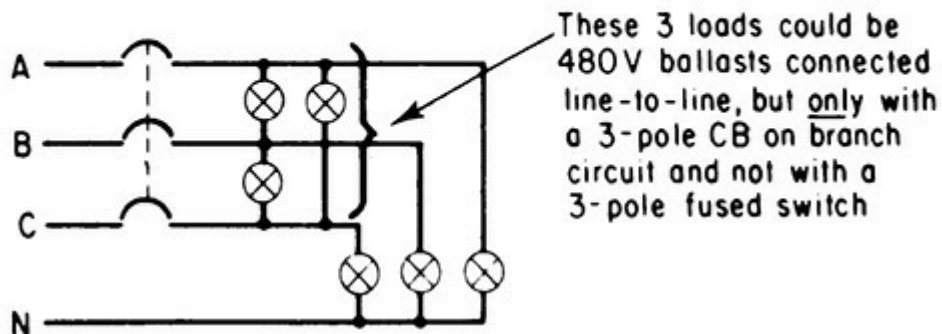

Fig. 210-3. Line-to-line loads may only be connected on multiwire circuits that conform to the exceptions given. Note that the single-pole breakers in the upper drawing would require a handle tie to comply with the common disconnecting means requirements. (Sec. 210.4.)

The UL Guide Card information addressing this point can easily be misinterpreted. The relevant text under the category “DIVQ” reads as follows: “Single-pole or multipole independent trip CBs with handle ties rated 120/240 V ac, are suitable for use on multiwire circuits with line-to-line or line-to-neutral connected loads.” This is not an open-ended permission to use single-pole breakers on applications such as Fig. 210-4. The only time such breakers can be used is when they are supplying a single appliance that requires both hot legs and a neutral.

Should fuse B open, the heater and motor would be in series on 115 volts, and the motor could burn out if not properly protected.

Fig. 210-4. Single-pole protection can expose equipment to damage. (Sec. 210.4.)

Figure 210-5 shows that a 2-pole CB, two single-pole CBs with a handle tie that enables them to be used as a 2-pole disconnect, or a 2-pole switch ahead of branch-circuit fuse protection will satisfy the requirement that both hot legs must be interrupted when the disconnect means is opened to deenergize a multiwire circuit to a split-wired receptacle. This Code rule provides the greater safety of disconnecting both hot conductors simultaneously to prevent shock hazard in replacing or maintaining any piece of electrical equipment where only one of two hot supply conductors has been opened.

ANY MULTIWIRE BRANCH CIRCUIT MUST HAVE A "MEANS" FOR SIMULTANEOUSLY DISCONNECTING ALL UNGROUNDED CONDUCTORS AT THE POINT WHERE THE BRANCH CIRCUIT ORIGINATES ...

... OR THIS MAY BE DONE ...

Multipole fused switch will satisfy as a disconnect for a multiwire branch circuit, provided there are no line-to-line connected loads on the circuit.

... BUT THIS WOULD BE A VIOLATION!

Only a 2-pole protective device (2-pole CB) may be used here to open both poles on any overcurrent when phase-to-phase load (240 V receptacle) is supplied.

Fig. 210-5.

It should also be noted that although a 2-pole switch ahead of fuses may satisfy as the simultaneous disconnect required ahead of split-wired receptacles, such a switch does not satisfy as the simultaneous multipole “branch-circuit protective device” that is required by Exception No. 2 of 210.4 when a multiwire circuit supplies any loads connected phase-to-phase (other than the single appliance covered in Exception No. 1). In such a case, a 2-pole CB must be used because fuses are single-pole devices and do not ensure simultaneous opening of all hot legs on overcurrent or ground fault.

It should be noted that the threat of motor burnout, shown in the diagram of Fig. 210-4, may exist just as readily where the 230-V resistance device and the 115-V motor are fed from a dual-voltage (240-V, 120-V) duplex receptacle as where loads are fixed wired. As shown in Fig. 210-6, the rule of 210.4 does clearly call for a 2-pole CB (and not single-pole CBs or fuses) for a circuit supplying a dual-voltage receptacle. In such a case, a line-to-line load and a line-to-neutral load could be connected and subjected to the condition shown in Fig. 210-4.

Fig. 210-6. A dual-voltage receptacle requires a 2-pole CB on its circuit. (Sec. 210.4.)

210.5. Identification for Branch Circuits. For grounding and grounded conductors this section simply directs the reader to comply with other Code rules that cover conductor color-coding or color-identification schemes. It directs that “grounded” and “grounding” conductors in branch circuits utilize the specific color identification given in 200.6 and 250.119. Those rules generally reserve the color green for equipment grounding conductors and white, gray, or three continuous white stripes on other than green-colored insulation for the grounded conductors in branch circuits.

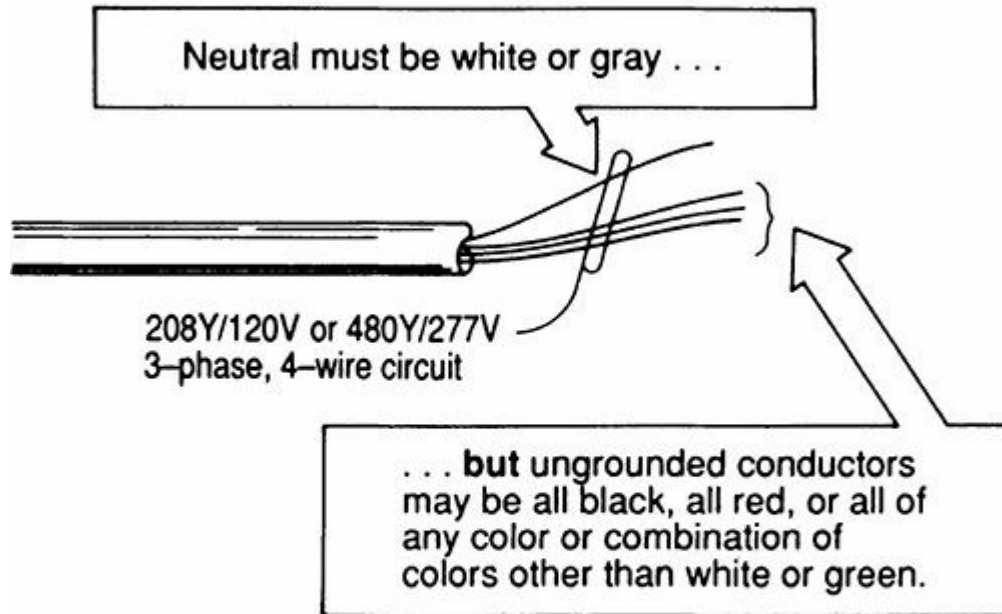

It should be noted that rules on color coding of conductors given in Art. 210 apply only to branch-circuit conductors and do not directly require color coding of feeder conductors. But the rules given in 200.6 and 250.119 must generally be observed, and would apply to feeder and service conductors. 215.12 also requires identification of phase legs of feeders to panelboards, switchboards, and so forth—and that requires some technique for marking the phase legs; those provisions are now harmonized with the ones here for branch circuits. Note that many design engineers have insisted on color coding of feeder conductors all along to afford effective balancing of loads on the different phase legs.

Color identification for branch-circuit conductors is divided into three categories:

Grounded conductor As indicated, grounded conductors must satisfy 200.6. That rule generally requires that the grounded conductor of a branch circuit (the neutral of a wye system or a

grounded phase of a delta) must be identified by a continuous white or gray color for the entire length of the conductor, or have three continuous white (or gray) stripes for its entire length on other than green insulation. Where wires of different systems (such as 208/120 and 480/277) are installed in the same raceway, box, or other enclosure, the neutral or grounded wire of one system must be white or gray or have the three continuous white (or gray) stripes on other than green insulation; and the neutral of the other system must be white with a color stripe, or be gray if the first one is white, etc., or it must be otherwise distinguished—such as by painting or taping. The point is that neutrals of different systems must be distinguished from each other when they are in the same enclosure [200.6(D) and [Fig. 210-7](#)]. For more, see 200.6.

WHEN BUILDING CONTAINS ONLY ONE SYSTEM VOLTAGE FOR CIRCUITS:

IF THERE ARE TWO SYSTEM VOLTAGES:

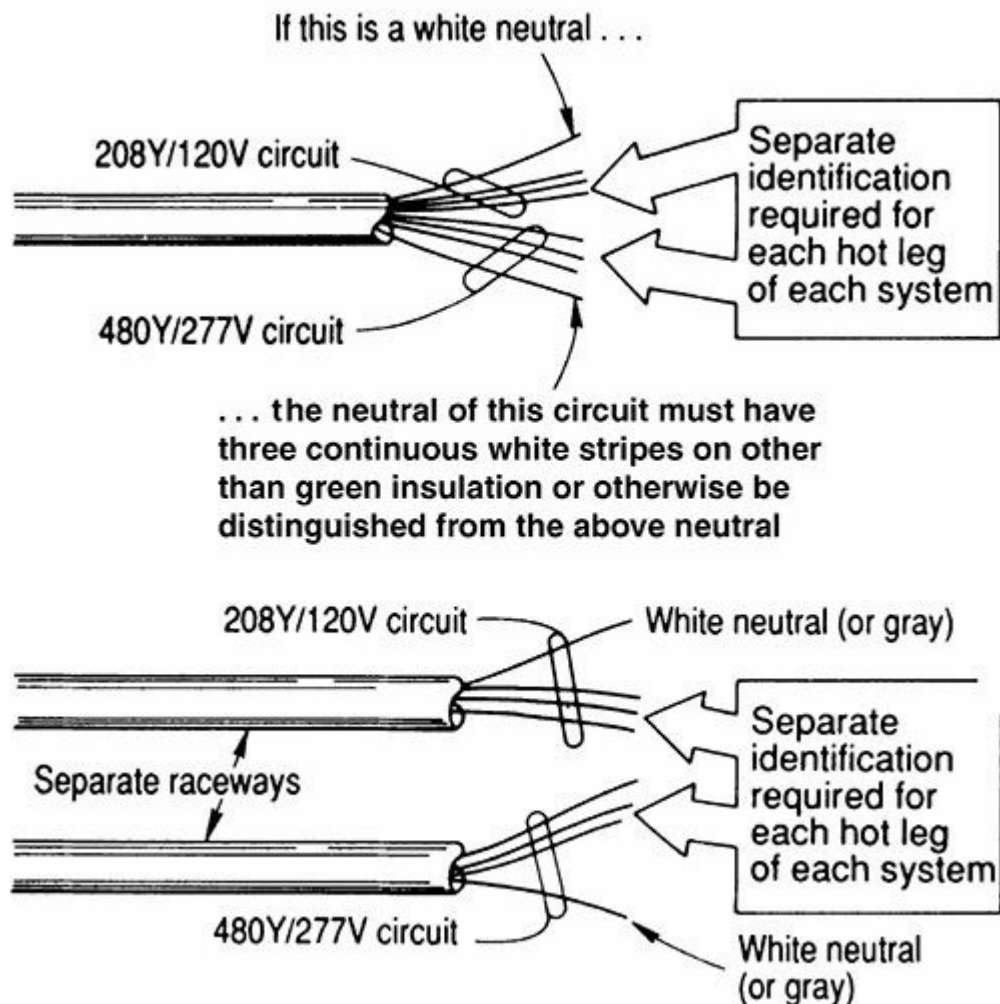

Fig. 210-7. Separate identification of ungrounded conductors is required only if a building utilizes more than one nominal voltage system. Neutrals must be color-distinguished if circuits of two voltage systems are used in the same raceway, but not if different voltage systems are run in separate raceways. [Sec. 210.5(C).]

Hot conductor The **NEC** requires that individual hot conductors be identified where a building has more than one nominal voltage system. In contrast to the rule for grounded circuit conductors, the coding rules for these wires apply anytime multiple voltage systems exist in a building, whether or not they happen to share an enclosure. Another difference is that the grounded conductor identification scheme applies over the entire length of the conductor for 6 AWG and smaller conductors, but the ungrounded conductors need only be identified at “termination, connection, and splice points.”

Grounding conductor An equipment grounding conductor of a branch circuit (if one is used) must be color-coded green or green with one or more yellow stripes—or the conductor may be bare [250.119].

In part (C), an important rule for branch circuits requires some means of identification of hot (ungrounded) conductors of branch circuits in a building that contains wiring systems operating at two or more different voltage levels. That means that one needs to identify all branch circuits including individual branch circuits, as well as single-phase and three-phase power circuits whether or not a neutral is part of the branch circuit. However, every branch-circuit panelboard—in both the 208Y/120-V system and the 408Y/277-V system—must have the means of identification marked on it—but in a key clarification for 2008, the panel identification label need only specify the system in use for circuits originating within it. It is not necessary to create complicated, fully reciprocal labels that describe every color code for every voltage system in the building. Such identification is also required in 215.12 for feeders, including the marking of feeder panels.

As of the 2017 **NEC**, the burden of circuit wiring identification has been significantly reduced in a case where a new voltage system is being added to an existing, already wired occupancy with one or more voltage systems in place. The exception allows the new system to be identified using whatever system has been designed for it, without triggering a requirement that the existing wiring be changed to accommodate and differentiate from the new system. The exception is contingent on markings being present on all distribution equipment that originates branch circuits on the new system, in addition to the posting required in (b), which specifically includes the phrase “other unidentified systems exist on the premises.”

This Code rule and that given in 215.12 restore the need to identify phase legs of branch and feeder circuits where more than one voltage system is used in a building. For instance, a building that utilizes both 208Y/120-V circuits and 480Y/277-V circuits must have separate and distinct color coding of the hot legs of the two voltage systems—or must have some means other than color coding such as tagging, marking tape (color or numbers), or some other identification that will satisfy the inspecting agency. And this new rule further states that the “means of identification must be permanently posted at each branch-circuit panelboard or similar branch-circuit distribution equipment”—to tell how the individual phases in each of the different voltage systems are identified (Fig. 210-7).

The wording of the new rule requires that the “means of identification” must distinguish between all conductors, including the system. But, if a building uses only one voltage system—such as

208Y/120 V or 240/120 V single phase, no identification is required for the circuit phase (the “hot” or ungrounded) legs. And where a building utilizes two or more voltage systems, the separate, individual identification of ungrounded conductors must be done whether the circuits of the different voltages are run in the same or separate raceways.

Color coding of circuit conductors (or some other method of identifying them), as required by 210.5(C), is a wiring consideration that deserves the close, careful, complete attention of all electrical people. Of all the means available to provide for the ready identification of the two- or three-phase legs and neutrals in wiring systems, color coding is the easiest and surest way of balancing loads among the phase legs, thereby providing full, safe, effective use of total circuit capacities. In circuits where color coding is not used, loads or phases get unbalanced, many conductors are either badly underloaded or excessively loaded, and breakers or fuses sometimes are increased in size to eliminate tripping due to overload on only one phase leg. Modern electrical usage—for reasons of safety and energy conservation, as well as full, economic application of system equipment and materials—demands the many real benefits that color coding can provide.

For the greater period of its existence, the **NEC** required a very clear, rigid color coding of branch circuits for good and obvious safety reasons. Color coding of hot legs to provide load balancing is a safety matter. 210.11(B) requires balancing of loads from branch-circuit hot legs to neutral. The rule of 220.61 bases sizing of feeder neutrals on clear knowledge of load balance in order to determine “maximum unbalance.” And mandatory differentiation of voltage levels is in the safety interests of electricians and others maintaining or working on electrical circuits, to warn of different levels of hazard.

Because the vast majority of electrical systems involve no more than two voltage configurations for circuits up to 1000 V, and because there has been great standardization in circuit voltage levels, there should be industry-wide standardization on circuit conductor identifications. A clear, simple set of rules could cover the preponderant majority of installations, with exceptions made for the relatively small number of cases where unusual conditions exist and the local inspector may authorize other techniques. Color coding should follow some basic pattern—such as the following:

- 120-V, 2-wire circuit: grounded neutral—white; ungrounded leg—black
- 240/120-V, 3-wire, single-phase circuit: grounded neutral—white; one hot leg—black; the other hot leg—red
- 208Y/120-V, 3-phase, 4-wire: grounded neutral—white; one hot leg—black; one hot leg—red; one hot leg—blue
- 240-V, delta, 3-phase, 3-wire: one hot leg—black; one hot leg—red; one hot leg—blue
- 240/120-V, 3-phase, 4-wire, high-leg delta: grounded neutral—white; high leg (208-V to neutral)—orange; one hot leg—black; one hot leg—blue
- 480Y/277-V, 3-phase, 4-wire: grounded neutral—gray; one hot leg—brown; one hot leg—orange; one hot leg—yellow
- 480-V, delta, 3-phase, 3-wire: one hot leg—brown; one hot leg—orange; one hot leg—yellow

By making color coding a set of simple, specific color designations, standardization will ensure all the safety and operating advantages of color coding to all electrical systems. Particularly today, with all electrical systems being subjected to an unprecedented amount of alterations and additions because of continuing development and expansion in electrical usage, conductor identification is a regular safety need over the entire life of the system. (Fig. 210-8.)

Fig. 210-8. Although only required for branch circuits in buildings with more than one nominal voltage, color identification of branch-circuit phase legs is needed for safe and effective work on grouped circuits. [Sec. 210.5(C).]

Of course, there are alternatives to “color” identification throughout the length of conductors. Color differentiation is almost worthless for color-blind electricians. And it can be argued that color identification of conductors poses problems because electrical work is commonly done in darkened areas where color perception is reduced even for those with good eyesight. The **NEC** already recognizes white tape or paint over the conductor insulation end at terminals to identify neutrals (200.6). Number markings spaced along the length of a conductor on the insulation (1, 2, 3, etc.)—particularly, say, white numerals on black insulation—might prove very effective for identifying and differentiating conductors. Or the letters “A,” “B,” and “C” could be used to designate specific phases. Or a combination of color and markings could be used. But some kind of conductor identification is essential to safe, effective hookup of the ever-expanding array of conductors used

throughout buildings and systems today. And the method used for identifying ungrounded circuit conductors must be posted at each branch-circuit panelboard to comply with requirements of 210.5(C). Note that 200.6(D) imposes the same requirement on grounded conductors if different systems share a common enclosure at any point. For usability, the marking protocol for both types of conductors should be grouped on the same legend plate or within the same documentation.

The **NEC** addresses this by recognizing that some occupancies with very sophisticated operations maintain the circuit identification protocols in documentation at central points. If such documentation is “readily available,” Sec. 210.5(C) and 200.6(D) now make the same allowance for grounded conductors and allow such on-site records or manuals to substitute for panelboard markings. This degree of sophistication becomes important when, for example, multiple branch circuits running at the same voltage but derived from differing separately derived systems happen to arrive in a common enclosure for some reason. In such cases, it may be very useful to know which wire is which, and the simple use of color would probably not be adequate for this purpose.

Part (C)(2) of this section is new as of the 2014 **NEC** and covers color coding for the ungrounded conductors of branch circuits that are derived from dc systems operating above 60 V. The requirement follows the customary industry practice of using red for positive and black for negative, either as the entire insulation color or in the form of a stripe along the entire length. For obvious reasons, if a stripe is used, the contrasting color cannot be that of the opposite polarity, or white, gray, or green. Imprinted positive (+) and negative (–) signs on the conductor insulation at least every 2 ft in accordance with 310.120(B) is also permitted. Another option, new as of the 2017 **NEC**, is using approved permanent marking methods such as shrink tubing with the same identifying markings. Just as in the case of 200.6 for coding grounded conductors, the rule for 6 AWG and smaller applies over the length of the conductor. For 4 AWG and larger, the rule only applies to “termination, connection, and splice points” and can be met by taping or tagging or other approved means. Note that in the case of approved permanent markings (shrink tubing, etc.), the same limitation applies equally to smaller conductors. It would clearly be prohibitive to require such methods to be used over the entire length of the conductor.

210.6. Branch-Circuit Voltage Limitations. Voltage limitations for branch circuits are presented here in 210.6. In general, branch circuits serving lampholders, fixtures, cord-and-plug-connected loads up to 12 A, or motor loads rated $\frac{1}{4}$ hp or less are limited to operation at a maximum voltage rating of 120 V. It should be noted that these rules, for the most part, are aimed at the manufacturers. But designers and installers should be aware of these limitations so that they do not unwittingly apply a given piece of equipment in an other than acceptable manner.

Part (A), occupancy limitation, applies specifically to dwelling units—one-family houses, apartment units in multifamily dwellings, and condominium and co-op units—and to guest rooms and suites in hotels and motels and similar residential occupancies, including college dormitories. In such occupancies, any luminaire or any receptacle for plug-connected loads rated up to 1440 VA or for motor loads of less than $\frac{1}{4}$ hp must be supplied at not over 120 V between conductors.

Note: The 120-V supply to these types of loads may be derived from (1) a 120-V, 2-wire branch circuit; (2) a 240/120-V, 3-wire branch circuit; or (3) a 208/120-V, 3-phase, 4-wire branch circuit. Appliances rated more than 1440 VA (e.g., ranges, dryers, water heaters) may be supplied by 240/120-V or 208/120-V circuits in accordance with 210.6(C)(6).

Caution: The concept of maximum voltage not over “120 V ... between conductors,” as stated in 210.6(A), has caused considerable discussion and controversy in the past when applied to split-

wired receptacles and duplex receptacles of two voltage levels. It can be argued that split-wired general-purpose duplex receptacles are not acceptable in dwelling units and in hotel and motel guest rooms because they are supplied by conductors with more than 120 V between them—that is, 240 V on the 3-wire, single-phase, 120/240-V circuit so commonly used in residences. The two hot legs connect to the brass-colored terminals on the receptacle, with the shorting tab broken off, and the voltage between those conductors does exceed 120 V. The same condition applies when a 120/240-V duplex receptacle is used—the 240-V receptacle is fed by conductors with more than 120 V between them.

That interpretation is not supported by the definition of a receptacle, by which a duplex receptacle is actually two receptacles on a single yoke, and each of those receptacles is considered as a separate device. In addition, the rule limits loads over 1440 VA, not devices, and until the load is plugged in, there is no issue. This rule is primarily of interest to manufacturers, who are obliged not to manufacture appliances in violation of these limits. All of that said, there is a legitimate concern with respect to the voltage on the yoke when maintenance is being performed, but the current requirements for a common disconnecting means in 210.4(B) and 210.7 fully address those issues. See [Fig. 210-9](#).

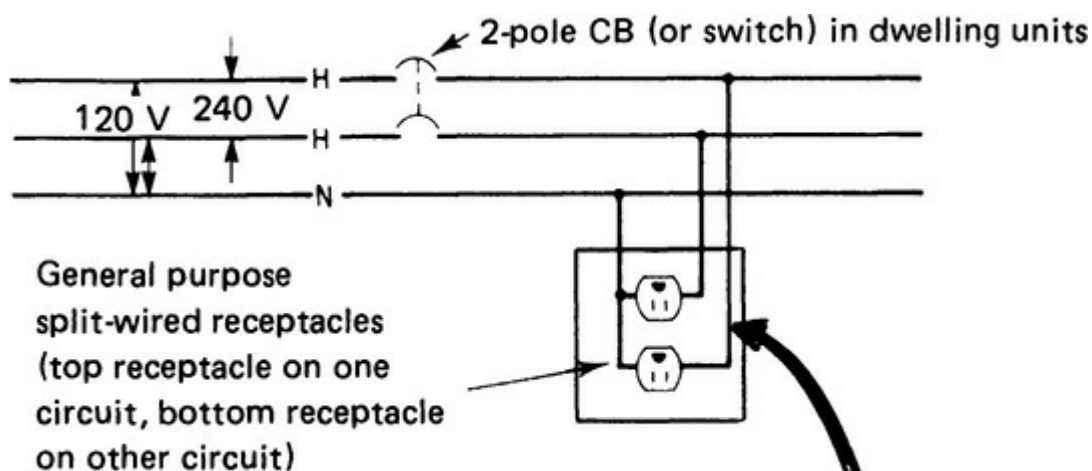

Fig. 210-9. Split-wired receptacles are permitted in residential occupancies (“dwelling units”) and in all other types of occupancies (commercial, institutional, industrial, etc.).

Part (B) begins a sequence of four voltage classifications that apply to all occupancies and that are limiting by reason of voltage alone. This part permits a circuit with not over 120 V between conductors to supply medium-base screw-shell lampholders, ballasts for fluorescent or HID lighting fixtures, and plug-connected or hard-wired appliances—in any type of building or on any premises ([Fig. 210-10](#)).

Fig. 210-10. In any occupancy, 120-V circuits may supply these loads. [Sec. 210.6(B).]

Part (C) applies to circuits with over 120 V between conductors (208, 240, 277, or 480 V) but not over 277 V (nominal) to ground. This is shown in Fig. 210-11, where all of the circuits are “circuits exceeding 120 V, nominal, between conductors and not exceeding 277 V, nominal, to ground.” Circuits of any of those voltages are permitted to supply incandescent luminaires with mogul-base screw-shell lampholders, electric-discharge and LED luminaires, or plug-connected or hard-wired appliances, or other utilization equipment.

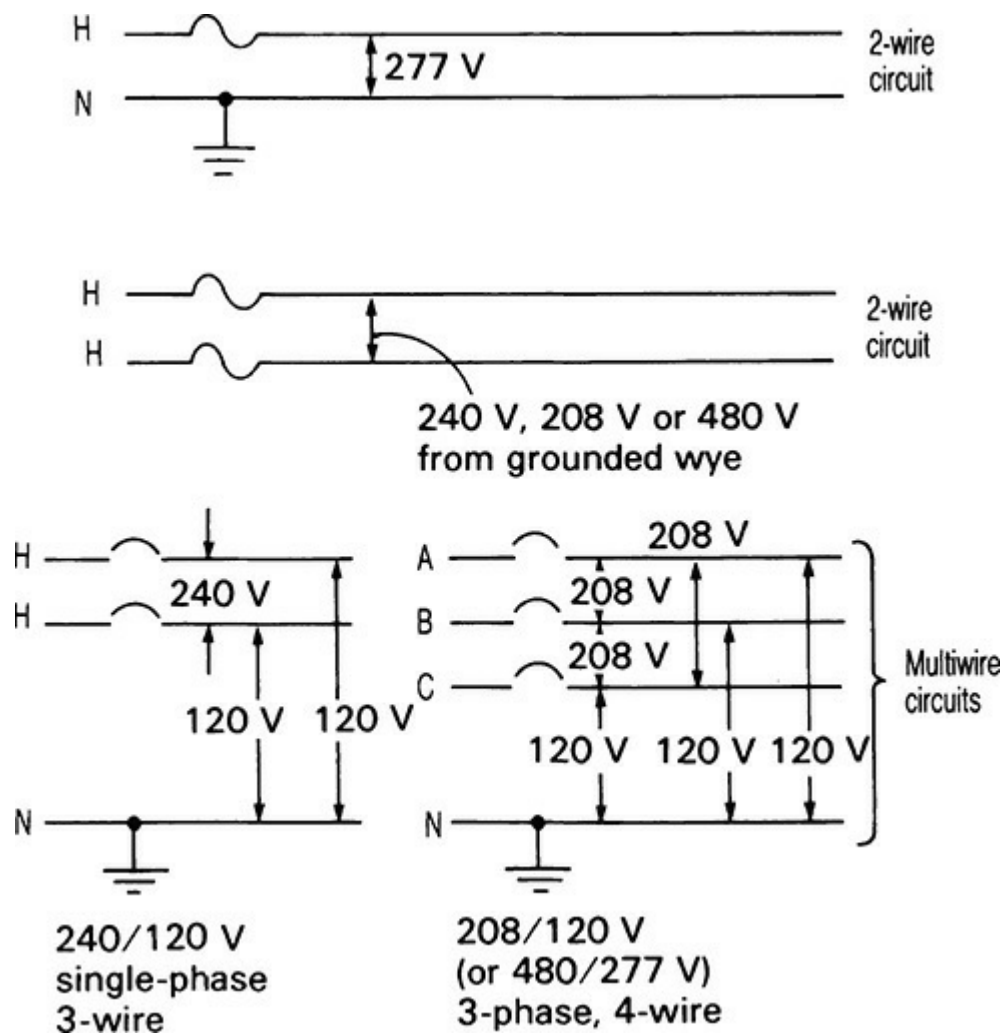

Fig. 210-11. These circuits may supply incandescent lighting with mogul-base screw-shell lampholders for over 120 V between conductors, electric-discharge ballasts, and cord-connected or permanently wired appliances or utilization equipment. [Sec. 210.6(C).]

It is important to note that this section no longer contains the requirement for a minimum 8-ft (2.5-m) mounting height for incandescent or electric-discharge fixtures with mogul-base screw-shell lampholders used on 480/277-V systems. Previously, this still had to be correlated with 225.7(C), which formerly required that luminaires connected to circuits over 120 V to ground up to 277 V not be located within 3 ft of “windows, platforms, fire escapes, and the like.” So, you could walk up and hug a 277-V bollard-style luminaire on the edge of a sidewalk, but a comparable luminaire on the side of a building had to have been out of reach. Fortunately, all these limitations in Art. 225 were removed in the 2011 **NEC**, so these positioning limitations no longer apply.

A UL-listed electric-discharge luminaire rated at 277 V nominal may be equipped with a medium-base screw-shell lampholder and does not require a mogul-base screw-shell. The use of the medium-base lampholder, however, is limited to “listed electric-discharge” or “listed light-emitting diode-type luminaires.” The **NEC** also permits listed incandescent luminaires with the usual medium bases to be supplied, provided the luminaire contains an integral autotransformer that reduces the voltage at the lamp to 120. For 277-V incandescent fixtures, 210.6(C)(3) continues the requirement that such fixtures be equipped with “mogul-based screw-shell lampholders.”

Fluorescent, mercury-vapor, metal-halide, high-pressure sodium, low-pressure sodium, and/or incandescent fixtures may be supplied by 480/277-V, grounded-wye circuits—with loads connected phase-to-neutral and/or phase-to-phase. Such circuits operate at 277 V to ground even, say, when

480-V ballasts are connected phase-to-phase on such circuits. Or lighting could be supplied by 240-V delta systems—either ungrounded or with one of the phase legs grounded, because such systems operate at not more than 277 V to ground.

On a neutral-grounded 480/277-V system, incandescent, fluorescent, mercury-vapor, metal-halide, high-pressure sodium, and low-pressure sodium equipment can be connected from phase-to-neutral on the 277-V circuits. If fluorescent or mercury-vapor fixtures are to be connected phase-to-phase, some Code authorities contend that autotransformer-type ballasts cannot be used when these ballasts raise the voltage to more than 300 V, because, they contend, the **NEC** calls for connection to a circuit made up of a grounded wire and a hot wire. (See 410.138.) On phase-to-phase connection these ballasts would require use of 2-winding, electrically isolating ballast transformers according to this interpretation. However, the actual wording in 410.138 states the restriction in terms not of whether the supply conductors are grounded, but rather that the supply system be a grounded one, and a 480-V luminaire connected to a 480Y/277-V system is connected to a grounded system.

210.6(C)(6) clearly permits either “cord-and-plug-connected or permanently connected utilization equipment” to be supplied by a circuit with voltage between conductors in excess of 120 V, and permission is intended for the use of 277-V heaters in dwelling units, as used in high-rise apartment buildings and similar large buildings that may be served at 480/277 V. This is OK in such locations as long as such equipment, if cord-and-plug-connected, is larger than the 1440 VA threshold set in the occupancy limitation in 210.6(A).

In 210.6(D), the **NEC** permits fluorescent and/or high-intensity discharge units to be installed on circuits rated over 277 V (nominal) to ground and up to 600 V between conductors—but only where the lamps are mounted in permanently installed luminaires on poles or similar structures for the illumination of areas such as highways, bridges, athletic fields, parking lots, at a height not less than 22 ft, or on other structures such as tunnels at a height not less than 18 ft (5.5 m). (See Fig. 210-12.) Part (D) covers use of lighting fixtures on 480-V ungrounded circuits—such as fed from a 480-V delta-connected or wye-connected ungrounded transformer secondary.

Fig. 210-12. Ungrounded circuits, at up to 600 V between conductors, may supply lighting only as shown. [Sec. 210.6(D).]

This permission for use of fluorescent and mercury units under the conditions described is based on phase-to-phase voltage rather than on phase-to-ground voltage. This rule has the effect of permitting the use of 240- or 480-V ungrounded circuits for the lighting applications described. But as described previously, autotransformer-type ballasts may not be permitted on an ungrounded system if they raise the voltage to more than 300 V (410.138). In such cases, ballasts with 2-winding transformation would have to be used.

Certain electric railway applications utilize higher circuit voltages. Infrared lamp industrial heating applications may be used on higher circuit voltages as allowed in 422.14 of the Code. 210.6(D)(2) allows utilization equipment other than luminaires to be connected at these voltages, whether hard-wired or cord-and-plug-connected. 210.6(D)(3) allows dc luminaires operating at these voltages, provided they are listed with an isolating ballast that only allows conventional voltages on the lamp circuit and where there would otherwise be a shock hazard while changing lamps. Additionally, luminaires with no provisions for changing lamps are permitted. This provision addresses luminaires that can run directly off photovoltaic circuits that easily run over 300 V dc; such luminaires can now be connected directly instead of relying on the inverter.

Part (E) covers medium-voltage circuits, limited to locations with qualified maintenance and supervision. Such circuits generally supply motors running at 2300, 4160, or even 13,800 V.

210.7. Multiple Branch Circuits. This section is very important because it extends the common-disconnect principle for multiwire branch circuits [210.4(B)] to all devices on a single strap or yoke. If a multiwire branch circuit arrives at a split receptacle, 210.4(B) will require that a common disconnect be installed because that is now a requirement for all multiwire branch circuits in all occupancies. However, what if two 2-wire branch circuits arrive at the same location? This provision assures that both these circuits will have a common disconnect as well, also for maintenance purposes.

This rule is functionally identical to the rule in 210.4(B) in terms of how the disconnect is defined. It is reasonably clear that handle ties could be used, or even a multipole fused switch. The rule is pointedly not written like 210.4(C) Exception No. 2, which requires an actual multipole CB to meet the electrical requirements that lie behind that provision. And, just as covered in the earlier discussion on this point under the 210.4(B) heading, a multipole switch immediately adjacent to the panel would be the only option for a fusible panel. It is also the only option when the two branch circuits leave the same panel from nonadjacent locations.

For example, suppose you wanted to use a snap-switch controlled receptacle for the lighting outlet in a dining room. The **NEC** specifically permits this arrangement in 210.52(B)(1) Exception No. 1; however, the required receptacle placements must still be observed, and this switched receptacle must not be on a small-appliance branch circuit (covered later). One way to do this is to split both sides of the receptacle, with the switch-controlled receptacle on the lighting circuit and the always-on receptacle connected to the appliance circuit. There are three options at this point. First, you can rearrange the panel so the lighting and the appliance circuits come off adjacent breakers and handle-tie those breakers together. That would definitely meet code. You could use a 2-gang opening, with one receptacle (either single or duplex) entirely controlled by the snap switch, and the receptacles on the adjacent yoke being connected to the appliance circuit. That would definitely meet Code.

Of course, the snap-switch-controlled receptacle(s) could even be in their own wall openings, as long as the switch-controlled receptacle(s) were not relied upon to meet the receptacle spacing rules in Sec. 210.52 generally. Remember that any receptacle outlet not controlled by a wall switch in a

dining room must be on the small appliance circuit. Finally, you could use a two-pole snap switch immediately adjacent to the panel, and have it disconnect both circuits. This last option requires a local interpretation of whether immediately adjacent to the panel satisfies the “at the point at which the branch circuits originate” wording in this section. As was discussed under 210.4(B), the case for allowing this practice is strong but not conclusive.

210.8. Ground-Fault Circuit-Interrupter Protection for Personnel. Since GFCIs need periodic testing, the parent language of this section requires all such devices, wherever located, to be readily accessible. The 2017 **NEC** settled a major, recurring area of controversy by adding unequivocal parent language at the beginning of 210.8 addressing how distances to receptacles potentially requiring GFCI protection are to be measured. They are measured along the path a cord could take without “piercing” a wall or doorway, etc., similar to the long established rule in 680.22(A)(5). The two receptacles shown in [Fig. 210-13](#) will require GFCI protection; one on the other side of the door, regardless of proximity, would not. Part (A) is headed “Dwelling Units.” The very specific definition of those words, as given in Art. 100 of the **NEC**, indicates that all the GFCI rules apply to:

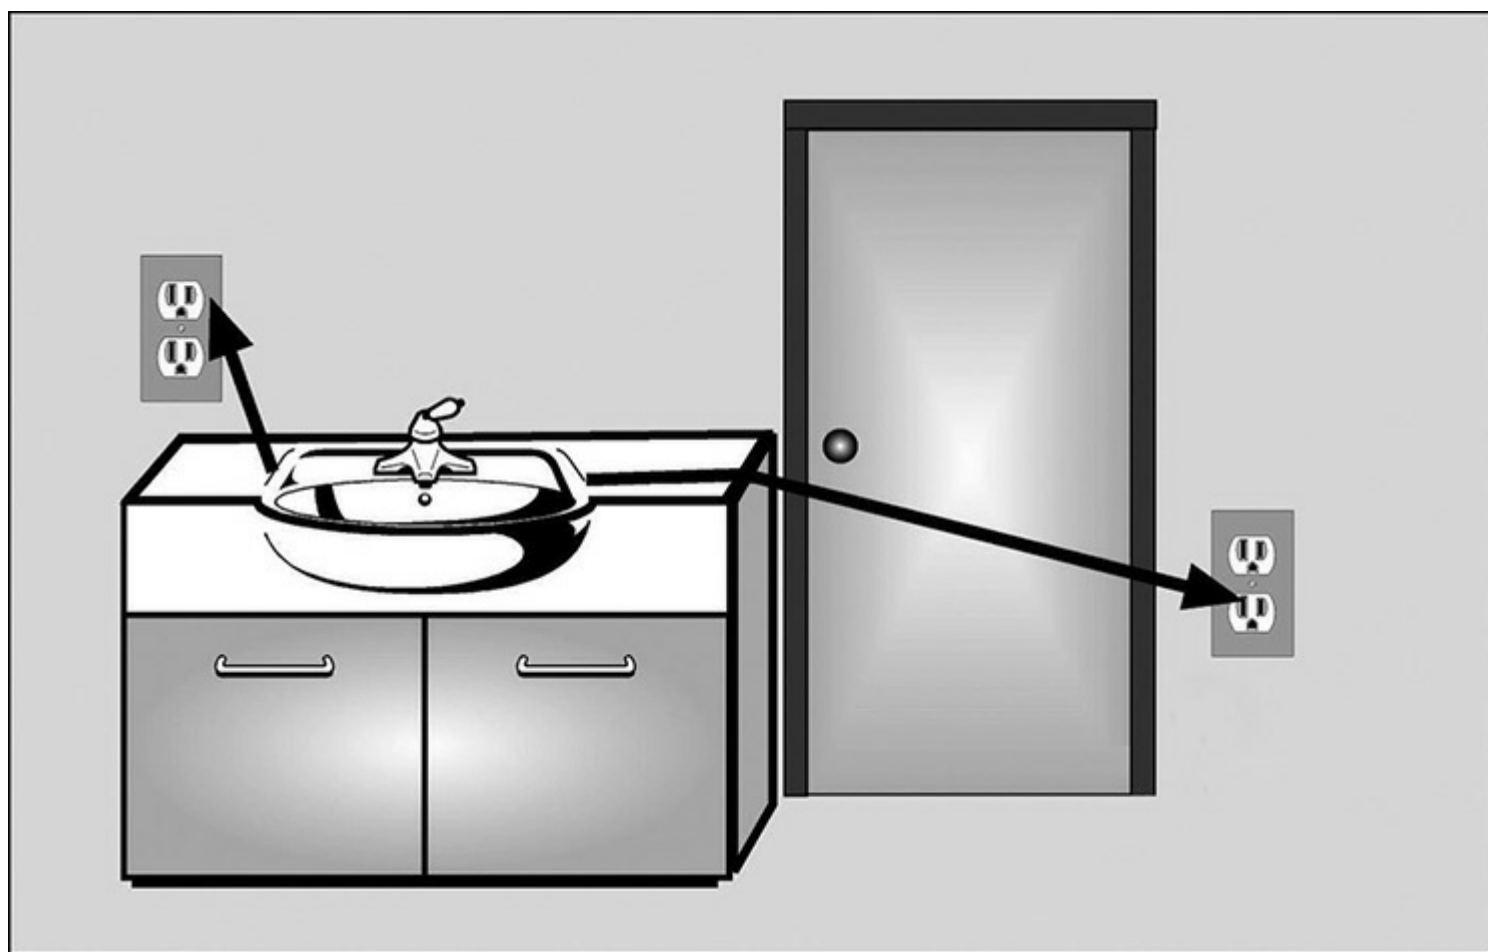

Fig. 210-13. This drawing shows receptacle placements near a kitchen sink.

- All one-family houses
- Each dwelling unit in a two-family house
- Each apartment in an apartment house
- Each dwelling unit in a condominium

GFCI protection is required by 210.8 for all 125-V, single-phase, 15- and 20-A receptacles

installed in bathrooms of dwelling units [part **(A)(1)**] and all other occupancies [part **(B)(1)**] and in garages of dwelling units ([Fig. 210-14](#)). The requirement for GFCI protection in “garages” is included because home owners do use outdoor appliances (lawn mowers, hedge trimmers, etc.) plugged into garage receptacles. Such receptacles require GFCI protection for the same reason as “outdoor” receptacles. In either place, GFCI protection may be provided by a GFCI CB that protects the whole circuit and any receptacles connected to it, or the receptacle may be a GFCI type that incorporates the components that give it the necessary tripping capability on low-level ground faults.

PROVIDE THIS PROTECTION...

... AND AT LEAST ONE MORE RECEPTACLE OUTLET must be installed [per 210.52(G)(1)] in the garage for using hand-held electric tools or appliances, and it must be GFCI-protected.

CEILING-MOUNTED RECEPTACLE for plugging in the power cord from an electric garage-door operator is "not readily accessible" but now must be GFCI protected as of the 2008 NEC because the former exception was deleted.

Fig. 210-14. GFCI protection is required for receptacles in garages as well as in bathrooms. [Sec.

210.8(A)(2).]

As just noted, GFCI protection is required by 210.8(B)(1) in bathrooms of all occupancies. This includes commercial office buildings, industrial facilities, schools, dormitories, theaters—bathrooms in ALL nondwelling occupancies. The rule here extends the same protection of GFCI breakers and receptacles to bathrooms in all nondwelling-type occupancies as for receptacles in bathrooms of dwelling units. It should be noted that there is no requirement to install a receptacle in bathrooms of other than dwelling units. But, if a 15- or 20-A, 125-V receptacle *is* installed in the bathroom of, say, an office building, then GFCI protection is required.

It is important to remember that a bathroom is defined in Art. 100 as an area that includes a basin and no fewer than one additional plumbing fixture. The 2014 **NEC** addressed a new residential architectural concept, where a master bedroom (or any other room) is configured with a shower (or tub or both) on one side of the room, and a basin with additional plumbing fixtures on the other side of the room. That makes one side of the room a bathroom, but not the other side because it plainly is not in the same area as the basin. To close this loophole, (A)(9) took effect as of the 2014 **NEC** and requires receptacles within 6 ft of the outside edge of a tub or shower stall in a dwelling to have GFCI protection.

The rule of 210.8(A)(2) requiring GFCI protection in garages applies to both attached garages and detached (or separate) garages associated with “dwelling units”—such as one-family houses or multifamily houses where each unit has its own garage. In 210.52 the Code requires at least one receptacle in an attached garage and in a detached garage if electric power is run out to the garage.

Part (A)(2) of Sec. 210.8 says that 15- and 20-A receptacles in tool huts, workshops, storage sheds, and other “accessory buildings” with a “floor located at or below grade level” at dwellings must be GFCI-protected. In addition to requiring GFCI protection for receptacles installed in a garage at a dwelling unit, other outbuildings, such as tool sheds and the like, must have GFCI protection for all 15- and 20-A, 125-V receptacles. In the 1996 **NEC**, the rule only applied to receptacles installed at “grade level portions.” The rewording as of the 1999 **NEC** requires GFCI protection for all 15- and 20-A, 125-V receptacles installed in an accessory building where the *building* has a floor that is “at or below grade level.” Obviously, that wording would eliminate the need for GFCI protection if the building’s floor is raised above “grade level,” such as by use of cinder blocks or stilts. Note, however, that the garage requirement applies wherever it is located in relation to grade level, even if you have to drive up a ramp.

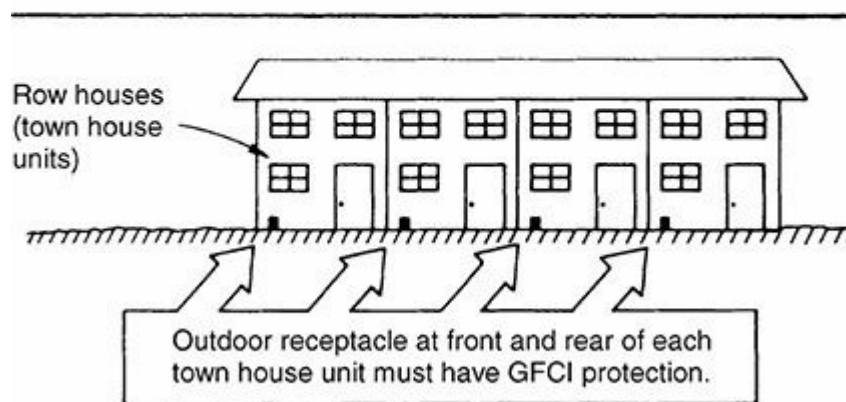

It should be noted that this rule in no way requires a receptacle to be installed in such a building. But, where a 15- or 20-A, 125-V receptacle is installed in such a location and if the area is “not intended as (one or more) habitable rooms” but instead “limited to storage areas, work areas, and areas of similar use,” it must be GFCI protected.

Note that the former exceptions for receptacles that were not readily accessible, such as for garage door openers, and single receptacles for dedicated uses such as freezers, have been entirely eliminated as of the 2008 **NEC** edition. Any receptacle of the specified amperage and voltage and phasing as described must have GFCI protection. The panel made the decision that the reliability of these devices has reached the point where special allowances need not be given.

Part (A)(3) of Sec. 210.8, on outdoor receptacles, requires GFCI protection of all 125-V, single-phase, 15- and 20-A receptacles installed “outdoors” at dwelling units. Because hotels, motels, and

dormitories are not “dwelling units” in the meaning of the Code definition, outdoor receptacles at such buildings are not covered here; see 210.8(B)(4) for those rules. The rule specifies that such protection of outdoor receptacles is required for all receptacles outdoors at dwellings ([Fig. 210-15](#)). The phrase “direct grade level access” was deleted from part **(A)(3)** a number of Code editions ago. Because the qualifier “grade-level access” was deleted, apartment units constructed above ground level would need GFCI protection of receptacles installed outdoors on balconies. Likewise, GFCI protection would be required for any outdoor receptacle installed on a porch or other raised part of even a one-family house even though there is no “grade-level access” to the receptacle, as in the examples of [Fig. 210-15](#).

210.8(A) (3). All 15- and 20-A, 125-V outdoor receptacles installed at dwelling units MUST BE GFCI protected.

In short, at dwellings ALL 15- and 20-A, 125-V receptacles installed outdoors must be GFCI protected.

Fig. 210-15. For dwelling units, all outdoor receptacles require GFCI protection. [Sec. 210.8(A) (3).]

The only exception to the rule of 210.8(A)(3) is for 15- and 20-A, 125-V receptacles that are installed to supply snow-melting and deicing equipment in accordance with Art. 426, and also pipe tracing as covered in Art. 427. Such a receptacle does not require GFCI protection as called for by Sec. 210.8(A)(3), but must have GFPE applied to the equipment as described in 426.28 (or 427.22),

provided it is installed on a dedicated circuit and in a not-readily accessible location. Under those circumstances to supply deicing and snow-melting equipment only, GFCI protection called for by this Code section may be omitted.

According to the rule of 210.8(A)(4) and (5), all 125-V, single-phase, 15- and 20-A receptacles installed in crawl spaces at or below grade and/or in unfinished basements must be GFCI-protected. This is intended to apply only to those basements or portions thereof that are unfinished (not habitable), and limited to “storage areas, work areas, and the like.” The rule of 210.52(G) requires that at least one receptacle outlet must be installed in the basement of a one-family dwelling, in addition to any installed for laundry equipment. The requirement that a receptacle be installed applies to basements of all one-family houses but not to apartment houses, hotels, motels, dormitories, and the like.

As in the case of garage locations, the former exceptions for dedicated use and for receptacles that were not readily accessible have been deleted, and for the same reasons. And here again this is very controversial, with particular concern registered around freezers and sump pumps. Note that it is at least theoretically possible to hard-wire critical equipment and avoid the issue; the requirement runs to the receptacle and not to the equipment. An exception here specifically exempts receptacles supplying “fire alarm and burglar alarm systems” from the need for GFCI protection. However, such a receptacle must be a single receptacle. This is not a conventional line-voltage smoke detector setup; the exception refers to a full fire alarm control panel instead. The receptacle is powering the internal power supply and stand-by battery charger in the unit.

According to part **(A)(6)**, GFCI protection is required for all 125-V, single-phase, 15- or 20-A receptacles installed in any kitchen of a dwelling unit where such receptacles are serving the countertop area. This will provide GFCI-protected receptacles for appliances used on countertops in kitchens in dwelling units. This would include any receptacles installed in the vertical surfaces of a kitchen “island” that includes countertop surfaces with or without additional hardware such as a range, grill, or even a sink. Because so many kitchen appliances are equipped with only 2-wire cords (toasters, coffee makers, electric fry pans, etc.), their metal frames are not grounded and are subject to being energized by internal insulation failure, making them shock and electrocution hazards. Use of such appliances close to any grounded metal—the range, a cooktop, a sink—creates the strong possibility that a person might touch the energized frame of such an appliance and at the same time make contact with a faucet or other grounded part—thereby exposing the person to shock hazard. Use of GFCI receptacles within the kitchen will protect personnel by opening the circuit under conditions of dangerous fault current flow through the person’s body ([Fig. 210-16](#)).

Fig. 210-16. GFCI protection must be provided for receptacles in kitchen. Receptacles in face of island cabinet structure in kitchen, if permitted, must be GFCI protected. [Sec. 210.8(A)(6).]

Part (A)(7) requires that 15- and 20-A, 125-V countertop receptacles installed within 6 ft (1.8 m) of a sink, such as a laundry, utility, or wet bar sink, be GFCI protected. Note that such receptacles may *not* be installed in the face-up position of the wet bar countertop, as covered in 406.5(G).

Although the requirement for GFCI protection of kitchen countertop receptacles is no longer based on their distance from the kitchen sink, the 6-ft (1.8 m) limitation is still the determining factor with

wet bar countertop receptacles, or any receptacle located within 6 ft of a sink. Any 15- or 20-A receptacles installed within 6 ft (1.8 m) from the outside edge of a sink must be provided with GFCI protection. Wording in the 2014 **NEC**, which removed the qualifying phrase “to serve countertop surfaces,” had the effect of requiring GFCI protection for under-sink receptacles for garbage disposers and other appliances. This was problematic, since these receptacles were generally not readily accessible locations. The 2017 **NEC** may have resolved this by specifying that the distance measurement be taken from the top inside edge of the sink. This must be read in concert with the clarification that distances are to be taken as the path of a cord, and that transit through a doorway doesn’t count. Putting these concepts together, it appears that once again these receptacles are exempted provided they are in a sink base with a fully closeable door, the usual condition. Note, however, the subsequent discussion regarding dishwasher circuits [210.8(D)].

210.8(A)(8) calls for GFCI protection of 15- and 20-A, 125-V-rated receptacles installed at dwelling unit boathouses. Boathouses are comparable to garages but with a greater exposure to water, and some dwellings come with boathouses that are sited with direct aquatic access to a body of water.

As of the 2014 **NEC**, all dwelling receptacles in “laundry areas” as covered in 210.8(A)(10) require GFCI protection. The term laundry area is undefined, but definitely includes the receptacle mandated by 210.52(F). A laundry hookup in an unfinished basement or one in a bathroom is already covered, but this rule covers other locations. It apparently was motivated by end-of-life reliability concerns of certain appliance manufacturers.

210.8(B). Other than Dwelling Units. These rules cover GFCI requirements for receptacles installed at commercial, industrial, and institutional occupancies. As of the 2017 **NEC**, all receptacles rated not over 150 V to ground (or less) and installed in accordance with the ten numbered applications that follow must have GFCI protection unless they are rated over 50 A single-phase, or over 100 A three-phase. The panel decided that the shock hazard was comparable on the larger circuits, and they were assured the technology was suitably evolved. All prior language about 15- and 20-A has been removed in favor of the new parameters. This is obviously a quantum leap from all prior code editions that only included 15- or 20-A, 125-V configurations. There is no delayed effective date on this provision, but in the case of three-phase receptacle circuits there don’t seem to be products available. Under 90.4 (third paragraph) the inspector may (is not required to do so) permit equipment compliant with the prior edition of the **NEC**. As given in (B)(1), all receptacles installed in bathrooms of such occupancies must be GFCI protected. There is no requirement for the installation of receptacles in bathrooms of these occupancies, but if a receptacle is installed, this rule calls for GFCI protection of that receptacle.

Part (B)(2) requires GFCI protection for receptacles installed in “kitchens”—regardless of accessibility or equipment supplied. The definition has been moved to Art. 100, and includes the phrase “with a sink and permanent facilities for preparing and cooking,” which excludes receptacles from the requirement for GFCI protection where installed in other areas of a commercial or institutional food service facility, such as a serving line or cafeteria area.

Part (B)(3) requires all rooftop receptacles to be GFCI protected, and 210.8(B)(4) mandates GFCI protection for similar receptacles installed outdoors, now also in all locations regardless of accessibility. The first exception to parts (3) and (4) eliminates the need for GFCI protection of receptacles installed to supply snow-melting or deicing equipment, provided the receptacles are “not

readily accessible.” The same allowance now extends to pipe tracing cables and similar installations covered by Art. 427. A second exception covering industrial occupancies with qualified maintenance and supervision correlates with 590.6(A) exception in waiving GFCI protection for equipment that would pose a greater hazard under a nonorderly shutdown, or for equipment designs that are inherently incompatible with GFCI protective devices. These instances are extremely unusual.

The exception following (3) addresses rooftop receptacles and makes the normal readily accessible requirement for GFCI receptacles applicable from the roof location, but not from grade or inside the building. It would be absurd and it is not necessary to construct a permanent stair to a rooftop location just so a GFCI receptacle could be accessed. Note that the rule under exception is in the parent wording of 210.8, and that is where this exception actually belongs.

The requirement [210.8(B)(5)] is to protect any receptacle within 1.8 m (6 ft) of a sink, similar to the rule in 210.8(A)(7). This rule applies to all sinks of any description, not just laundry, utility, and wet bar sinks; however, it comes with an exception for receptacles adjacent to sinks in industrial laboratories where the removal of power could create a greater hazard. An example would be a receptacle adjacent to a lab hood sink for which a showing can be made that power to a mixer or other process is essential to the orderly, perhaps even nonexplosive, completion of reactions carried out in those locations.

A second exception exempts GFCI protections for receptacles near sinks in the patient care areas of hospitals, although the GFCI receptacle requirements in hospital bathrooms continue in effect. This allowance recognizes that in some areas, particularly in critical care areas, there will often be sinks within 6 ft of the “minimum of 14 receptacles” required by 517.19(B)(1). These receptacles require the very highest standard of reliability, and for that reason must be connected to two different supply sources (normal and emergency) from different transfer switches. An outage here could literally kill a critically ill patient reliant on life-support equipment of some sort that is plugged into one of these receptacles.

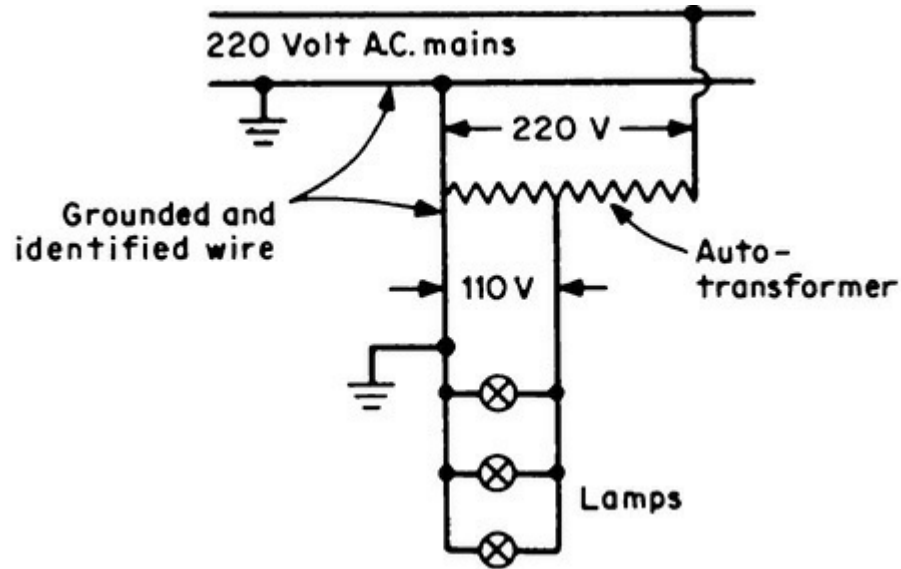

Three new areas were added to the list effective with the 2011 **NEC**. Item (6) requires the protection for any indoor wet location and item (7) requires the protection for locker rooms if they have showering areas associated with them. Item (8) takes the long-standing requirement in 511.12 for GFCI protection of service area receptacles in commercial repair garages and extends it to all comparable receptacles in any nonresidential occupancy. The broadened requirement does not apply to vehicle exhibition halls and showrooms.

The 2017 **NEC** added two new applications that mirror customary residential applications. Now provisions in (B)(9) and (B)(10) match (A)(4) and (A)(5) in requiring protection for crawl spaces and for unfinished basements or unfinished areas of basements that do not constitute habitable room.

210.8(C) requires GFCI protection for all boat hoist “outlets” on all circuits operating not over 240 V, regardless of amperage, that are provided in “dwelling-unit locations.” As a standalone provision, it covers hard-wired hoists as distinct from receptacle connections covered by (A).

210.8(D), new as of the 2014 **NEC**, requires GFCI protection for any outlet supplying a dwelling unit dishwasher. The receptacle protection rules in (A) do not guarantee GFCI coverage because a hard-wired appliance would be otherwise uncovered. As in the case of laundry equipment, some appliance manufacturers raised concerns about end-of-life appliance failures. As in the case of appliances, rules addressing receptacles in crawl spaces do not protect luminaires. As of the 2017 **NEC**, crawl space lighting outlets now require GFCI protection [Part (E)] on the circuit level, and in all occupancies.

210.9. Circuits Derived from Autotransformers. The top of Fig. 210-17 shows how a 110-V system for lighting may be derived from a 220-V system by means of an autotransformer. The 220-V system either may be single phase or may be one leg of a 3-phase system. That hookup complies with the basic rule. In the case illustrated, the “supplied” system has a grounded wire solidly connected to a grounded wire of the “supplying” system: 220-V single-phase system with one conductor grounded.

Autotransformer used to derive a 2-wire 110-V system for lighting from a 220-V power system. (210.9.)

Fig. 210-17. Autotransformers with and without grounded conductors are recognized. (Sec. 210.9, Exceptions Nos. 1 and 2.)

Autotransformers are commonly used to supply reduced voltage for starting induction motors.

Exception No. 1 permits the use of an autotransformer without a grounded conductor connection for modest 208- to 240-V transformations or vice versa (see Fig. 210-17). Typical applications include cooking equipment, heaters, motors, and air-conditioning equipment. This has been allowed since the 1971 **NEC**.

Buck or boost transformers are designed for use on single- or 3-phase circuits to supply 12/24 or 16/32-V secondaries with a 120/240-V primary. When connected as autotransformers the kVA load they will handle is large in comparison with their physical size and relative cost.

Exception No. 2 permits 480- to 600-V or 600- to 480-V autotransformers without connection to

grounded conductor—but only for industrial occupancies with qualified maintenance and supervision. The reason for this basic rule requiring continuity of a grounded circuit conductor has to do with predictability of voltage to ground. If the circuit in Fig. 210-17 is fed right to left (600 V ungrounded in, 480 V ungrounded out), and if the top conductor becomes grounded due to an insulation failure, the bottom conductor (common to both sides) will now be running 600 V to ground. This means that the 480-V derived system on the left will now run 480 V line-to-line, but 600 V to ground. The result is OK with appropriate supervision, and it has a very long track record of successful applications, but it must be taken into consideration at all times.

210.10. Ungrounded Conductors Tapped from Grounded Systems. This section permits use of 2-wire branch circuits tapped from the outside conductors of systems, where the neutral is grounded on 3-wire dc or single-phase, 4-wire, 3-phase, and 5-wire, 2-phase systems.

Figure 210-18 illustrates the use of unidentified 2-wire branch circuits to supply small motors, the circuits being tapped from the outside conductors of a 3-wire dc or single-phase system and a 4-wire, 3-phase wye system.

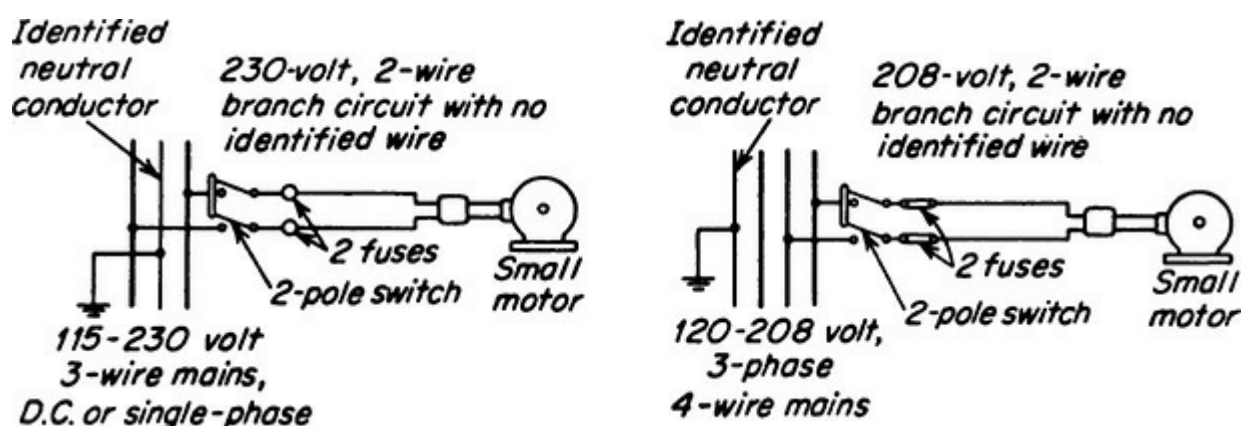

Fig. 210-18. Tapping circuits of ungrounded conductors from the hot legs of grounded systems. (Sec. 210.10.)

All poles of the disconnecting means used for branch circuits supplying permanently connected appliances must be operated at the same time. This requirement applies where the circuit is supplied by either CBs or switches.

In the case of fuses and switches, when a fuse blows in one pole, the other pole may not necessarily open, and the requirement to “manually switch together” involves only the manual operation of the switch. Similarly, when a pair of CBs is connected with handle ties, an overload on one of the conductors with the return circuit through the neutral may open only one of the CBs; but the manual operation of the pair when used as a disconnecting means will open both poles. The words “manually switch together” should be considered as “operating at the same time,” that is, during the same operating interval, and apply to the equipment used as a disconnecting means and not as an overcurrent protective device.

CBs with handle ties are, therefore, considered as providing the disconnection required by this section. The requirement to “manually switch together” can be achieved by a “master handle” or “handle tie” since the operation is intended to be effected by manual operation. The intent was not to require a common trip for the switching device but to require that it have the ability to disconnect ungrounded conductors by one movement of the hand. For service disconnecting means, see Sec. 230-71.

210.11. Branch Circuits Required. After following the rules of 220.10 to ensure that adequate branch-circuit capacity is available for the various types of load that might be connected to such circuits, the rule in 210.11(A) requires that the minimum required number of branch circuits be determined from the total computed load, as covered in 220.10, and from the load rating of the branch circuits used.

For example, a 15-A, 120-V, 2-wire branch circuit has a load rating of 15 A times 120 V, or 1800 VA. If the load is resistive, like incandescent lighting or electric heaters, that capacity is 1800 W. If the total load of lighting that was computed from 220.12 were, say, 3600 VA, then exactly two 15-A, 120-V, 2-wire branch circuits would be adequate to handle the load, provided that the load on the circuit is not a “continuous” load (one that operates steadily for 3 h or more). Because 210.19(A) requires that branch circuits supplying a continuous load be loaded to not more than 80 percent of the branch-circuit rating, if the above load of 3600 VA was a continuous load, it could *not* be supplied by *two* 15-A, 120-V circuits loaded to full capacity. A continuous load of 3600 VA could be fed by *three* 15-A, 120-V circuits—divided among the three circuits in such a way that no circuit has a load of over 15 A times 120 V times 80 percent, or 2880 VA. If 20-A, 120-V circuits are used, because each such circuit has a continuous load rating of 20 times 120 times 80 percent, or 1920 VA, the total load of 3450 VA can be divided between two 20-A, 120-V circuits. The examples here use 120 V and not 115 or 110 V because 120 V is the standard voltage required to be used for load calculations in 220.5(A).

example Given the required unit load of 3 VA/sq ft for dwelling units (Table 220.12), the Code-minimum number of 20-A, 120-V branch circuits required to supply general lighting and general-purpose receptacles (not small appliance receptacles in kitchen, dining room, etc.) in a 2200-sq-ft one-family house is three circuits. Each such 20-A circuit has a capacity of 2400 VA. The required total circuit capacity is 2200 times 3 VA/sq ft, or 6600 VA. The next step is to divide 6600 by 2400, which equals 2.75. Thus, at least three such circuits would be needed.

example In 220.12, the **NEC** requires a minimum unit load of 3 VA/sq ft for general lighting in a school, as shown in Table 220.12. For a small school of 1500 ft², *minimum capacity for general lighting* would be

$$1500 \text{ ft}^2 \times 3 \text{ VA/ft}^2 \quad \text{or} \quad 4500 \text{ VA}$$

By using 120-V circuits, when the total load capacity of branch circuits for general lighting is known, it is a simple matter to determine how many lighting circuits are needed. By dividing the total load by 120 V, the total current capacity of circuits is determined:

$$\frac{4500 \text{ VA}}{120 \text{ V}} = 37.5 \text{ A}$$

But, because the circuits will be supplying continuous lighting loads (over 3 h), it is necessary to multiply that value by 1.25 in order to keep the load on any circuit to not more than 80 percent of the circuit rating. $37.5 \times 1.25 = 46.9$. Then, using either 15- or 20-A, 2-wire, 115-V circuits gives

$$\frac{1.25 \times 37.5 \text{ A}}{15 \text{ A}} = 3.1$$

which means four 15-A circuits, or

$$\frac{1.25 \times 37.5 \text{ A}}{20 \text{ A}} = 2.3$$

which means three 20-A circuits. And then each circuit must be loaded without exceeding the 80 percent maximum on any circuit.

Part **(B)** of 210.11 makes clear that a feeder to a branch-circuit panelboard and the main busbars in the panelboard must have a minimum ampacity to serve the *calculated* total load of lighting, appliances, motors, and other loads supplied. And the amount of feeder and panel ampacity required for the general lighting load must not be less than the amp value determined from the circuit voltage and the total volt-amperes resulting from the minimum unit load from Table 220.12 (volt-amperes per square foot) times the area of the occupancy supplied by the feeder—even if the actual connected load is less than the calculated load determined on the volt-amperes-per-square-foot basis. (Of course, if the connected load is greater than that calculated on the volt-amperes-per-square-foot basis, the greater value of load must be used in determining the number of branch circuits, the panelboard capacity, and the feeder capacity.) Then, because this is actually a feeder calculation, the lighting loads determined by Table 220.12 then can be made subject to the demand factors in Table 220.42 as applicable for the specific occupancy.

It should be carefully noted that the first sentence of 210.11(B) states, “Where the load is computed on a volt-amperes-per-square-foot basis, the *wiring system* up to and including the branch-circuit panelboard(s) shall be provided to serve not less than the calculated load.” Use of the phrase “wiring system up to and including” requires that a feeder must have capacity for the total minimum branch-circuit load determined from square-foot area times the minimum unit load (volt-amperes per square foot from Table 220.12). And the phrase clearly requires that amount of capacity to be allowed in every part of the distribution system supplying the load. The required capacity would, for instance, be required in a subfeeder to the panel, in the main feeder from which the subfeeder is tapped, and in the service conductors supplying the whole system (Fig. 210-19).

Fixture layout for 277-volt lighting system is a 92,000-VA actual load that draws 111 amps per phase . . .

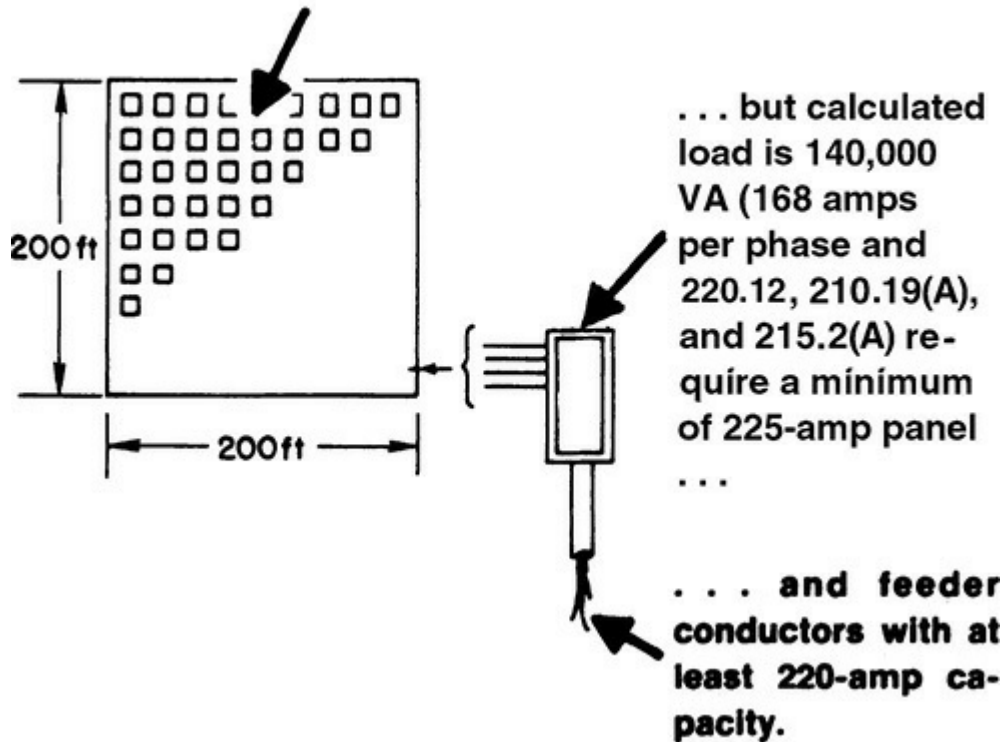

Fig. 210-19. Capacity must be provided in service and feeder conductors, as well as a branch-circuit panelboard that is adequate for the calculated load.

Actually, reference to “wiring system” in the wording of 210.11(B) presents a requirement that goes beyond the heading, “Branch Circuits Required,” of 210.11 and, in fact, constitutes a requirement on *feeder* capacity that supplements the rule of the second sentence of 215.2(A). This requires a feeder to be sized to have enough capacity for the load—as determined by part (A) of this article (which means, as computed in accordance with 220.10). However, as previously noted, the required feeder capacity can be reduced to the extent the **NEC** permits for the feeder in question.

The second part of 210.11(B) affects the required minimum number of branch circuits. Although the feeder and panelboard must have a minimum capacity to serve the *calculated* load, it is only necessary to install the number of branch-circuit overcurrent devices and circuits required to handle the actual connected load in those cases where it is less than the calculated load. The last sentence of 210.11(B) is clearly an exception to the basic rule of the first sentence of 210.11(A), which says that “The minimum number of branch circuits *shall* be determined from the *total computed* load. . . .” Instead of having to supply *that minimum* number of branch circuits, it is necessary to have only the number of branch circuits required for the actual total “connected load.” However, the branch-circuit panelboard would also need to have sufficient space to install the numbers of circuits calculated, because that panel is part of the wiring system at the feeder level.

example For an office area of 200 × 200 ft, a 3-phase, 4-wire, 480/277-V feeder and branch-circuit panelboard must be selected to supply 277-V HID lighting that will operate continuously (3 h or more). The actual continuous connected load of all the luminaires is 92 kVA. What is the minimum size of feeder conductors and panelboard rating that must be used to satisfy Sec. 210.11(B)?

$$200 \text{ ft} \times 200 \text{ ft} = 40,000 \text{ sq ft}$$

$$40,000 \text{ sq ft @ minimum of } 3.5 \text{ VA/sq ft} = 140,000 \text{ VA}$$

The minimum computed load for the feeder for the lighting is

$$140,000 \text{ VA} \div [(480 \text{ V})(1.732)] = 168 \text{ A per phase}$$

The actual connected lighting load for the area, calculated from the lighting design, is

$$92,000 \text{ VA} \div [(480 \text{ V})(1.732)] = 111 \text{ A per phase}$$

Sizing of the feeder and panelboard must be based on 168 A, not 111 A, to satisfy 210.11(B). The next step is to correlate the rules of Sec. 210.11(A) and (B) with those of 215.2(A)(1). The rule of 215.2(A)(1) requires a feeder to be sized for the “computed load” as determined by parts II, III, and IV in Art. 220. Because the entire lighting load is assumed to operate continuously in this type of occupancy, the feeder to supply the continuous calculated load of 168 A must have an ampacity at least equal to that load times 1.25. This is not for the sake of the wire, whose ampacity is by definition a *continuous* current-carrying capacity expressed in amperes. This is for the sake of the internal calibration of a conventional CB, which requires the heat sink effect of a cooler wire bolted to it. Therefore, 215.2(A)(1) assures that in any load calculation under conditions of continuous loading, a phantom capacity will be built into the feeder size. Further, 110.14(C)(1)(b) requires that the terminations on the circuit breaker be made based on wire sizes evaluated under the 75°C column of Table 310.15(B)(16). This is true whenever using a CB or fused switch that is not UL-listed for continuous operation at 100 percent of rating, as required in 215.3. Finally, since this 3-phase, 4-wire feeder will be feeding predominantly electric-discharge lighting with a strong triplen harmonic content, 310.15(B)(5)(c) will require that the neutral be counted as current carrying, and with four wires carrying current in the same raceway, 310.15(B)(3)(a) will then impose an 80 percent derating factor on the feeder conductors for mutual conductor heating.

$$168 \text{ A} \times 1.25 = 210 \text{ A [215.2(A)(1)]}$$

1. Assuming use of a non-100 percent rated protective device, the overcurrent device must be rated not less than $1.25 \times 168 \text{ A}$, or 210 A—which calls for a standard 225-A circuit breaker or fuses (the standard rating above 210 A).
2. Although feeder conductors with an ampacity of 210 A would satisfy the rule of 215.2(A) and be adequate for the load, they might not be properly protected (240.4) by a 225-A device after derating. The feeder must have a 75°C table ampacity that is not less than 210 A ($168 \text{ A} \times 1.25$) before derating *but* must also be properly protected by the 225-A rated device *after* derating. Additional calculations are required to make a final determination.
3. Using Table 310.15(B)(16), the smallest size of feeder conductor that would be protected by 225-A protection after 80 percent derating for a number of conductors is a No. 4/0 THHN or XHHW copper, with a 230 A value in the 75°C column and a 90°C ampacity of 260 A before derating ($260 \text{ A} \times 0.8 = 208 \text{ A}$). Remember: To satisfy 215.2(A)(1), the 75°C column is used. And, where 90°C-insulated conductors are used, any “deratings” needed may be applied against the ampacity value shown in the 90°C column in Table 310.15(B)(16).
4. Because the UL and 110.14(C)(1)(b) requires that conductors larger than No. 1 AWG must be used at no more than their 75°C ampacities to limit heat rise in equipment terminals, the selected No. 4/0 THHN or XHHW copper conductor must not operate at more than 230 A—which is the table value of ampacity for a 75°C No. 4/0 copper conductor. And the load current of 168 A is well within that 230 A maximum. Further, the 225-A CB will protect the 4/0 feeder conductors under the conditions of use, because the final ampacity of these conductors is 208 A and a 225-A overcurrent device is the next higher standard size, allowable in these size ranges by 240.4(B).

Thus, all requirements of 215.2(A) and UL are satisfied.

5. Note that the minimum feeder size came out 210 A, and the ampacity of the feeder conductors chosen came out 208 A in item 3 above. To some, this may look like the feeder size needs to be further increased, but not so. Comparing these two numbers is comparing apples and oranges.

The required feeder size to overcome mutual conductor heating in distant parts of the feeder raceway is one calculation, involving the middle of the wire. And it turns out that a 4/0 feeder will carry this load safely because under the conditions of use its ampacity (continuous load capacity) is 208 A, although actually loaded to 168 A. Further, the same size wire will fulfill its heat sink responsibilities at the CB terminals because, using the 75°C column of Table 310.15(B)(16), the ampacity of this wire is 230 A, and all it needs to be, inclusive of the required 25 percent phantom loading, is 210 A. These two calculations are entirely independent and should be done on separate pieces of paper.

6. The calculation of ampacities for conductors carrying continuous loads under nonstandard conditions of use and correlating those calculations with other rules on allowable terminating sizing involves some of the most complex analysis of any Code application. Any such analysis involves integrating key general rules in the first three chapters of the **NEC** together with specific application provisions in the remainder of the **NEC**. For this reason, and because the end of the Code, in Annex D Example 3(a), contains a fully developed example of one of these calculations fully worked out, line-by-line and with all applicable **NEC** provisions specifically cited, a full explanation of this calculation process will be reserved for the end of the book. Refer to [Chap. 9](#) for this information.

The rule in 408.30 requires the panelboard here to have a rating not less than the loads as calculated in Art. 220—which, in this case, means the panel must have a busbar rating not less than 168 A. Since the bus assembly must, in this case, be assumed to be distributing this load on a continuous basis, the 125 percent rule in 215.2(A)(1) will apply here as well, resulting in a minimum bus size of 210 A. A 225-A panelboard (i.e., the next standard rating of panelboard above the minimum calculated value of load current—210 A) is therefore required, even though it might seem that a 125-A panel would be adequate for the actual load current of 111 A.

The number of branch-circuit protective devices required in the panel (the number of branch circuits) is based on the size of branch circuits used and their capacity related to connected load. If, say, all circuits are to be 20-A, 277-V phase-to-neutral, each pole may be loaded not more than 16 A because 210.19(A)(1) requires the load to be limited to 80 percent of the 20-A protection rating. With the 111 A of connected load per phase, a single-circuit load of 16 A calls for a minimum of $111 \div 16$, or 8 poles per phase leg after rounding up. Thus, a 225-A panelboard with 24 breaker poles, assuming perfectly balanced loading across all of the connected branch circuits.

However, the minimum number of positions available in the panel must accommodate the calculated load of 168 A per phase. The result would probably be a 42-circuit panel (the usual next larger panel size above the calculated result of 11 per phase or 33 circuits), but with some number between 33 and 42 left as spare or vacant positions. Whether those positions could be reassigned to other loads depends on how the inspector interprets 210.11(B). The prudent option is to combine a modest increase in the number of connected circuits so each is not fully loaded, and then leave the balance of the calculated vacant positions for future developments.

Part **(C)(1)** of 210.11 requires that two or more 20-A branch circuits be provided to supply all the receptacle outlets required by 210.52(B) in the kitchen, pantry, dining room, breakfast room, and any similar area of any dwelling unit—one-family houses, apartments, and motel and hotel suites with cooking facilities or serving pantries. That means that at least one 3-wire, 20-A, 240/120- or 208/120-V circuit shall be provided to serve only receptacles for the small-appliance load in the

kitchen, pantry, dining room, and breakfast room of any dwelling unit. Of course, two 2-wire, 20-A, 120-V circuits are equivalent to the 3-wire circuit and could be used. If a 3-wire, 240/120-V circuit is used to provide the required two-circuit capacity for small appliances, the 3-wire circuit can be split-wired to receptacle outlets in these areas, provided a common disconnecting means is installed to meet 210.4(B) and 210.7.

Part (C)(2) of 210.11 requires that at least one 120-V 20-A branch circuit be provided for the one or more laundry receptacles installed, as required by 210.52(F), at the laundry location in a dwelling unit. Further, the last sentence of part (C)(2), in conjunction with 210.52(F), prohibits use of the laundry circuit for supplying outlets that are not for laundry equipment. Receptacle outlets for the laundry must be located at any anticipated laundry equipment locations because 210.50(C) requires them to be within 6 ft (1.8 m) of the intended appliance location (Fig. 210-20).

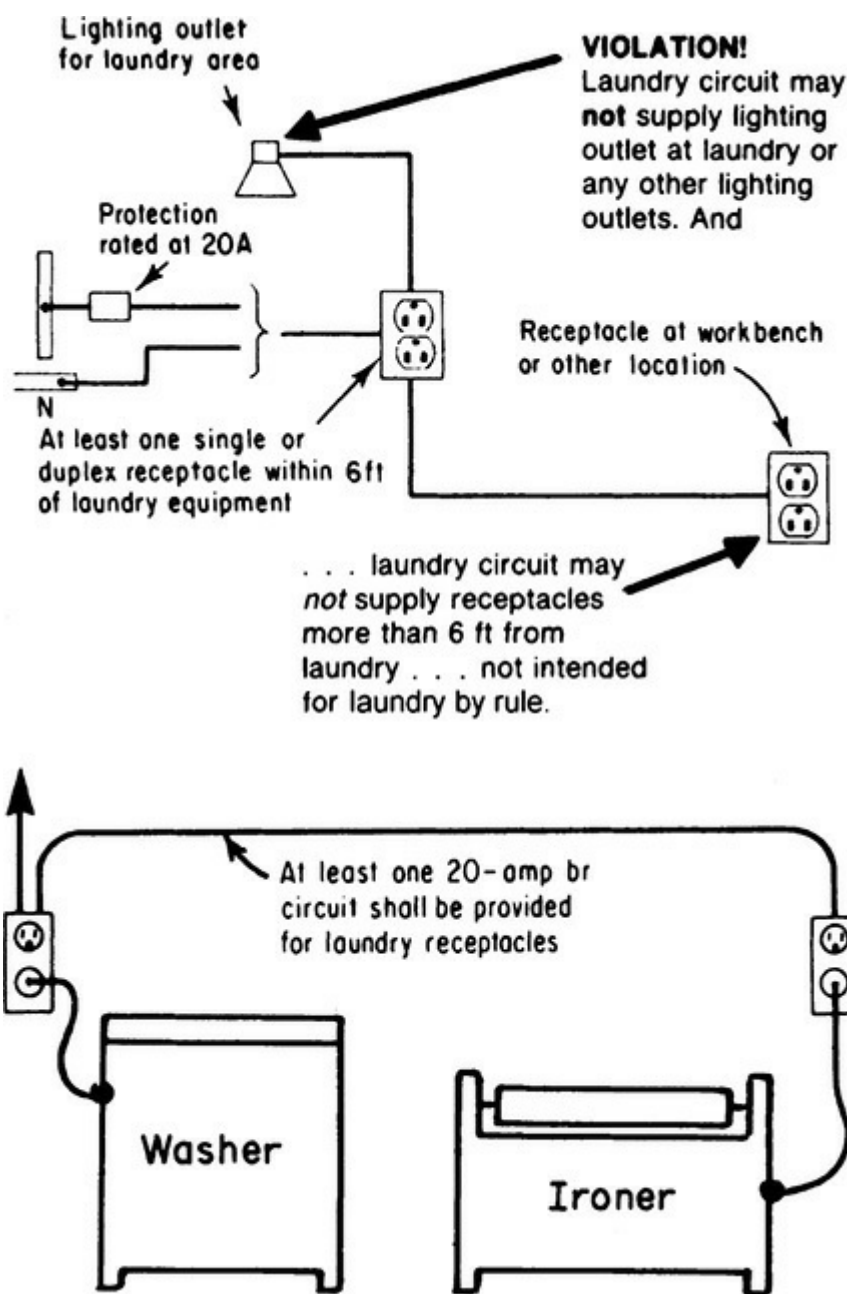

Fig. 210-20. No “other outlets” are permitted on 20-A circuit required for laundry receptacles. [Sec. 210.11(C).]

Part (C)(3) of 210.11 requires a dedicated branch circuit to supply receptacle outlets within a

dwelling unit's bathrooms. This must be a 120-V 20-A circuit, and it may supply receptacles in bathrooms only! The wording recognizes supplying more than one bathroom from a single 20-A circuit. And the exception allows limited installation of "other" outlets on this circuit where the circuit supplies only a single bathroom. So the basic rule puts all bathroom receptacles on a single circuit, or more, provided such circuits serve only bathroom receptacles. Then, as a trade-off, a 20-A circuit can supply all the loads in a bathroom, but as soon as it serves some load other than a receptacle, it must serve only a single bathroom. This exception allows for a simple and practical method of complying with listing instructions that often apply to exhaust fans over a tub, where they will generally require GFCI protection. Use the exception, and make sure that the fan is on the load side of the receptacle. Of course at this point all the wiring in a bath wired this way would need to be 12 AWG to match the 20-A circuit configuration.

As printed through 2016, the 2014 **NEC** included the indefinite article "a" ahead of "bathroom receptacle outlet(s)." This literally meant that once you supplied any bathroom receptacle, no matter how unlikely to be used, you had met the minimum requirement. This has been corrected in the 2017 **NEC**, which says "supply the bathroom receptacle outlet(s)" [emphasis supplied]. There was no documentation to support the printed version, and it was recently formally declared an erratum by NFPA. That resolves the issue in terms of 2014 **NEC** enforcement.

New as of the 2017 **NEC** is a requirement (D) [partially relocated from 210.52(G)] to add a 20-A, 120-V dedicated circuit for dwelling unit garage receptacle outlets. Only one circuit is required regardless of the number of vehicle spaces under cover, and whether or not multiple garages are present. The one or more receptacles in a detached garage are also included, if the detached garage is powered. As in previous Codes, this is not a requirement to provide power to detached garages, only how to circuit them if they are powered. There is an exception to the dedicated circuit rule; "readily accessible outdoor receptacle outlets" may also be connected to this circuit.

210.12. Arc-Fault Circuit Interrupter Protection. The arc-fault circuit interrupter (AFCI) devices are similar to, but different from, the more commonly recognized GFCIs. But while the GFCI operates on the basis that any current difference between the hot and the neutral (or the hot and the hot for 250-V single-phase devices) greater than 5 mA is "unauthorized" current flow to ground, causing it to open the circuit under such conditions, the AFCI operates to open the circuit either on a low-level current imbalance exceeding about 30 mA or when it senses a specific waveform anomaly that is indicative of an arcing fault.

Advances in electronics have made it possible for the internal chip to recognize the specific waveform characteristics of an arcing-type fault and to operate a mechanical ratchet to open the circuit, thereby providing a greater level of protection against the potential for shock, electrocution, and property damage that these typically high-impedance, low-current malfunctions can present.

There are two broad classifications of arcing failures that can be addressed by AFCI technology, namely, a line-to-line or line-to-ground failure that can occur in parallel with a connected load or even with no energized load in operation, or a failure between two severed ends of the same conductor, or at a poor connection point for such a conductor, either one in series with a connected load. The first AFCI devices in wide usage, configured as an additional tripping provision in certain CBs (and designated as "Branch/Feeder AFCIs" by UL), addressed the more common parallel events only, and the **NEC** permitted the use of this more limited protection until January 1, 2008. Meanwhile, the only design prior to that time that addressed the series failure was configured as part

of a duplex receptacle akin to a GFCI receptacle. After that time, the default AFCI protective device had to be a “combination type” device that could respond to both parallel and series failures. These are designated by UL as an “Outlet/Branch Circuit AFCI,” and if located as the first outlet on a branch circuit, provide series protection for the entire branch circuit and parallel protection for all downstream portions of the circuit. The history and terminology presented in this paragraph and those following is essential to fully understand the expanded content as of the 2014 **NEC**, which includes no fewer than six protective options.

AFCI protective schemes must combine the best protective features of both parallel and series protective devices, preferably in the form of what the **NEC** refers to as a “combination-type” device, meaning one that responds to both parallel and series arcing failures. *This designation has nothing to do with a device that provides both AFCI and GFCI protection*, although the technology is mutually compatible. All AFCI protective devices, whether in the form of a receptacle or a CB, must be mounted in a readily accessible location so the test and reset functions can be easily performed.

Much of the activity over the prior five code cycles in this section has involved successive attempts to integrate the different forms of AFCI devices into a practical framework that involved as broad a spectrum of manufacturing involvement as possible. There are untold millions of dwellings with overcurrent systems that will not accept modern CB designs, and for which the owners will likely resist the expense of a new service.

The “outlet/branch-circuit” devices are just now becoming routinely available on the market. The reason for this has been the severely restrictive nature of the **NEC** conditions for which such a device had been permitted to qualify as the required AFCI protection for a branch circuit. Under the 2005 **NEC** the device had to be located not over 6 ft from the point of branch circuit origination with the distance to be measured along the conductors, and metallic wiring methods employed between the two locations. Under the 2008 **NEC**, the distance could be of any length, but the wiring methods had to be of steel, either as a cable assembly (e.g., steel Type AC, but not the usual Type MC with aluminum armoring) or as one of three specified steel tubular raceways (IMC, RMC, or EMT) but not, technically, wireways or other wiring methods even if made of steel. The 2011 **NEC** added conventional Type MC cable (whether steel or aluminum) to the list, but Type AC cable must be steel only. The panel substantiated this disparity because Type AC cable lacks a crush resistance test.

The 2011 **NEC** also added a second exception recognizing nonmetallic conduit encased in concrete as a permitted wiring method to the first outlet. This is feasible in high-rise construction where poured concrete is often used to embed wiring systems.

AFCIs are now required to protect all circuits that supply outlets (receptacle and lighting) in dwelling-unit kitchens (as of the 2014 **NEC**), family rooms, dining rooms, living rooms, parlors, libraries, dens, bedrooms, sunrooms, recreation rooms, closets, hallways, laundry areas (as of the 2014 **NEC**), or similar rooms or areas. Most receptacle outlets in bathrooms, basements, garages, and outdoors require GFCI protection. The 2014 **NEC** also expanded this requirement to include devices, which results in AFCI coverage to an indoor snap switch controlling an outdoor light, which would not have otherwise been covered. Due to a lack of consensus in the voting at the comment stage for the 2017 **NEC**, no changes were made in 210.12(A) because the relevant text under the rule reverted to previous edition text. The result is that virtually all 120-V wiring on 15-A and 20-A branch circuits in a dwelling unit must now have some form of residual current detection, and in most

areas a failure in the branch-circuit wiring itself will also be detected and opened. Although it would be theoretically possible to omit protection of a lighting circuit that serves only a bathroom or a garage, as a practical matter all general-purpose lighting and receptacle outlets throughout the entire dwelling must be protected on installations governed as of the 2014 **NEC** and thereafter.

An exception allows wiring to a fire alarm system to omit AFCI protection entirely on an individual branch circuit run in any of the common steel wiring methods, although steel wireways were omitted due to a panel mistake in the 2014 cycle. An effort to correct this in the 2017 edition failed when, as previously noted, the entire text reverted to 2014 **NEC** language. Remember that this reference is to a full red-box fire alarm control panel governed by 760.41(B) or 760.121(B), and not the usual 120 V reciprocally alarming residential smoke detector installation.

There are still problems in the overall picture, but unmistakable progress as well. Not all manufacturers are currently making two-pole AFCI CBs, although most now are. This is important because, just as in the case of GFCI protection, a two-pole device is required to be used with a multiwire branch circuit. Some, but not all manufacturers make AFCIs in bolt-on configurations frequently specified for commercial and multifamily residential applications. Of course, the bolt-on configuration can be used anywhere but it is more prevalent in the larger quasi-commercial applications. Until the supply chain becomes completely up to speed on current applications, this will be an issue, particularly on retrofits. Note that at least one manufacturer of two-pole AFCIs also makes classified AFCI CBs that are rated for a number of competitors' panels, so that could be another way out for now. Be careful because such classification ratings are limited to some extent, particularly for applications involving available fault currents over 10 kA.

Perhaps the most encouraging development has been in the area of receptacle style AFCIs. The steady expansion of mandated AFCI applications, together with the January 1, 2014, passing of the effective date for AFCI protection on replaced receptacles in 406.4(D)(4), and the advent of additional options for installing outlet branch-circuit AFCI devices (see below) has combined to result in the first wide-scale market entry of these protective devices.

Sec. 210.12(A) has been reformatted into a list of six acceptable AFCI installation procedures, three of which break new ground.

(1) A listed combination-type device ahead of the entire circuit ([Fig. 210.21](#)). This has been the usual method and has been acceptable as long as these devices have been on the market. If GFCI protection is also required, add a GFCI receptacle or receptacles as needed. At least one manufacturer offered a “dual function” device (this is the term of art, because this is fundamentally different from a “combination AFCI” that protects against both parallel and series arcing events), but the AFCI portion was a branch/feeder device that is no longer recognized as providing full protection. Now that kitchens are included in the required coverage there will probably be renewed manufacturing interest in true dual function devices.

Fig. 210-21. A combination AFCI CB meets all requirements [210.12(A)(1)].

(2) A listed branch/feeder AFCI device (Fig. 210.22) ahead of the entire circuit in concert with a listed outlet branch-circuit device (Fig. 210.23) at the first “outlet box” on the circuit, and this box needs to be marked as such. If GFCI protection is required and the panel manufacturer offers a dual function breaker use that, or place a master-trip (faceless) GFCI ahead of any receptacles (or other loads) requiring protection. Since a two-gang box is a single outlet, this combination could be so located and still meet all requirements. *Note that there are no wiring method limitations on this method*, in contrast with (5) and (6). This was new as of the 2014 **NEC**, and there are some issues with the literal text. Since any box under 100 cu. in. and not equipped with device yoke support drillings is classified by product standards as an outlet box, that puts the downstream AFCI protection at the first outlet box after the panel, perhaps a 4-in. sq. box on a basement ceiling, and in addition the text does not accommodate multiple downstream AFCI devices protecting multiple branches of a circuit. These questions will need to be addressed with the inspector, because the likely intent was to address the first box that is at the location of an outlet, and there should be no objection if the circuit splits as long as all outlets are protected. Note that the box in the wall and not the faceplate outside the wall gets the first outlet marking. The concept is for the inspector to be able to see the wiring arrangement during the rough inspection.

Fig. 210-23. An outlet branch-circuit receptacle AFCI [210.12(A)(2-6)]. (Courtesy, Leviton)

(3) A listed supplemental arc protection CB ahead of the entire circuit with an outlet branch-circuit protective device as the first outlet. This also was new as of the 2014 **NEC**, and as of this writing this type of CB is still not available on the market. The rules, and the problems with the wording of those rules, are the same as in (2). Additional limitations include a requirement that the branch-circuit wiring from breaker to first device be “continuous,” which is not further defined but presumably means without joint or splice. Finally, the wiring cannot extend over 50 ft for 14 AWG or 70 ft for 12 AWG wiring.

(4) A listed outlet branch-circuit AFCI in combination with a listed branch-circuit protective device. This option was also new as of the 2014 **NEC** and follows the same requirements (and also has the same editorial problems) as in (3), with one additional and very important requirement. The exact combination must be “identified” as meeting applicable requirements for a “system combination-type AFCI” and be listed as such. This is a misuse of the word “identified” since any listed combination would automatically be generally recognizable as suitable for the purpose. Presumably, the intent was to require a marking by the manufacturer. This option is particularly intriguing because it opens the door to the possibility of fuses qualifying as the overcurrent device. The current UL outline of investigation allows for reductions in the permitted circuit length to the first device, and also calls for reciprocal marking on both devices warning against replacing a device at either end without replacing both at the same time.

The reciprocal marking requirement is the issue that caused further progress on AFCIs in this cycle to founder. The CB manufacturers decided that they would not mark their usual breakers as being suitable for the front end of a system combination AFCI regardless of markings that might occur on particular outlet branch-circuit devices. The AFCI receptacle manufacturers accused the breaker manufacturers of, in effect rent seeking, using the regulatory process to maintain their market share. They requested the panel to remove the limitation of a reciprocal marking on the breaker, and the panel supported that position, but in the end not by the required two-thirds majority. This contentious issue will be an emotional, major focus of the panel’s attention in the 2020 **NEC** cycle.

(5) A listed outlet branch-circuit AFCI placed at the first outlet of a circuit wired using steel wiring methods or MC cable of any composition. This method is carried over from the 2011 **NEC**.

(6) A listed outlet branch-circuit AFCI placed at the first outlet of circuit wired using MC cable or either metallic or nonmetallic raceways embedded in concrete (at least 2 in. under the surface) for the portion from the panel to the first outlet. This method is also carried over from the 2011 **NEC**.

Part (B) is new as of the 2014 **NEC** and applies the AFCI requirements for dwelling units to student rooms in dormitories. The 2017 **NEC** added “and devices,” which aligns this with 210.12(A) for conventional dwelling units. Note that the paragraph title is “Dormitory Units,” which suggests that the rules apply with designated units and not to collective lounge spaces and hallways, but this is far from clear and subject to interpretation.

Part (C) brings the guest rooms and suites of hotels into the same set of AFCI protective options that govern dwelling units. This requirement is a new addition to the 2017 **NEC**.

Part (D), originally from the 2011 code edition, requires any wiring in areas subject to 210.12 that is modified, extended, or replaced, be brought into compliance with AFCI provisions. This can be

accomplished in the usual way of providing a conventional branch/feeder AFCI in the panel. It can also be accomplished, with an outlet branch-circuit AFCI, located at the first receptacle outlet of the existing branch circuit. The 2017 **NEC** extended these provisions to dormitory units.

Note that the wiring method limitations for new installations do not apply in these cases. The first receptacle outlet could have been wired in Type NM cable and the outlet/branch-circuit AFCI could still be installed. This language addresses the reality that many older dwelling units are supplied through obsolete panels that cannot accommodate modern branch/feeder AFCIs. However, the presence of an obsolete panel is not required to invoke this wiring extension/modification permission. The 2014 **NEC** did grant relief from the AFCI upgrade requirement for incidental circuit extensions not over 6 ft in length and which do not involve any additional devices or outlets. The exception allows for such common activities as the collection of existing branch circuit wiring into a pull box that then connects to a nearby panel as part of a service upgrade.

210.13. Ground-Fault Protection of Equipment. This rule, new in the 2014 **NEC**, creates a GFPE requirement for large branch circuits that parallels the one in 215.10 for feeders. Although harmless, this rule will have little practical application. Most cases cited for it, under close examination, turn out to be feeders and not branch circuits.

210.17. Guest Rooms and Guest Suites. A guest room in a hotel or motel, if it contains permanent provisions for cooking, must meet all the rules for outlet circuiting and receptacle placements that a dwelling unit must meet. A plug-in microwave oven wouldn't, by itself, trigger this classification, but a permanent cooktop certainly would. If so, the guest room or suite would be subject to AFCI coverage, no fewer than two small-appliance branch circuits, etc.

210.18. Rating. A branch circuit is rated according to the rating of the overcurrent device used to protect the circuit. A branch circuit with more than one outlet must normally be rated at 15, 20, 30, 40, or 50 A (see [Fig. 210-24](#)). That is, the protective device must generally have one of those ratings for multioutlet circuits, and the conductors must meet the other size requirements of Art. 210.

BASIC RULE —

Circuit voltage shall not exceed 150 volts to ground for circuits supplying lampholders, fixtures or receptacles of standard 15-amp rating. For incandescent or electric-discharge lighting under certain conditions, voltage to ground may be as high as 300 volts. In certain cases, voltage for electric discharge lighting may be up to 600 volts "between conductors" and may be an ungrounded circuit.

EXCEPTION —

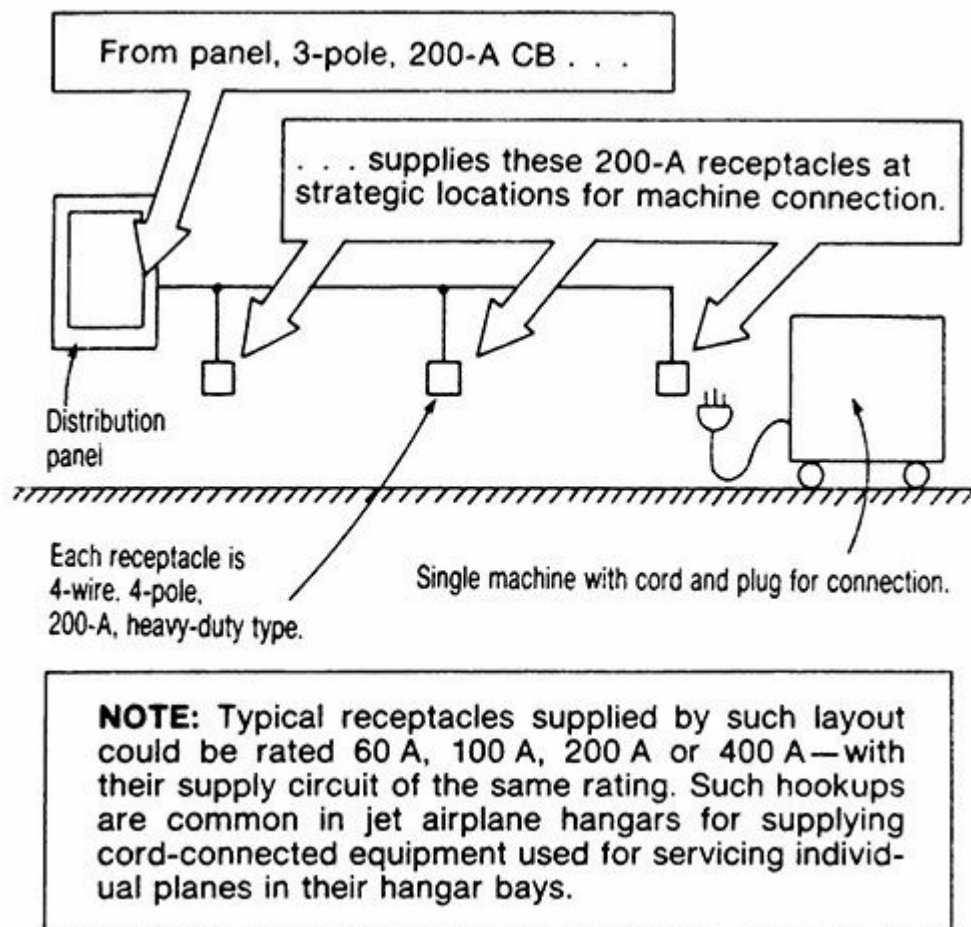

Fig. 210-24. A multioutlet branch circuit must usually have a rating (of its overcurrent protective device) at one of the five values set by 210.18. (Sec. 210.18.)

Under the definition for “receptacle” in **NEC Art. 100**, it clearly provides that a duplex receptacle is two receptacles and not one—even though there is only one box and therefore one outlet. However, a circuit that supplies only one duplex receptacle is still usually not an “individual branch circuit” because it normally will be likely to supply more than one utilization equipment through its separate receptacles, and therefore flunk the definition of “individual branch circuit” in Art. 100. If an individual branch circuit is required for any reason, and the purpose is to supply cord-and-plug connected utilization equipment, a single receptacle must be installed. One example is the individual branch circuit required in 422.16(B)(4)(5) for a cord-and-plug connected range hood.

The exception to the rule of 210.18 gives limited permission to use multioutlet branch circuits rated over 50 A—but only to supply nonlighting loads and only in industrial places where maintenance and supervision ensure that only qualified persons will service the installation. This exception recognizes a real need in industrial plants where a machine or other electrically operated equipment is going to be provided with its own dedicated branch circuit of adequate capacity—in effect, an individual branch circuit—but where such machine or equipment is required to be moved around and used at more than one location, requiring multiple points of outlet from the individual branch circuit to provide for connection of the machine or equipment at any one of its intended locations (see [Fig. 210-25](#)). For instance, there could be a 200-A branch circuit to a special receptacle outlet or a 300-A branch circuit to a single machine. In fact, the wording used here actually recognizes the use of such a circuit to supply more than one machine at a time, but other realities of application make such an approach impractical.

Fig. 210-25. A circuit to a single load device or equipment may have any rating. (Sec. 210.18.)

It is important to note that it is the size of the overcurrent device that actually determines the rating of any circuit covered by Art. 210, even when the conductors used for the branch circuit have an ampere rating higher than that of the protective device. In a typical case, for example, a 20-A CB in a panelboard might be used to protect a branch circuit in which 10 AWG conductors are used as the circuit wires. Although the load on the circuit does not exceed 20 A, and 12 AWG conductors would have sufficient current-carrying capacity to be used in the circuit, the 10 AWG conductors with their rating of 30 A were selected to reduce the voltage drop in a long homerun. The rating of the circuit is 20 A, because that is the size of the overcurrent device. The current rating of the wire does not enter into the ampere classification of the circuit.

210.19. Conductors—Minimum Ampacity and Size. In past **NEC** editions, the basic rule of this section has said—and still does say—that the conductors of a branch circuit must have an ampacity that is not less than the maximum current load that the circuit will supply. Obviously, that is

a simple and straightforward rule to ensure that the conductors are not operated under overload conditions. But, where the load to be served is “continuous,” other concerns must be addressed.

210.19(A)(1). General. Part (A)(1) of this section says that branch circuit wiring supplying a continuous current load must have an ampacity (the continuous current-carrying capacity expressed in amperes as evaluated under the conditions of use) not less than 125 percent of the continuous-current load portion of the circuit, plus any noncontinuous load. The idea of the rule is that 125 percent of a total continuous-load current portion of the circuit plus the noncontinuous load gives a circuit rating such that the continuous-load current does “not exceed 80 percent of the rating of the branch circuit evaluated after subtracting the noncontinuous load.” One is the flip side of the other. (See Fig. 210-26 for a simple application.)

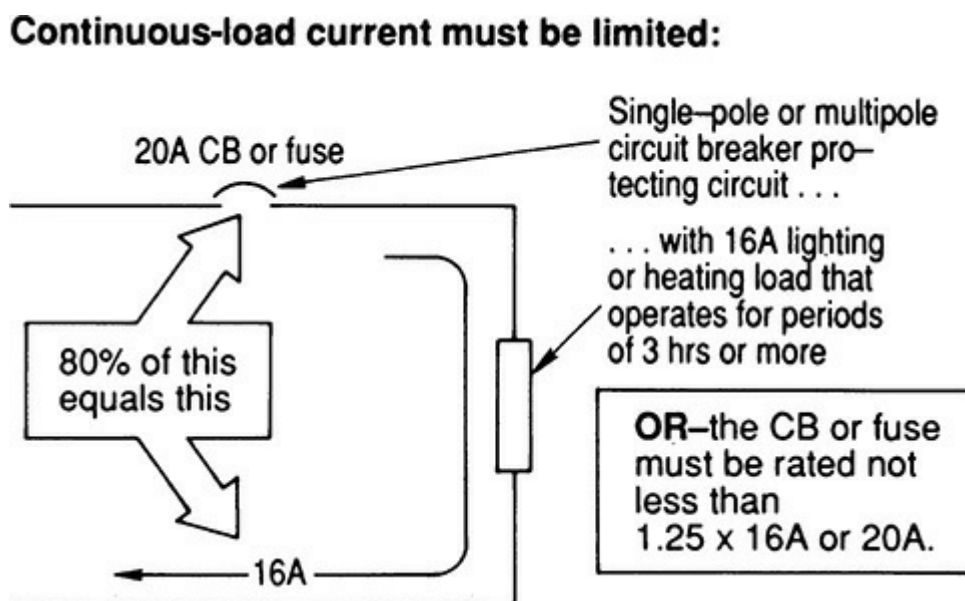

Fig. 210-26. Branch-circuit protective device must be rated not less than 125 percent of the continuous-load current. [Sec. 210.19(A).]

This portion of the rule covers how the wire and the device or load interrelate. The second half of the rule, new for the 2014 **NEC**, covers how the wire relates to its environment. After any applicable adjustment factors for ambient heat or mutual conductor heating have been applied, the resulting ampacity must be at least equal to the load whether or not that load is continuous.

The exception covers an overcurrent device including the assembly in which it is installed that has been listed for operation at 100 percent of its rating for continuous duty. In such cases, there is no derating for the continuous portion of the load. Remember that the ampacity of a conductor reflects its ability to carry current on a continuous basis. Continuous loads do not bother conductors, but they do cause problems with overcurrent devices and the **NEC** builds in additional capacity in the circuit wiring so, where it is connected to the overcurrent device, it will be cool and capable of providing a heat sink for the device to which it is connected. A 100 percent-rated device does not require this feature.

Note, however, that as a practical matter this allowance will never be used for branch circuits. The smallest CB with this capability has a 400-A frame size and tripping elements set for 100 or 125 A, depending on the manufacturer. Although there are industrial applications for this provision, the far more common application will be on feeder circuits. This book includes extensive coverage of this

topic in its coverage of Art. 215.

The entire process of correlating **NEC** rules for continuously loaded conductors with the requirements for derating and with the restrictions on conductor sizing at terminations is very possibly the most complicated calculation process in the **NEC**, and also one of the most essential to learn correctly. After all, what do electricians do but select and install wires? Because this process involves rules from many different locations in the code, and because the **NEC** now includes a comprehensive example written by this author that correlates this information, please refer to the discussion at the end of this book on Annex D, Example D3(a) for a systematic walk-through of how to apply the rules. They are not simple, but there are some basic principles to keep you on the right track, such as every wire having a middle and two ends and not confusing the rules that apply to one part of a circuit with rules that apply only to another part.

This part of 210.19(A) concludes with an informational note addressing voltage drop. This topic is fully addressed in this book in its coverage of Art. 215.

The wording of the rule in 210.19(A)(2) requires the circuit conductors to have an ampacity not less than “the rating of the branch circuit” only for a multioutlet branch circuit that supplies receptacles for cord- and plug-connected loads. The concept here is that receptacles provide for random, indeterminate loading of the circuit; and, by matching conductor ampacity to the amp rating of the circuit fuse or CB, overloading of the conductors can be avoided. But for multioutlet branch circuits that supply fixed outlets—such as lighting fixture outlets or hard-wired connections to electric heaters or other appliances—it is acceptable to have a condition where the conductor ampacity is adequate for the load current. But where there is no standard rating of protective device that corresponds to the conductor ampacity, the circuit fuse or CB rating is the next higher standard rating of protective device above the ampacity value of the conductor (Fig. 210-27).

Fig. 210-27. This is the basic rule for any multioutlet branch circuit supplying one or more receptacles. [Sec. 210.19(B).]

The receptacle limitation now correlates with 240.4(B)(1), which disallows the use of the familiar next-higher-standard-size-device permission for circuits that supply multiple receptacles. This rule [210.19(A)(2)] requires fully sized conductors if more than one receptacle is supplied by the branch circuit; the rule in 240.4(B)(1) now also applies when more than one receptacle is supplied. The title of this section has also been adjusted by adding the words “with more than one receptacle.” A review of the definition of the word “receptacle” in Art. 100 shows that if you consider a circuit with just

one duplex receptacle, the rule in 210.19(A)(2) requires fully sized branch circuit conductors, and the conflict that used to exist with 240.4(B)(1) has been removed.

For multioutlet branch circuits (rated at 15, 20, 30, 40, or 50 A), the ampacities of conductors usually correspond to standard ratings of protective devices when there is only one circuit in a cable or conduit. But when circuits are combined in a single conduit so that more than three current-carrying conductors are involved, the ampacity derating factors of Table 310.15(B)(3)(a) often result in reduced ampacity values that do not correspond to standard fuse or CB ratings. It is to such cases that the rule of 210.19(A)(2) may be applied.

For instance, assume that two 3-phase, 4-wire multioutlet circuits are run in a single conduit. Two questions arise: (1) How much load current may be put on the conductors? and (2) What is the maximum rating of overcurrent protection that may be used for each of the six hot legs? Evaluate this problem assuming that the outlets supply receptacle outlets, and then evaluate it again assuming that the circuit supplies fluorescent lighting.

The eight wires in the single conduit (six phases and two neutrals) must be taken as eight conductors when applying 310.15(B)(3)(a) because the neutrals to electric-discharge lighting carry harmonic currents and must be counted as current-carrying conductors [310.15(B)(5)(c)]. Table 310.15(B)(3)(a) then shows that the No. 14 wires must have their ampacity reduced to 70 percent (for 7 to 9 wires) of the 20-A ampacity given in Table 310.15(B)(16) for 14 AWG THW, assuming that is the insulation type. With the eight No. 14 wires in the one conduit, then, each has an ampacity of 0.7×20 , or 14 A. Because 210.19(A)(2) requires circuit wires to have an ampacity at least equal to the rating of the circuit fuse or CB if the circuit is supplying receptacles, use of a 15-A fuse or 15-A CB would not be acceptable in such a case because the 14-A ampacity of each wire is less than “the rating of the branch circuit” (15 A) if more than one receptacle is supplied. On the other hand, if the circuits here are supplying fixed lighting outlets, 210.19(A)(2) would not apply and 210.19(A)(1) would accept the 15-A protection on wires with 14-A ampacity. In such a case, it is not only necessary that the design load current on each phase must not exceed 14 A, but if the lighting load is continuous (operating steadily for 3 h or more), the load on each 15-A CB or fuse must not exceed 0.8×15 , or 12 A [as required by 210.19(A)(1)].

In part (A)(3), the rule also calls for the same approach to sizing conductors for branch circuits to household electric ranges, wall-mounted ovens, counter-mounted cooking units, and other household cooking appliances (Fig. 210-28).

Fig. 210-28. Sizing circuit conductors for household electric range. [Sec. 210.19(A)(3).]

The maximum demand for a range of 12-kW rating or less is sized from **NEC** Table 220.55 as a load of 8 kW. And 8000 W divided by 240 V is approximately 33 A. Therefore, No. 8 conductors with an ampacity of 40 A may be used for the range branch circuit.

On modern ranges the heating elements of surface units are controlled by five-heat unit switches. The surface-unit heating elements will not draw current from the neutral unless the unit switch is in one of the low-heating positions. This is also true to a greater degree as far as the oven-heating elements are concerned, so the maximum current in the neutral of the range circuit seldom exceeds 20 A. Because of that condition, Exception No. 2 permits a smaller size neutral than the ungrounded conductors, but not smaller than No. 10.

A reduced-size neutral for a branch circuit to a range, wall-mounted oven, or cooktop must have an ampacity of not less than 70 percent of the circuit rating, which is determined by the current rating or setting of the branch-circuit protective device. This is a change from previous wording that required a reduced neutral to have an ampacity of at least 70 percent of “the ampacity of the ungrounded conductors.” Under that wording, a 40-A circuit (rating of protective device) made up of No. 8 TW wires for the hot legs could use a No. 10 TW neutral—because its 30-A ampacity is at least 70 percent of the 40-A ampacity of a No. 8 TW hot leg ($0.7 \times 40 \text{ A} = 28 \text{ A}$). But if No. 8 THHN (55-A ampacity) is used for the hot legs with the same 40-A protected circuit, the neutral ampacity would have to be at least 70 percent of 55 A ($0.7 \times 55 \text{ A} = 38.5 \text{ A}$) and a No. 10 TW (30 A) or a No. 10 THW (35 A) could not have been used. The newer wording bases neutral size at 70 percent of the protective-device rating ($0.7 \times 40 \text{ A} = 28 \text{ A}$), thereby permitting any of the No. 10 wires to be used, and does not penalize use of higher temperature wires (THHN) for the hot legs.

Exception No. 1 permits taps from electric cooking circuits ([Fig. 210-29](#)). Because Exception No. 1 says that taps on a 50-A circuit must have an ampacity of at least 20 A, No. 14 conductors—which have an ampacity of 20 A in Table 310.15(B)(16)—may be used.

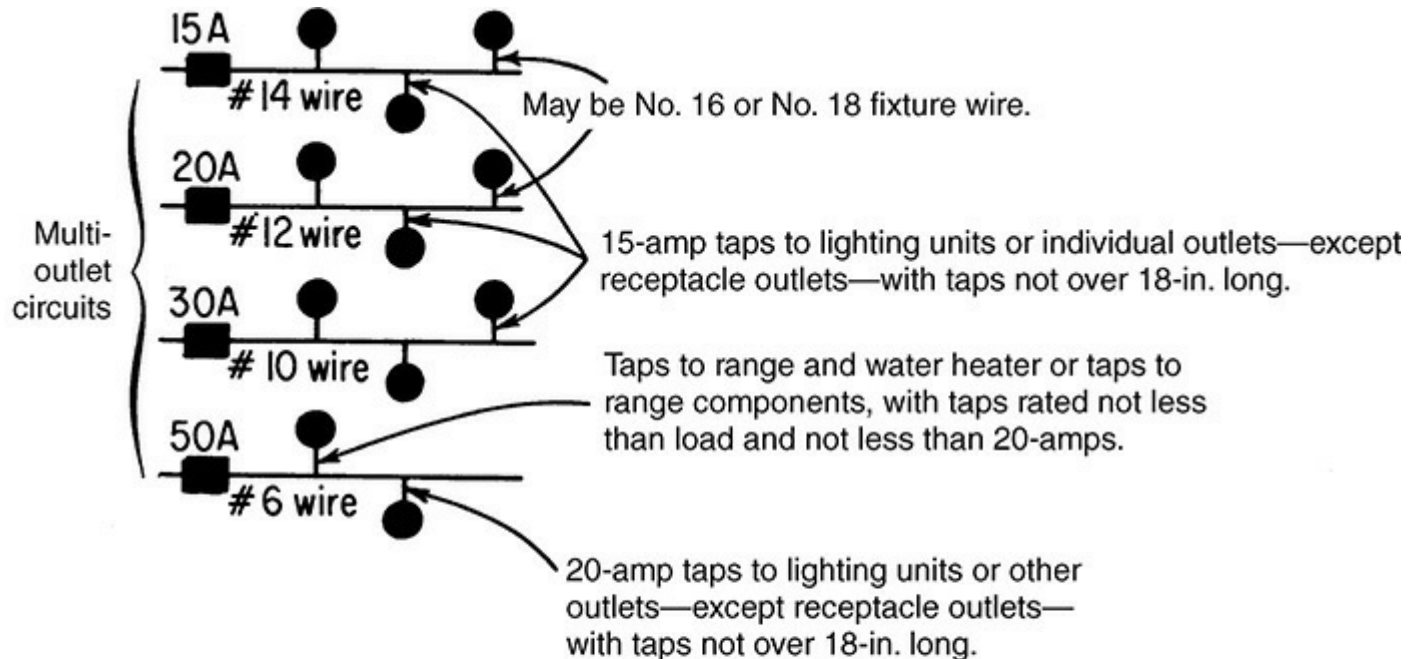

Fig. 210-29. Tap conductors may be smaller than wires of cooking circuit. [Sec. 210.19(A)(3), Exception No. 1.]

Exception No. 1 applies to a 50-A branch circuit run to a counter-mounted electric cooking unit

and wall-mounted electric oven. The tap to each unit must be as short as possible and should be made in a junction box immediately adjacent to each unit. The words “not longer than necessary for servicing the appliance” mean that it should be necessary only to move the unit to one side in order that the splices in the junction box become accessible.

210.19(A)(4) sets No. 14 as the smallest size of general-purpose circuit conductors. But tap conductors of smaller sizes are permitted as explained in Exceptions Nos. 1 and 2 (Fig. 210-30). No. 14 wire, not longer than 18 in. (450 mm), may be used to supply an outlet unless the circuit is a 40- or 50-A branch circuit, in which event the minimum size of the tap conductor must be No. 12.

Branch circuit taps—as covered in 210.19 and 210.20—are considered protected by the branch circuit overcurrent devices.

Fig. 210-30. Tap conductors may be smaller than circuit wires. [Sec. 210.19(A)(3), Exception Nos. 1 and 2.]

The wording of 210.19(A)(4), Exception No. 1, specifically excludes receptacles from being installed as indicated here because they are not tested for such use. That is, when tested for listing, receptacles are not evaluated using 18-in. (450-mm) taps of the size specified in Table 210.24 and protected as indicated by 210.19(A)(4), Exception No. 1. As a result, receptacles have been prohibited from being supplied by tap conductors, as is permitted by this exception for other loads. It is not permitted to install 14 AWG pigtails on receptacles connected to 20-A branch circuits.

210.20. Overcurrent Protection. The previous section covered the minimum size of a wire used in a branch circuit; this covers the permitted size of a branch-circuit overcurrent protective device. And here again, the overcurrent device must be rated at not less than 125 percent of any continuous loading plus 100 percent of any noncontinuous loading. This is another example of a code rule that requires correlation while making calculations so as to be certain that all requirements are satisfied. Refer to the detailed discussion at the end of this book [Annex D, Example D3(a)] where all

the concepts are integrated.

210.21. Outlet Devices. Specific limitations are placed on outlet devices for branch circuits: Lampholders must not have a rating lower than the load to be served; and lampholders connected to circuits rated over 20 A must be heavy-duty type (i.e., rated at least 660 W if it is an “admedium” type and at least 750 W for other types). Because fluorescent lampholders are not of the heavy-duty type, this excludes the use of fluorescent luminaires on 30-, 40-, and 50-A circuits. The intent is to limit the rating of lighting branch circuits supplying fluorescent fixtures to 20 A. The ballast is connected to the branch circuit rather than the lamp, but by controlling the lampholder rating, a 20-A limit is established for the ballast circuit. Most lampholders manufactured and intended for use with electric-discharge lighting for illumination purposes are rated less than 750 W and are not classified as heavy-duty lampholders. If the luminaires are individually protected, such as by a fuse in the cord plug of a luminaire cord connected to, say, a 50-A trolley or plug-in busway, some inspectors have permitted use of fluorescent luminaires on 30-, 40-, and 50-A circuits. But such protection in the cord plug or in the luminaire is supplementary (240.10), and branch-circuit protection of 30-, 40-, or 50-A rating would still exclude use of fluorescent fixtures according to 210.21(A). High-intensity discharge lighting such as metal-halide luminaires frequently incorporates heavy-duty mogul-base lampholders and would not be limited by this rule.

210.21(B) contains four paragraphs of importance. Part **(B)(1)** reads: “A single receptacle installed on an individual branch circuit shall have an ampere rating of not less than that of the branch circuit.” Since the branch-circuit overcurrent device determines the branch-circuit rating (or classification), a single receptacle (not a duplex receptacle) supplied by an individual branch circuit cannot have a rating less than the branch-circuit overcurrent device, as shown in Fig. 210-31. Exceptions apply for specialized applications where the single receptacle configuration must correlate with motor rules in one case and with the inherently special short-time usages associated with welders in the other.

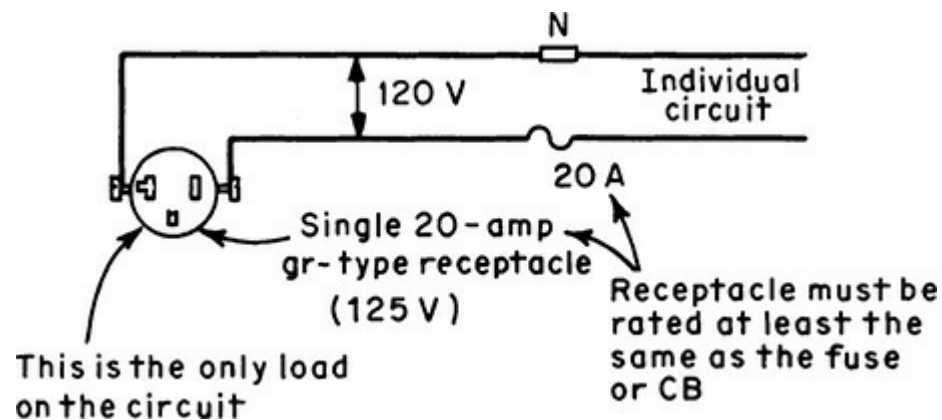

Fig. 210-31. Receptacle amp rating must not be less than circuit protection rating for an individual circuit. [Sec. 210.21(B).]

Part (B)(2) requires that receptacles installed in multiple on a branch circuit, *including just one duplex receptacle installed on a branch circuit with only the one outlet*, must not have a cord-and-plug-connected load in excess of 80 percent of the receptacle rating. Per Part (B)(3), on circuits having two or more receptacles or outlets, receptacles shall be rated as follows:

- On 15-A circuits—not over 15-A rating
- On 20-A circuits—15- or 20-A rating

- On 30-A circuits—30-A rating
- On 40-A circuits—40- or 50-A rating
- On 50-A circuits—50-A rating

Note that on 15-A circuits, a 20-A configured receptacle is not permitted, even though a 15-A receptacle is permitted on a 20-A circuit (unless it is a single receptacle on an individual branch circuit). The Code entitles any user to believe that if a 20-A plug will fit into the receptacle, the circuit will have the capability of safely supplying that load. Exceptions apply in instances where a multioutlet branch circuit is used for multiple cord-and-plug-connected welders (to correlate with Art. 630) and for electric-discharge lighting applications where a receptacle rating of not less than 125 percent of the load is sufficient. For multioutlet branch circuits rated over 50 A, as permitted under the limited conditions described in the discussion on the Exception to 210.18, every receptacle must have a rating not less than the branch-circuit rating. Part (D)(4) allows range receptacle configurations to use the same Table 220.55 loading calculations as other elements of the circuit.

210.22 and 210.23. Permissible Loads. As of the 2014 **NEC**, what was just Sec. 210.23 has been divided for editorial purposes. Sec. 210.22 covers individual branch circuits and provides that a single branch circuit to one outlet or load may serve any load and is unrestricted as to amp rating. Sec. 210.23 covers circuits with more than one outlet, which are subject to **NEC** limitations on use as follows (the word “appliance” stands for any type of utilization equipment):

1. Branch circuits rated 15 and 20 A may serve lighting units and/or appliances. The rating of any one cord- and plug-connected appliance shall not exceed 80 percent of the branch-circuit rating. Appliances fastened in place may be connected to a circuit serving lighting units and/or plug-connected appliances, provided the total rating of the fixed appliances fastened in place does not exceed 50 percent of the circuit rating ([Fig. 210-32](#)). Example: 50 percent of a 15-A branch circuit = 7.5 A. A permanently connected ventilating fan/light combination installed in a bathroom ceiling and drawing, say, 2.5 A, is permitted to be connected to a lighting circuit. However, the same appliance configured with a heating element drawing an additional 9 A could not be connected to the aforementioned lighting circuit. However, no hard-wired loads, such as range hoods or other appliances, regardless of current draw, are permitted to be connected to the specialized appliance circuits covered in 210.11(C). The bathroom receptacle circuits, the small-appliance branch circuits, and the laundry circuits are entirely reserved for cord-and-plug-connected loads in the designated areas.

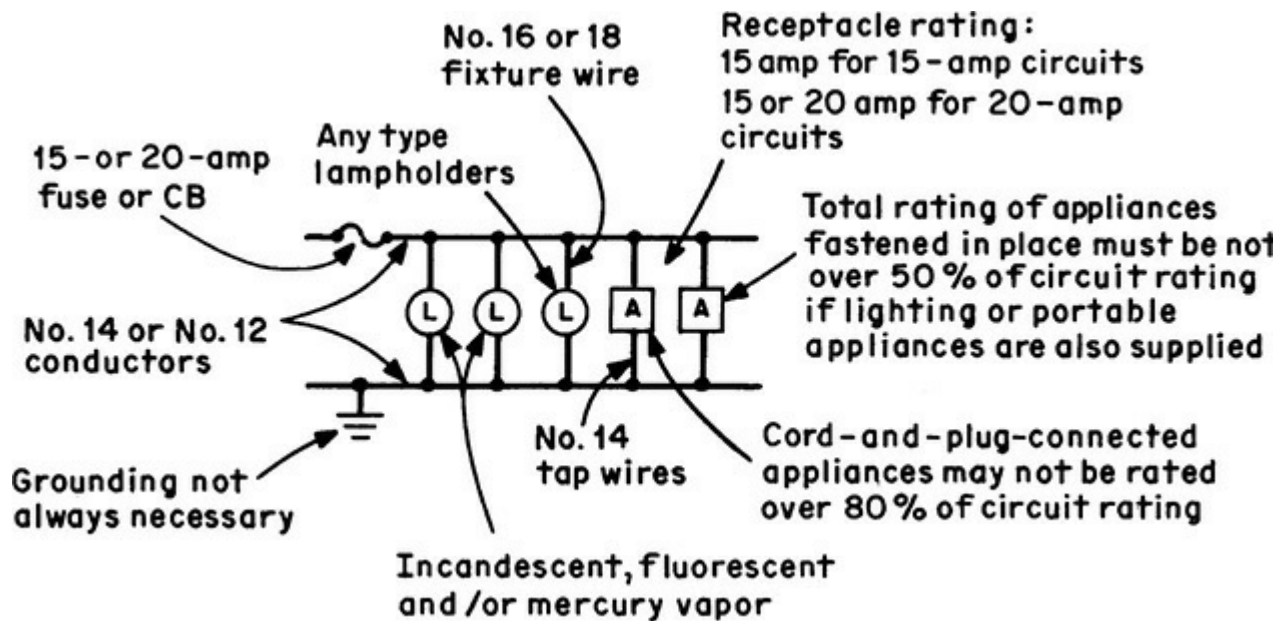

Fig. 210-32. General-purpose branch circuits—15 or 20 A. [Sec. 210.23(A).]

However, modern design usually provides separate circuits for individual fixed appliances of any significant load. In commercial and industrial buildings, separate circuits should be provided for lighting and separate circuits for receptacles.

- Branch circuits rated 30 A may serve fixed lighting units (with heavy-duty-type lampholders) in other than dwelling units or appliances in any occupancy. Any individual cord-and-plug-connected appliance that draws more than 24 A may not be connected to this type of circuit (Fig. 210-33).

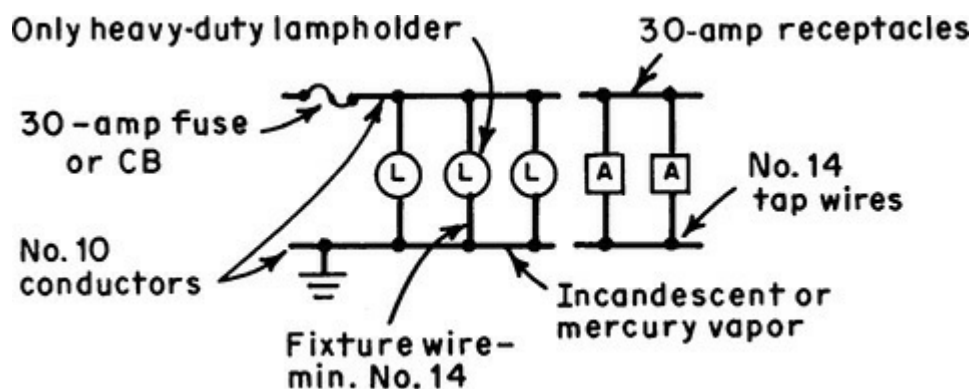

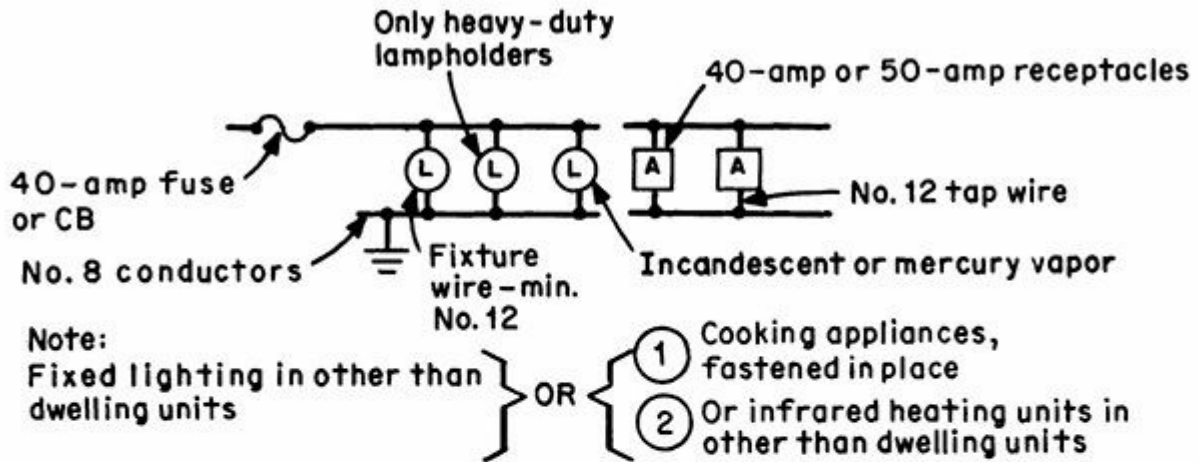

Fig. 210-33. Multioutlet 30-A circuits. [Sec. 210.23(B).]

Because an individual branch circuit—that is, a branch circuit supplying a single outlet or load—may be rated at any ampere value, it is important to note that the omission of recognition of a 25-A multioutlet branch circuit does not affect the full acceptability of a 25-A individual branch circuit supplying a single outlet. A typical application of such a circuit would be use of No. 10 TW aluminum conductors [rated at 25 A in Table 310.15(B)(16)], protected by 25-A fuses or CB, supplying, say, a 4500-W water heater at 240 V. The water heater is a load of $4500 \div 240$, or 18.75 A, which is taken as 19 A per 220.5(A). Then, because 422.13 designates water heaters as continuous loads (in tank capacities up to 120 gal), the 19-A load current multiplied by 125 percent equals 24 A and satisfies 422.10(A) on the required minimum branch-circuit rating. The 25-A rating of the circuit overcurrent device also satisfies 422.11(E)

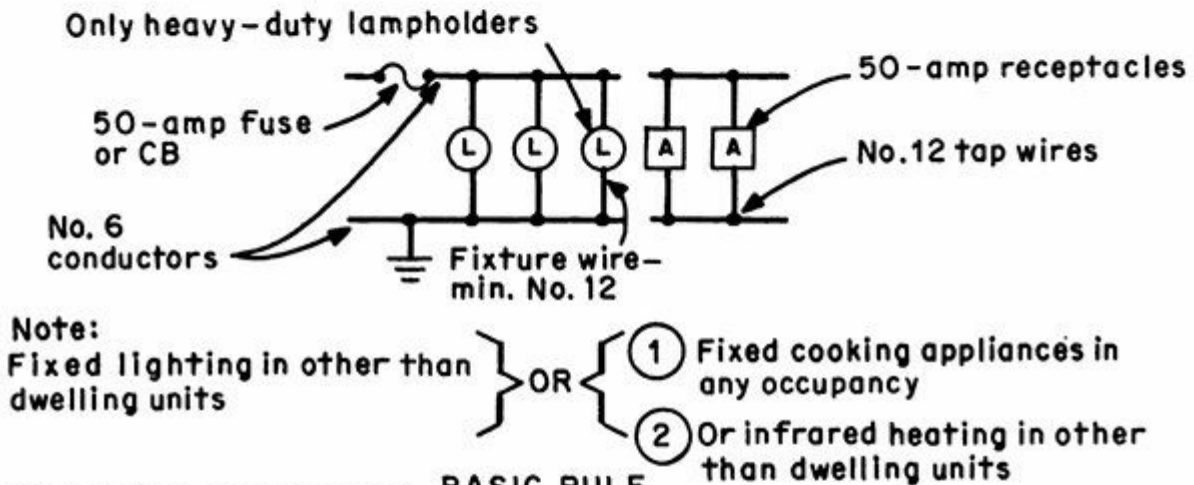

(3), which says that the overcurrent protection must not exceed 150 percent of the ampere rating of the water heater. Note that although the 25-A circuit is permitted in this case, a 30-A circuit is also permitted, and far more common. The 19-A load applied at 150 percent is just under 30 A, and the next-higher standard-sized protective device is permitted.

3. Branch circuits rated 40 and 50 A may serve fixed lighting units (with heavy-duty lampholders) or infrared heating units in other than dwelling units or cooking appliances in any occupancy (Fig. 210-34). It should be noted that a 40- or 50-A circuit may be used to supply any kind of load equipment—such as a dryer or a water heater—where the circuit is an individual circuit to a single appliance. The conditions shown in that figure apply only where more than one outlet is supplied by the circuit. Figure 210-35 shows the combination of loads.

Multioutlet 40-amp circuits

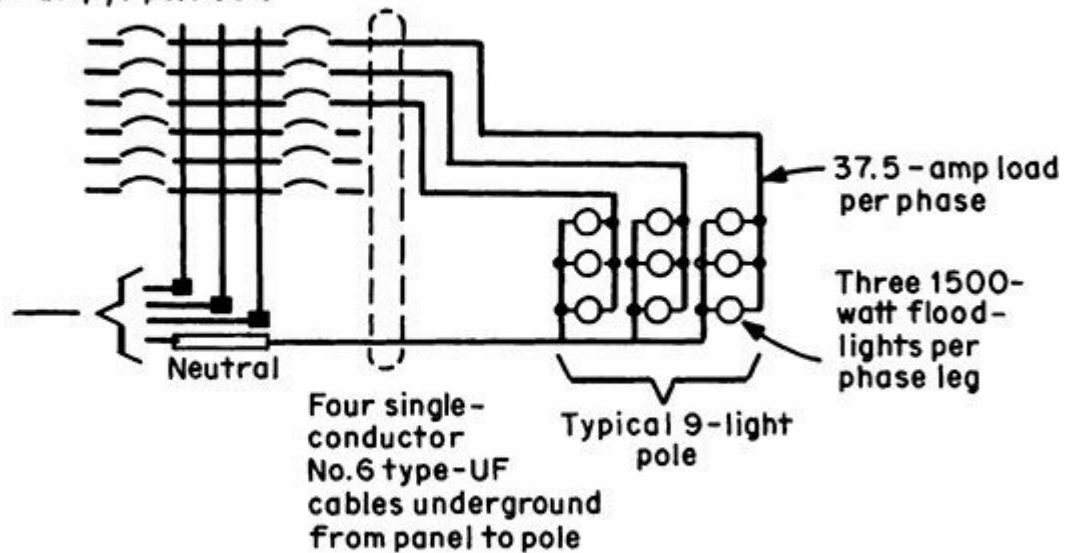

Multioutlet 50-amp circuits

Panel with 400-amp bus and all 50-amp, 1-pole CB's

BASIC RULE

TYPICAL EXAMPLE

50-amp, 3-phase, 4-wire circuits to supply incandescent floodlights on pole for lighting of a baseball field.

Fig. 210-34. Larger circuits. [Sec. 210.23(C).]

NOTE: Usually, all outlets on the circuit would supply the same type of load – i.e., all lamps or all cooking units, etc.

Fig. 210-35. Only specified loads may be used for multioutlet circuit. [Sec. 210.23(C).]

4. A multioutlet branch circuit rated over 50 A—as permitted by 210.18—is limited to use only for supplying industrial utilization equipment (machines, welders, etc.) and may not supply lighting outlets.

Except as permitted in 660.4 (and 517.71 for medical purposes) for portable, mobile, and transportable medical x-ray equipment, branch circuits having two or more outlets may supply only the loads specified in each of the preceding categories. It should be noted that any other circuit is not permitted to have more than one outlet and would be an individual branch circuit.

It should be noted that the requirement calling for heavy-duty-type lampholders for lighting units on 30-, 40-, and 50-A multioutlet branch circuits excludes the use of fluorescent lighting on these circuits because lampholders are not rated “heavy-duty” in accordance with 210.21(A) (Fig. 210-36). High-intensity discharge units with mogul lampholders may be used on these circuits provided tap conductor requirements are satisfied.

Fig. 210-36. Watch out for this limitation on fluorescent equipment. (Sec. 210.23.)

210.24. Branch-Circuit Requirements—Summary. Table 210.24 summarizes the requirements for the size of conductors where two or more outlets are supplied. The asterisk note also indicates that these ampacities are for copper conductors where derating is not required. Where more than three conductors are contained in a raceway or a cable, 310.15(B)(3)(a) specifies the load-current derating factors to apply for the number of conductors involved. A 20-A branch circuit is required to have conductors that have an ampacity of 20 A and also must have the overcurrent protection rated 20 A where the branch circuit supplies two or more outlets. Refer to the detailed discussion of conductor ampacity and load-current limits covered at Annex D, Example D3(a).

210.25. Branch Circuits in Buildings with More Than One Occupancy. The first part of this rule states that branch circuits within a dwelling unit may not supply loads in any other dwelling or its associated loads. This is a basic safety concern. In the past, there have been cases where the supply of loads in adjacent dwellings has resulted in injury and death where people mistakenly thought everything was electrically isolated when it was not. As a result, supply of any loads other than those “within that dwelling unit or loads associated only with that dwelling unit” has long been prohibited.

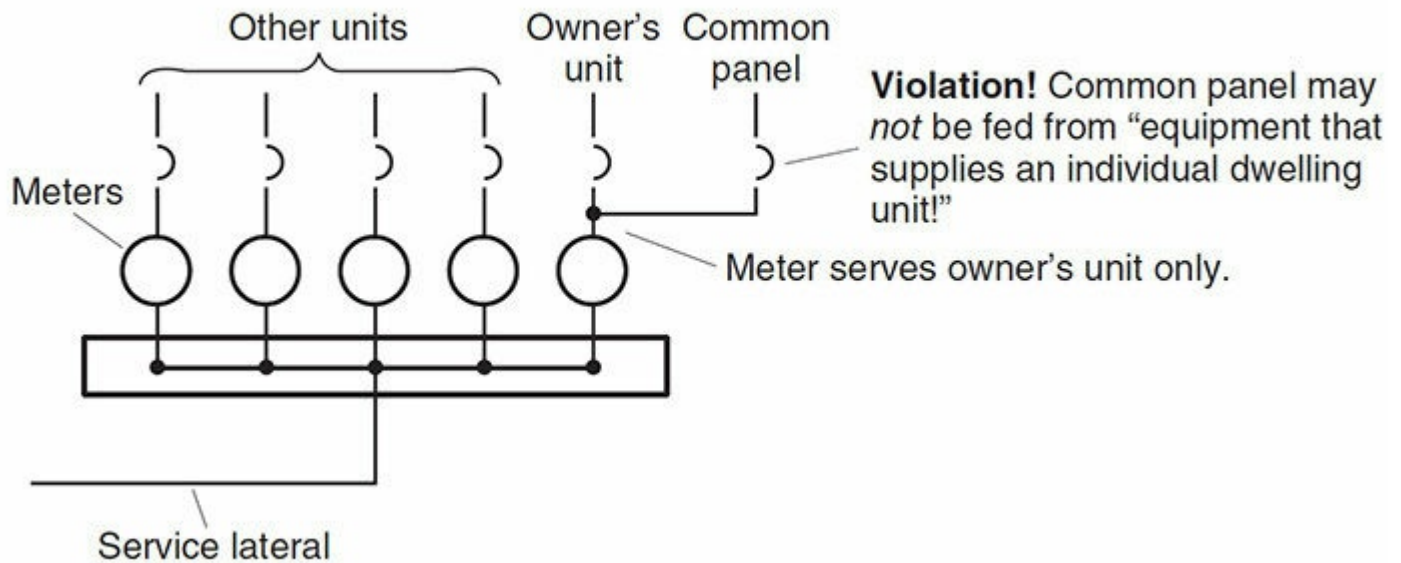

It should be noted that a common area panel is required in virtually every two-family and multifamily dwelling, and now, in multioccupant commercial buildings as well. The explosion of local ordinances regarding interconnected smoke detectors in such occupancies, as well as the growth of the so-called common area and the vast array of equipment that may be supplied in such an area, today, has assured us that a common area panel must be provided. Indeed, in some of the more expensive complexes, the common load may be equal to, or greater than, the combined load of all of the dwellings. Remember that loads such as lighting for the parking lot, landscape, hallways,

stairways, walkways, and entrance ways, as well as fountain pumps, sprinkler systems and so forth—in short, any common area load—must be supplied from this common area panel. At one time, and until the 2008 **NEC** for commercial occupancies, the landlord could reach an agreement with a tenant to trade-off rent for coverage of common-area electrical charges. Those days are over.

The second part [210.25(B)] addresses installation of the common area panel at two-family and multifamily dwellings, and multioccupancy commercial buildings. Basically stated, a separate panel to supply common area loads must be provided and it must be supplied directly from the service conductors, have its own meter, be suitable for use as service equipment, or be supplied from a disconnect that is, and so forth. That statement is based on the change in wording that now prohibits supplying the common area panel from “equipment that supplies an individual dwelling unit or tenant space.” Clearly, if a meter supplying any individual unit was also used to monitor usage on the common area panel, the literal wording of 210.25 would be violated because that “equipment” (the meter) supplies “an individual dwelling unit.”

The literal wording would also be satisfied if the whole building were on a single meter. In such a case, the common area panel would be supplied from “equipment” that supplies many dwellings or tenant spaces, not “an individual” unit. But, even then, the common area panel would have to be supplied directly from the single meter and satisfy other rules (e.g., be suitable as service equipment) as necessary. In no case may the common area panel be supplied from a panel in another dwelling or, as it now states, from any equipment that supplies a single unit ([Fig. 210-37](#)). Although supplying the entire building at the expense of the owner is still an option, with the escalating cost of energy such arrangements are almost unheard of in new construction.

Multifamily or multitenant occupancy

Multifamily or multitenant occupancy

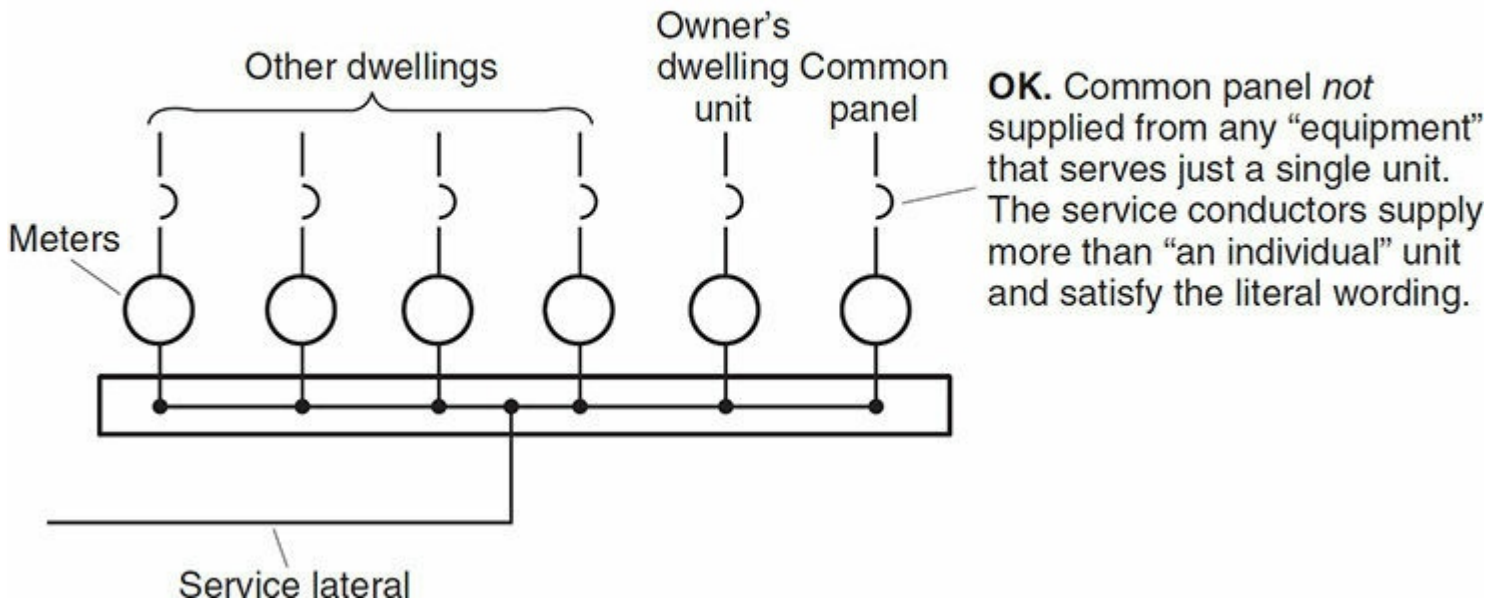

Fig. 210-37. Rewording of this rule has answered a number of questions regarding its application. The rule clearly prohibits the supply of the common area panel from any individual unit's "equipment." The term "equipment" is defined in Art. 100 and includes virtually every part of an electrical installation. As indicated by the literal wording, the common area panel must be supplied from a point in the system that serves more than a single unit. In the diagram, that would be the service lateral because beginning with the taps to the individual meters, the "equipment" is serving one unit. And the common area panel may not be supplied from such equipment.

210.50. General. Part (B) simply requires that wherever it is known that cord- and-plug-connected equipment is going to be used, receptacle outlets must be installed. That is a general rule that applies to any electrical system in any type of occupancy or premises. This rule is of critical importance in commercial occupancies, because there are no prescriptive requirements regarding receptacle placements in such locations, and abuses are very common. For example, a receptionist's station in an insurance office, located in the middle of the floor plan with at least 5 ft separating the

nearest part of the desk to any wall, and the usual desktop electrical equipment at least 7 ft from any wall, was wired from day one on extension cords with no floor receptacles at the station. The inspector could, and did use this rule to require power to be brought out to the location. Another example came up in a renovated college office building. On the rough inspection the inspector noted that in a 4.5-m (15-ft) square room there were only two receptacle outlets. The inspector pointed out that although there were no specific rules regarding receptacle placements in the room, if at any time he came back and found electrical equipment in a seemingly semipermanent location connected by extension cords, he would fail the work under this section. Perhaps, he suggested, with the walls still open the college might consider additional receptacles, and then duly documented the conversation. Additional receptacles were provided.

Part (C) applies to dwelling units and requires receptacles for specific appliances, such as a receptacle for a washing machine, be within 1.8 m (6 ft) of the appliance location. If possible, good design would result in a far closer placement.

210.52. Dwelling-Unit Receptacle Outlets. This section sets forth a whole list of rules requiring specific installations of receptacle outlets in all “dwelling units”—that is, one-family houses, apartments in apartment houses, and other places that conform to the definition of “dwelling unit.” As indicated, receptacle outlets on fixed spacing must be installed in every room of a dwelling unit except the bathroom. The Code rule lists the specific rooms that are covered by the rule requiring receptacles spaced no greater than 12 ft (3.7 m) apart in any continuous length of “wall space.”

What immediately follows is a list of locations that automatically disqualify a receptacle from being counted as satisfying one of the mandatory placement requirements that follow. Any receptacle that is an integral part of a lighting fixture or an appliance or in a cabinet may not be used to satisfy a placement requirement. For instance, a receptacle in a medicine cabinet or lighting fixture may not serve as the required bathroom receptacle. And a receptacle in a post light may not serve as the required outdoor receptacle for a one-family dwelling. Any receptacle located over 1.7 m (5½ ft) above the floor does not qualify, and any receptacle that is controlled by a wall switch in accordance with 210.70(A)(1) Exception No. 1 does not qualify either.

This last provision was new in the 2008 **NEC**. It is very common, and still permitted to use the allowance in 210.70(A) and leave a floor or table lamp plugged in to a receptacle controlled by a wall switch as the light in the room. Now, however, the receptacle used for this purpose does not qualify for the perimeter placement rules in 210.52(A). The simple way to address this is to split the hot side of a duplex receptacle so one half can be on all the time and the other half controlled by the switch ([Fig. 210-38](#)). This meets all **NEC** rules because 210.52(A) does not require two receptacles at each location, only one, although duplex receptacles are far more commonly used for obvious reasons. Be careful, however, about using this procedure if multiple circuits are involved, because the common disconnecting means requirements in 210.7 will apply. It is always permitted to install a quadruplex (double duplex) receptacle outlet, with the different circuits supplying different device yokes without any common-disconnect limitations.

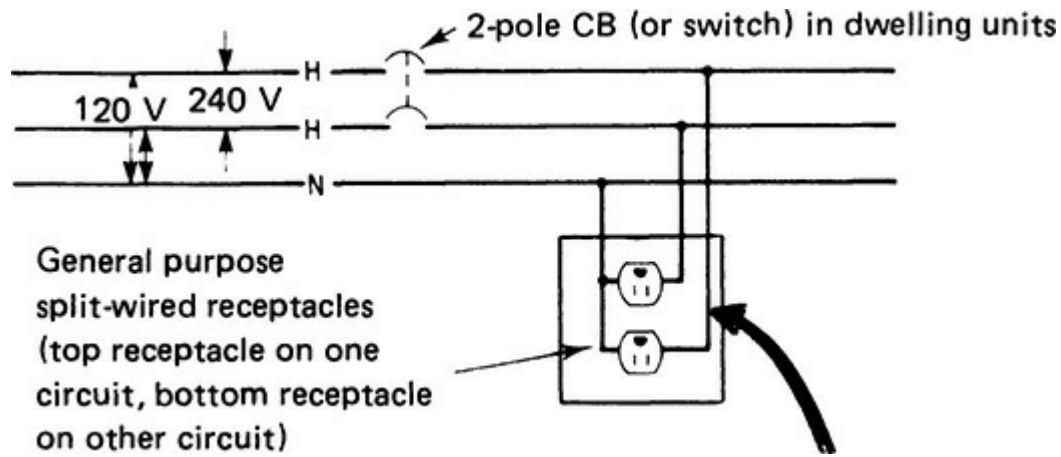

Fig. 210-38. Split-wiring of receptacles to control one of the receptacles may be done from the same hot leg of a 2-wire circuit or with separate hot legs of a 3-wire, 240/120-V circuit.

In part (A), the required receptacles must be spaced around the designated rooms and any “similar room or area of dwelling units.” The wording of this section ensures that receptacles are provided—the correct number with the indicated spacing—in those unidentified areas so commonly used today in residential architectural design, such as greatrooms and other big areas that combine living, dining, and/or recreation areas.

As shown in Fig. 210-39, general-purpose convenience receptacles, usually of the duplex type, must be laid out around the perimeters of living room, bedrooms, and all the other rooms. Spacing of receptacle outlets should be such that no point along the floor line of an unbroken wall is more than 6 ft (1.8 m) from a receptacle outlet. Care should be taken to provide receptacle outlets in smaller sections of wall space segregated by doors, fireplaces, bookcases, or windows.

Fig. 210-39. From any point along wall, at floor line, a receptacle must be not more than 6 ft away. Required receptacle spacing considers a fixed glass panel as wall space and a sliding panel as a doorway. [Sec. 210.52(A)(1) and (2).]

The 2011 **NEC** made two additions to the list in 210.52(A)(2)(1). First, “and similar openings” went in as catch-all wording. The other addition is more interesting and perhaps more far reaching than the panel anticipated. The list of spaces not considered as candidates for the perimeter receptacle spacing requirements now includes “fixed cabinets.” There are many rooms with extensive fixed cabinets that fully occupy multiple walls of the room. By the literal text of this new exclusion, it might be possible to supply such a room with only one or two receptacles, even though there will be obvious furniture placements in front of such cabinets. The 2017 **NEC** made a stab at fixing this, by modifying the cabinet exclusion so it only applied to cabinets without “countertops or similar work surfaces.” However, by not addressing the fundamental issue, the result can still be a library styled room with no requirements for receptacle outlets.

This provision came into the **NEC** in the context of the new 210.52(A)(4) that excludes receptacles serving the countertops (and similar work surfaces) specified in 210.52(C) from being counted as perimeter receptacles in 210.52(A). Without the fixed cabinet exclusion, it would be literally required to install, for an extended run of wall-mounted counters, both receptacles to serve the countertops, and additional receptacles, perhaps in the toe spaces, to meet the 6-ft rule in 210.52(A)(1). This would have been preposterous.

However, as written the “fixed cabinet” exclusion applies to any habitable room, not just the rooms covered by 210.52(C). As previously noted some rooms could lose most of their receptacles and end up with a plethora of extension cords, exactly opposite to the intent of this section generally. There are other problems as well. A wall cutout for a refrigerator now gets a receptacle because it now would be considered isolated wall space over 2 ft wide. It is no longer permissible to place the outlet for the appliance above the counter just to the side of the cutout, even though many owners appreciate the convenience of not pulling out a heavy appliance to unplug it. Even more absurd is the literal requirement to position a receptacle outlet in the cutout space for an electric range (in addition to the range receptacle if provided) because that too is now isolated wall space over 2 ft wide.

At one time, there were no prescriptive rules for countertop receptacle placements and the only rules that applied were the usual 6-ft and 2-ft provisions. When the 2-ft and 1-ft countertop rules entered the **NEC**, the counters became much more heavily populated with receptacles (and deservedly so), but the usual perimeter spacing rules for contiguous walls never failed to apply, until the 2011 **NEC**. Previously kitchens, etc., in the process of complying with 210.52(C), simply had many more receptacles than the minimum number required by 210.52(A), and that was fine. This will require considerable effort to correct in a subsequent code cycle. Until it is, expect considerable controversy regarding the apparently unintended consequences of these changes.

In determining the location of a receptacle outlet, the measurement is to be made along the floor line of the wall and is to continue around corners of the room, but is not to extend across doorways, archways, fireplaces, passageways, or other space unsuitable for having a flexible cord extended across it. The location of outlets for special appliances within 6 ft (1.8 m) of the appliance [Sec. 210.50(C)] does not affect the spacing of general-use convenience outlets but merely adds a requirement for special-use outlets.

Figure 210-40 shows two wall sections 9 ft and 3 ft wide extending from the same corner of the room. The receptacle shown located in the wider section of the wall will permit the plugging in of a lamp or appliance located within 6 ft (1.8 m) of either side of the receptacle.

Fig. 210-40. Location of the receptacle as shown will permit the plugging in of a lamp or appliance located 6 ft on either side of the receptacle. [Sec. 210.52(A).]

Receptacle outlets shall be provided for all wall space within the room except individual isolated sections that are less than 600 mm (2 ft) in width. For example, a wall space 23 in. wide and located between two doors would not need a receptacle outlet.

The Code-making panel receives proposals almost every code cycle to not count spaces behind a door swing, or in wider spaces than the 600 mm (2 ft) considered here, etc., and consistently rejects them. The panel is aware that often the rules will end up with receptacles in locations for which permanent furniture placements are unlikely, and still intends the rules to apply as written. The reason is to assure that at least some receptacle outlets will not be obstructed by furniture placements, and thereby be available for vacuum cleaner plugs and other transient uses.

In measuring receptacle spacing for exterior walls of rooms, the fixed section of a sliding glass door assembly is considered to be “wall space” and the sliding glass panel is considered to be a doorway. Many years ago the entire width of a sliding glass door assembly—both the fixed and movable panels—was required to be treated as wall space in laying out receptacles “so that no point along the floor line in any wall space is more than 1.8 m (6 ft)” from a receptacle outlet. The wording takes any fixed glass panel to be a continuation of the wall space adjoining it, but the sliding glass panel is taken to be the same as any other doorway (such as with hinged doors) (Fig. 210-39). Although this change was generally viewed as reducing the number of receptacles, this is not necessarily the case. If two sliding glass units are mullied together, the frequent result is an isolated glass panel roughly 900 mm (3 ft) wide. Since this glass panel is wall space, and since it is more than 600 mm (2 ft) wide, a receptacle outlet must be provided in this space. And since it is obviously impracticable to put a receptacle in a glass window, the only solution is a floor receptacle (see further).

Part (A)(2)(3) requires fixed room dividers and railings to be considered in spacing receptacles. This is illustrated by the sketch of Fig. 210-41. In effect, the two side faces of the room divider provide additional wall space, and a table lamp placed as shown would be more than 6 ft (1.8 m) from both receptacles “A” and “B.” Also, even though no place on the wall is more than 6 ft (1.8 m) from either “A” or “B,” a lamp or other appliance placed at a point such as “C” would be more than 6 ft (1.8 m) from “B” and out of reach from “A” because of the divider. This rule would ensure

placement of a receptacle in the wall on both sides of the divider or in the divider itself if its construction so permitted.

Fig. 210-41. Fixed room dividers must be counted as wall space requiring receptacles. [Sec. 210.52(A).]

Fig. 210-42. Fixed room dividers must be counted as wall space requiring receptacles. [Sec. 210.52(A).]

Note that nothing limits the usual 1.8-m (6-ft) rule from extending around the base of a fixed wall divider, as long as a cord doesn't traverse a walkway. For example, if "A" were 600 mm (2 ft) from the divider, and if the divider only projected 600 mm (2 ft), then "C" would still be considered to be covered by "A" because a 1.8-m (6-ft) cord run out and back along the divider and then over to "A" would not have to rely on an extension cord. Although the usual design preference is to put the receptacle in the room, there are construction difficulties that arise from time to time that make this approach worth considering.

Recessed or surface-mounted floor receptacles must be within 18 in. (450 mm) of the wall to qualify as one of the "required" receptacle outlets in a dwelling. The previous wording used in Sec. 210.52(A)(3) indicated floor-mounted receptacles were not considered to fulfill the requirement of 210.52(A) unless they were "located close to the wall." The use of a specific dimension, regardless of its arbitrary nature, is much more desirable than the relative term "close." The use of nonspecific, relative, and subjectively interpreted terms—such as "close" or "large"—opens the door for conflict and makes applying or enforcing a given rule much more difficult.

The use of either surface-mounted or recessed receptacle outlets has grown since "railings" were required to be counted as "wall space" by the 1993 Code. Now, where floor-mounted receptacle outlets are provided—either surface-mounted or recessed—to serve as a required receptacle outlet in a dwelling for any so-called wall space, such an outlet must be no more than 18 in. (450 mm) from the wall ([Fig. 210-42](#)).

Fig. 210-42. Any floor receptacle outlet that is intended to serve as one of the required outlets in a dwelling must be no more than 18 in. (450 mm) from the “wall space.”

Note that any railing, whether constructed to protect a stairway to a lower level or to form the edge of a balcony, is classified as wall space and subject to the placement rules as applicable. This requires evaluation in the field. For example, some balcony spaces are long and narrow with doorways opening along their long dimension. Generally such spaces are classified as hallways and need only one receptacle, assuming they are over 3 m (10 ft) long; and such a receptacle could be put in conventional wall space. In other cases balconies are, to all intents and purposes, the wall of a habitable room. In such cases, they will likely be used for furniture placements and the usual spacing rules will apply.

In spacing receptacle outlets so that no floor point along the wall space of the rooms designated by 210.52(A) is more than 6 ft (1.8 m) from a receptacle, a receptacle that is part of an appliance must not generally be counted as one of the required spaced receptacles. However, the second paragraph of 210.52 states that a receptacle that is “factory installed” in a “permanently installed electric baseboard heater” (not a portable heater) may be counted as one of the required spaced receptacles for the wall space occupied by the heater. Or a receptacle “provided as a separate assembly by the manufacturer” may also be counted as a required spaced receptacle. But, such receptacles must not be connected to the circuit that supplies the electric heater. Such a receptacle must be connected to another circuit.

Because of the increasing popularity of low-density electric baseboard heaters, their lengths are frequently so long (up to 14 ft) that required maximum spacing of receptacles places receptacles above heaters and produces the undesirable and dangerous condition where cord sets to lamps, radios, TVs, and the like will droop over the heater and might droop into the heated-air outlet. And UL rules prohibit use of receptacles above almost all electric baseboard heaters for that reason. Receptacles in heaters can afford the required spaced receptacle units without mounting any above heater units. They satisfy the UL concern and also the preceding note near the end of 210.52(A) that calls for the need to minimize the use of cords across doorways, fireplaces, and similar openings—and the heated-air outlet along a baseboard heater is such an opening that must be guarded (Fig. 210-43).

BUT WATCH THIS!

Separate circuiting required for heater and receptacle.

Fig. 210-43. Receptacles in baseboard heaters may serve as “required” receptacles. [Sec. 210.52(A).]

An informational note at the end of 210.52 points out that the UL instructions for baseboard heaters (marked on the heater) may prohibit the use of receptacles above the heater because cords plugged into the receptacle are exposed to heat damage if they drape into the convection channel of the heater and contact the energized heating element. The insulation can melt, causing the cord to fail.

A rewrite of 210.52(B) serves to clarify application and prohibits one longtime practice. Part **(B)(1)** of this section requires two, or more, 20-A branch circuits to supply all receptacle outlets required by 210.52(A) and (C) in the kitchen, and so forth. And part **(B)(2)** states that no other outlets may be supplied from those small appliance branch circuits. Those two requirements had both been contained in part **(B)(1)** of the 1993 and previous Codes. However, because the two rules were combined in a single paragraph, it was not always easy to determine to which part a given exception applied.

The basic rule of 210.52(B)(1) states that those receptacles required every 12 ft [Sec. 210.52(A)], those that serve countertop space [210.52(C)], and the refrigerator receptacle in the kitchen, dining room, pantry, and so forth, must be supplied by one of the two, or more, 20-A small appliance branch

circuits.

The wording used here must be carefully examined. Because the wording only specifically permits the refrigerator receptacle and those receptacles required by 210.52(A) and (C) on the small appliance branch circuits, the installation of any other receptacles on the small appliance branch circuits is effectively prohibited. Any receptacle installed for specific equipment, such as dishwashers, garbage disposals, and trash compactors—which are *not* required by part (A) or (C)—must be supplied from a different 15- or 20-A branch circuit, which could be a multioutlet general-purpose branch circuit if the load meets the 50 percent test in 210.23(A).

The exceptions to part (B)(1) are exceptions to the rule that *all required* receptacle outlets must be supplied from the two, or more, 20-A branch circuits. The first exception recognizes the use of a switched receptacle supplied from a general-purpose branch circuit where such a receptacle is provided instead of a lighting outlet in accordance with Exception No. 1 to 210.70(A). That rule specifically excludes kitchens from employing a switched receptacle instead of a lighting outlet, but, in those other rooms and areas identified in 210.52(B)(1), particularly dining rooms, a wall-switched receptacle outlet supplied from a general-purpose branch circuit is permitted and should count as a required receptacle (Fig. 210-44).

Fig. 210-44. For those rooms and areas identified by Sec. 210.52.(B)(1), other than the kitchen, a wall-switch-controlled receptacle may be supplied from a general-purpose branch circuit and serve as one of the required receptacles. In the drawing, both halves must be switched, and as depicted, the receptacle does not qualify as meeting the normal 210.52(A) placement rules for this location.

Be very careful, however, about attempting to split a duplex receptacle to do this. Since the entire yoke must be disconnectable in a single motion at the panel, the lighting circuit and the small-appliance branch circuit must have a common disconnect. This may or may not be feasible. If not, and the owner insists on wall switch control of floor or table lighting in the room, a two-gang opening must be provided, with one yoke connected to a small-appliance branch circuit, and the other to the local lighting circuit. Note also that no “always on” receptacle can be connected to a lighting circuit

in this room, so either the switched side is a single receptacle, or it could be a duplex with both halves switched.

In 210.52(B)(1), Exception No. 2, the Code recognizes the supply of the required receptacle for a specific appliance (broadened in the 2017 cycle from the prior limitation to refrigerators) from an individual 15-A branch circuit. Many refrigerators and other specific appliances installed in dwellings are rated at 12 A or less, often far less, and could be supplied from a 15-A circuit. Rather than mandate the use of a 20-A-rated circuit for those cases where a 15-A circuit is adequate, it is permissible to use a 15-A-rated circuit, provided the supply to the refrigerator (or comparable) receptacle is a dedicated branch circuit—that is, *no* other outlets supplied. Remember that in this case the 15-A receptacle must be a single receptacle.

It should be noted that it is no longer permissible to supply an outdoor receptacle from the small appliance branch circuit. This was recognized years ago in 210.52(B)(1), Exception No. 2, and served to limit the number of GFCIs needed at a dwelling. That is, because grade-level-accessible outdoor receptacles were required to have GFCI protection, the Code permitted supplying the outdoor receptacle using the feed-through capability of the GFCIs installed in the kitchen rather than require an additional GFCI device, which provided for economy. Now, however, supplying an outdoor receptacle from the small appliance branch circuit is prohibited (Fig. 210-45).

Fig. 210-45. Summary of Sec. 210.52(B)(1) and its two exceptions. As indicated, supply of an outdoor receptacle from any of the two, or more, 20-A small appliance branch circuits is prohibited. The switched receptacle cannot be used to meet spacing requirements, and a 15-A refrigerator circuit, if used (and not shown in this drawing), must be an individual branch circuit.

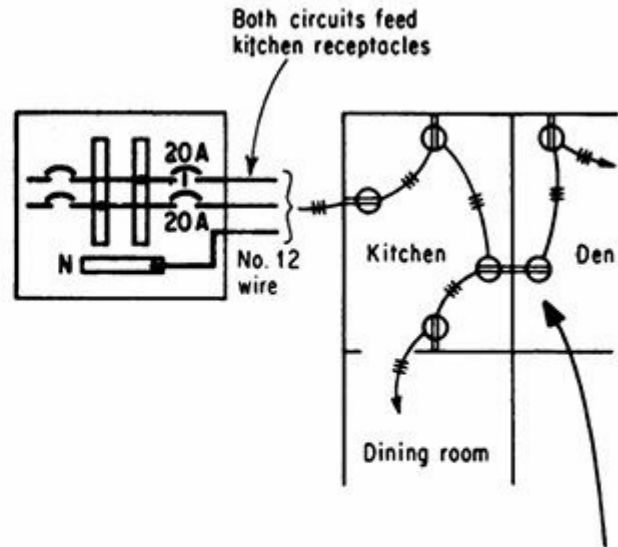

210.52(B)(2) states that only those outlets identified in part (B)(1)—and no other outlets—may be installed on the two, or more, small appliance branch circuits. Outlets for lighting and hard-wired

appliances, as well as “unrequired” receptacles for equipment, must be installed on 15- or 20-A general-purpose circuits.

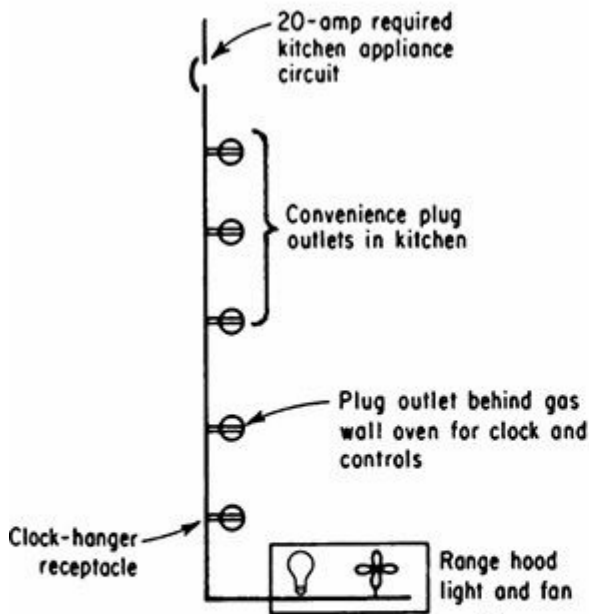

The first exception to 210.52(B)(2) allows a clock hanger receptacle to be installed on a small appliance branch circuit, or it may be supplied from a general-purpose circuit. The second recognizes a receptacle provided for control power or clock, fan, or light in a gas-fired cooking unit. Note that only a *receptacle* outlet is permitted. Any hard-wired connection for such auxiliary functions on a gas-fired unit must be supplied from a general-purpose branch circuit and *not* from the small appliance branch circuits (Fig 210-46).

VIOLATION—Circuit for kitchen, dining room, etc., may not serve laundry

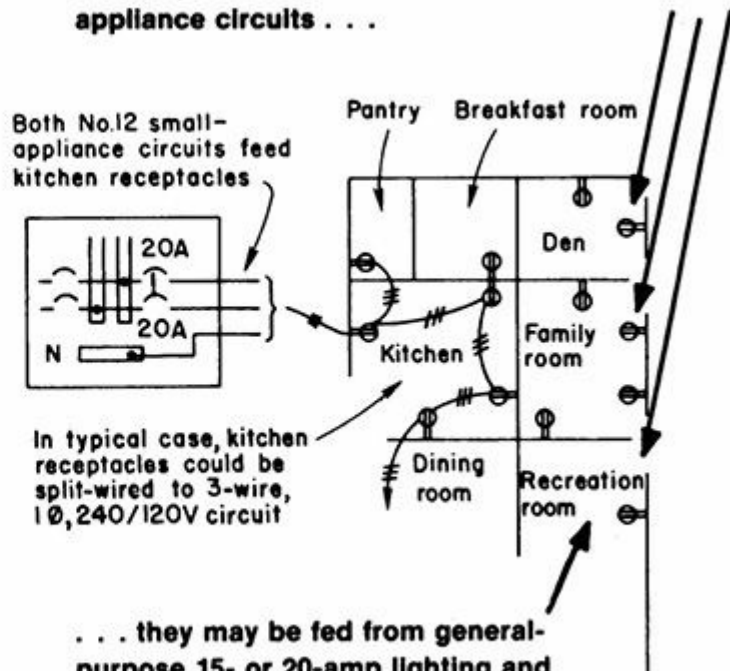

VIOLATION—Small-appliance circuits may not have any outlets in other than designated rooms

VIOLATION—Small-appliance circuit must supply only receptacle outlets and not other loads

All receptacles in these rooms must be spaced in accordance with 210.52(A)—i.e., 12 ft apart—but they MAY NOT be fed by 20-amp small appliance circuits . . .

In typical case, kitchen receptacles could be split-wired to 3-wire, 1Ø, 240/120V circuit

. . . they may be fed from general-purpose 15- or 20-amp lighting and appliance circuits.

Fig. 210-46. A summary of Sec. 210-52(B)(2) and its two exceptions. A clock-hanger receptacle and/or a receptacle for the supply of auxiliary equipment on a gas-fired range, oven, or cooktop may also be supplied from the two, or more, small appliance branch circuits.

The rule of 210.52(B)(3) places a limit on the number of “kitchens” that a small appliance branch circuit may serve. Any given 20-A small appliance branch circuit may supply only a single kitchen. Given the reality that some dwellings are equipped with more than one kitchen, this rule will ensure that adequate capacity is available for countertop receptacles in *both* kitchens. Note that it is still permissible to supply a kitchen and, say, a dining room, or any other rooms or “similar areas,” from a given 20-A small appliance branch circuit. Although this is not desirable, *all* rooms identified in part **(B)(1)** may be supplied from such a circuit.

Section 210.52(C) presents requirements and restrictions regarding installation of countertop receptacles in kitchens and dining rooms. The 2017 **NEC** has extended this concept to add “and Work Surfaces.” This includes the other permanent surfaces now commonly added in kitchens, such as built-in desks for computer work, paying bills.

This section is broken into five subparts—**(C)(1)** through **(5)**. The first four subparts identify those counter spaces in the kitchen and dining room that must be provided with receptacle outlets and indicate the number required, while the last subpart, **(C)(5)**, indicates where the receptacle outlet must be installed.

In part **(C)(1)**, the **NEC** puts forth the spacing requirements for receptacle outlets installed at counter spaces along the wall. Basically stated, each wall counter space that is 12 in. (300 mm) or wider must have at least one receptacle outlet to supply cord-and-plug-connected loads. The receptacles must be placed so that no point along the wall line is more than 24 in. (600 mm) from an outlet. That translates into one outlet every 4 ft. It should be noted that the term “measured horizontally” is intended to recognize application, as shown in [Fig. 210-47](#). The wording is supposed to indicate that there is no need to measure “around the corner” in that case. But, watch out! Some inspectors believe that such application is in violation. In doing so, they are applying the same logic that measures the dimensions of two walls meeting at a corner per 210.52(A)(1) in this manner, and the wording of the two provisions is parallel (“along the floor line” and “along the wall line”). Check with your local electrical inspector to verify acceptability. In spite of numerous attempts to get this language clarified, the Code-making panel has yet to do so.

Any point along the wall line of each length of countertop must *not* be over 24 in., measured horizontally, from a receptacle outlet.

Fig. 210-47. The term “measured horizontally” can essentially be translated as “when you are facing the counter.” There is no need to measure around the corner here because that would effectively measure the area twice. However, this is far from clear. Many inspectors apply the same principles that apply to wall placements, and therefore measure the entire unbroken wall line. Repeated efforts to clarify this have failed.

The exception to 210.52(C)(1) eliminates the need for receptacles where the countertop wall space is behind a range or sink. Where the dimensions are equal to or less than those shown in [Fig. 210-48](#), a receptacle outlet is not required. Note, however, that for the majority of corner applications where the sink or range is on the diagonal, the distance to the corner will exceed 450 mm (18 in.) and qualify for a receptacle in that space. The 450-mm (18-in.) dimension is the altitude of an isosceles triangle whose base is 900 mm (36 in.) and many sinks or ranges will at least equal that width. If this is the case, great care and foresight may be required to avoid major construction problems. Such locations often involve window placements or other difficulties that must be carefully anticipated. Further, the decision to count such spaces in the placement rules is appropriate. The space behind such a sink, for example, works well for a number of appliances, including electric teakettles, that must be routinely refilled with water.

Sink or range extending from face of counter

Sink or range mounted in corner

Fig. 210-48. This diagram—Fig. 210.52 in the **NEC**—provides guidance for countertop receptacles located behind sinks and range tops.

As given in subpart **(C)(2)** and **(C)(3)**, each freestanding (island) countertop that measures 24 in. (600 mm) or more by 12 in. (300 mm) or more must be provided with one receptacle outlet. The same dimensions apply to peninsular countertops, which are countertops that extend from another counter

or a wall.

The dimensions are to be measured, as of the 2017 **NEC**, from the “connected perpendicular wall.” Prior editions back to the 1993 edition measured from the “connecting edge.” Because the orientation of the long dimension was unspecified, that wording meant that even a 1-ft peninsula (assuming standard 25-inch counter stock) needed its own receptacle. This often resulted in ferocious resistance on the part of owners who did not want to see their decorative peninsula ends molested by receptacles.

Island and peninsula receptacles often involve significant construction issues. Not all peninsulas have base cabinets underneath them. Many are in effect a permanently attached kitchen table, with not much more than a table leg to support the open end and bar stools arranged around the three open sides. Electrical contractors have been forced to literally glue a length of surface metal raceway and box to their underside in order to comply with these rules. If a range or sink creates two peninsulas out of one (see discussion at (C)(4) below), it is very likely that at least one of the two peninsulas or islands resulting from the partition will present construction difficulties.

As shown in [Fig. 210-49](#), a creative alternative that involved redefining the peninsula often avoided these construction difficulties and pleased the owners. If the wall-mounted receptacle were within the horizontal extent of the peninsula dimension, then that receptacle became the peninsular countertop receptacle. The 2017 **NEC**, by defining the measurement point as the perpendicular connecting wall, has effectively provided that the heretofore alternative approach is now the correct approach. If a rule says to measure the size of something, and it also says where to begin your measurement, then it follows that where you start your measurement is necessarily where the measured object starts.

Fig. 210-49. The 2017 **NEC** no longer measures a peninsula from a “connecting edge” (1993–2014 **NEC**); now it is measured from the “connected perpendicular wall.” The receptacle within the wall space of its extension to the wall therefore serves the peninsula and satisfies 210.52(C)(3).

The **NEC** did not formerly cover, with any clarity, another related problem, namely, how long can a peninsula or island get before more than one receptacle is required. There was an answer to this, but it also involved interpretation, in this case as to whether 210.52(C) supersedes 210.52(A), or merely augments 210.52(A) and both rules continue to apply. The plethora of receptacles required on a wall-mounted counter clearly meets the required 210.52(A) placements many times over, but what about peninsulas and islands?

A kitchen island or peninsula clearly and permanently divides the room, and as we have seen, a fixed room divider in the form of “a free-standing bar-type counter” invokes conventional placement requirements, as per 210.52(A)(2)(3). On this basis, it was not unreasonable to require an additional

receptacle on an island or peninsula that is over 1.8 m (6 ft long). And, in conjunction with the interpretation offered as to how to place the connecting edge of a peninsula and thereby measure its length, that would be the cut point on how far out a peninsula could extend (or an island could be long) before an additional receptacle would be required. However, the new text of 210.52(A)(4) makes this approach obsolete. In perhaps another unintended consequence of the new rule, an island or peninsula can now be of indefinite length; since 210.52(A) cannot be applied to them, the only remaining rule is 210.52(C)(2) or (3) as applicable, namely, no fewer than one receptacle for either.

Subpart (C)(4) covers the longtime rule regarding pieces of countertops that are separated by cooktops, sinks, and so forth. As indicated, each such piece must be treated as an individual counter. And, if the dimensions are as described in parts (C)(1), (C)(2), or (C)(3), as applicable, of this section, at least one receptacle outlet must be provided. The concluding language makes it clear that if a range, counter-mounted cooktop or sink has less than 300 mm (12 in.) of space behind it, the counter is considered continuous and the rules will apply to each side independently. For example, if a range is located in a peninsula, the outer end of the peninsula, for code purposes, is now an island. The inner end of the peninsula is now, for code purposes, a short peninsula. In both instances, the applicable rules must be applied independently to each segment in order to determine whether one or more receptacles are required in that segment.

The requirements given in 210.52(C)(5) mandate where the required receptacle outlets may be installed. That is, a given receptacle outlet may not be counted as one of the required outlets unless it is installed on top of, but not more than 500 mm (20 in.) above, the counter it is intended to serve, and note that no receptacle may be installed face-up in a countertop per 406.5(G). That is a “make sense” proposition inasmuch as a receptacle installed face-up would eventually become a “drain” for soup, milk, water, or whatever else is eventually spilled on the counter. Only the so-called tombstone or doghouse enclosures would be acceptable for surface mounting. However, there are now pop-up receptacles designed for countertop use that withdraw into the countertop when not in use, and when withdrawn, only show a small, almost flat metal circle. This is not a face-up mounting and as of the 2011 edition, the **NEC** now expressly recognizes these constructions. Although not entirely clear, it is assumed that the 20 in. must be measured from the counter surface, *not* the top of the backsplash. In addition, and in correlation with 210.52(3), a receptacle mounted inside an appliance garage, or otherwise not readily accessible due to the placement of a sink, range top, or other appliance fastened in place, does not qualify as providing the required countertop coverage.

Note that the basic rule generally requires the outlet to be mounted above, or on top of, the counter. The basic rule does *not* recognize installation of an outlet *below* the counter space. However, where the counter does not extend more than 6 in. (150 mm) beyond “its support base,” the exception to 210.52(C)(5) permits installation of a receptacle outlet below, but not more than 300 mm (12 in.) below the counter. And where the outer edge of the countertop *does* extend more than 6 in. beyond its support base, any “below-the-countertop” receptacles must be installed so that the receptacle, itself, is not more than 6 in. from the outer edge. That would necessitate the use of either a surface-mounted receptacle or plug-mold type of receptacle to ensure that when measuring from the face of the receptacle or edge of the plug mold, the distance to the outer edge of the countertop overhang is not more than 6 in.

Note that the allowance for a receptacle mounted below the countertop only applies to island and peninsular counters, and even on those counters the exception will not apply unless the counter is flat. If there are two levels to the counter for any reason, then the receptacle has to be placed in the

vertical rise between the two levels. Further, if there are suspended upper cabinets over the island or peninsula such that a receptacle could be mounted so as to be not more than 500 mm (20 in.) above the counter, then that opportunity must be used, and a placement on the side of a base cabinet is not allowed.

The **NEC** is trying to minimize instances where the exception will be used in order to lessen the opportunities for toddlers to pull over dangerous appliances that could severely injure them by spilling hot liquid on their heads or otherwise. On the other hand, the **NEC** also recognizes that a flat island or peninsula is like someone's kitchen table, and a mandatory tombstone outlet is a nonstarter in the mind of the public. The result is a reasonable compromise that minimizes the instances of base-mounted receptacles; ultimately the parents are responsible for policing how they connect kitchen appliances when toddlers are in the house. The other exception allows receptacles below a counter, whether for an island or otherwise, in construction for the physically disabled. The usual procedure here is to mount surface metal raceway with receptacles under the counter lip where someone in a wheel chair can reach it easily ([Fig. 210-50](#)).

Inaccessible receptacles.

This receptacle is rendered inaccessible by refrigerator...

...therefore another receptacle must be installed to serve countertop.

Receptacle located behind an appliance, making the receptacle inaccessible, does not count as one of the required “countertop” receptacles.

Fig. 210-50. This section indicates where required outlets intended to serve counter space in dwellings must be installed. Remember that below-the-counter mounting is only permitted on a flat island or peninsula, and where the overhang does not exceed 150 mm (6 in.).

Part **(D)** requires the installation of at least one receptacle outlet adjacent to and within 3 ft of each washbasin location in bathrooms of dwelling units—and 210.60 requires the same receptacle in bathrooms of hotel and motel guest rooms and suites. This receptacle may be mounted in an adjacent wall, or partition, or within the side or face of the vanity not more than 12 in. below the vanity’s countertop. The Code requires a dedicated circuit for bathroom receptacles installed in dwellings. In every bathroom, at least one receptacle outlet must be installed at each basin and any such outlet(s) must be supplied from the dedicated 20-A branch circuit ([Fig. 210-51](#)), as required by 210.11(C)(3).

If a bathroom has two basins, two receptacles will usually be required unless the basins are small and very close together, or unless a receptacle is mounted between the basins, perhaps horizontally in a backsplash. And yes, receptacle outlets have been successfully installed in, yes in, bathroom mirrors, but a receptacle on each side is usually more cost effective. The **NEC** also recognizes the same pop-up style receptacles for mounting in bathroom countertops to comply with these requirements as it does for kitchen countertops in 210.52(C)(5).

210.52(D). Receptacle outlets installed in bathrooms in dwellings must be supplied from dedicated—no other outlets—20-A branch circuit . . . unless the circuit supplies only one bathroom.

LOCATION of receptacle will vary, depending upon available wall space. Arrows show several possibilities. A receptacle in a medicine cabinet or in the bathroom lighting fixture does not satisfy this rule. The receptacle must also be located not more than 36 in. from the edge of the sink. It should be noted that mounting on an adjacent wall or partition is clearly permitted.

Fig. 210-51. A dedicated 20-A branch circuit must be provided to supply required receptacle outlets installed “adjacent” to bathroom sinks, as well as any other receptacle outlets installed in the bathroom. The outlet installed below the counter space here is now clearly acceptable, provided it is not more than 300 mm (12 in.) below the basin countertop. The 2014 **NEC** clarified that this vertical distance limitation applied whether the receptacle was wired in the basin cabinet or on an adjacent

wall.

Part (E) requires that at least one outdoor receptacle “readily accessible from grade” and not more than 6 ft 6 in. (2.0 m) above grade” must be installed at the front and back for every one-family house (“a one-family dwelling”) and grade-level accessible unit in a two-family dwelling. Receptacles on decks and porches now are eligible to count among the required outdoor receptacles provided they are within the prescribed height limitation and can be reached easily from grade, such as through permanent stairs. And note that there will be a receptacle outlet on that deck or porch. Why? Because the **NEC** now requires that every deck, balcony, and porch that is accessible from within any dwelling unit (whether one, two, or multifamily construction) (and attached thereto) have a receptacle outlet for the outdoor space, located not over 2.0 m (6½ ft) above the walking surface, and accessible from that outdoor space. This wording is less restrictive in the 2014 **NEC**, having formerly been required to be within the actual perimeter of the space. The exception for small porches and balconies in the 2008 Code has not returned. Any balcony or porch, no matter how small, is viewed as a likely candidate for seasonal lighting if nothing else, and therefore will require a receptacle outlet.

Part (E) also requires that townhouse-type multifamily dwellings be provided with at least one GFCI-protected outdoor receptacle outlet not over 2.0 m (6½ ft) above grade. The front-and-back provision does not apply to multifamily construction, but the outdoor porch, deck, and balcony provisions do apply. Thus, for multifamily housing only one outdoor receptacle is required, and located at either the front or the back, and anywhere accessible from grade, such as up some porch steps. The distinction between multifamily housing and single- or two-family construction is not obvious because it relies on construction details that must be reviewed, preferably with the local building official. Specifically, it must be determined whether the separations between occupancies are fire separation walls of specified hourly ratings, or true fire walls that are made of masonry or concrete, run from grade to roof line or above, and that will survive a conflagration on one side.

Fire walls define buildings per Art. 100, so much depends on this evaluation. Due to their expense, most fire separations are not fire walls but rather other fire-resistant construction that has enough of an hourly rating to allow the occupants to escape in an orderly way, as defined by the local building code. In some cases, a building will have both for other reasons. For example, there are many examples of structures with eight dwelling units as depicted in [Fig. 210-52](#) that have a fire wall down the middle, creating two four-family dwellings. This has been done at various times to avoid expensive fire alarm systems and sprinklers that would otherwise have been required at the time if the structure had qualified as a single building. Most electrical inspectors will defer to the judgment of the local building official as to how the local building code classifies the nature of an occupancy separation.

Fig. 210-52. Front and rear-receptacle outlets are required outdoors for town-house-type structures as shown, but only if true fire walls divide the structure into multiple single- or two-family dwellings. With mere fire separation walls and not true fire walls, this is multifamily housing and only one outdoor receptacle per unit is required. [Sec. 210.52(E).]

Part (F) requires that at least one receptacle—single or duplex or triplex—must be installed for the laundry area of a dwelling unit. Such a receptacle and any other receptacles for special appliances must be placed within 6 ft (1.8 m) of the intended location of the appliance. Exceptions apply for multifamily housing where central laundry facilities are provided on site for the occupants, or in other than one-family dwellings in instances where on-site laundry facilities are not to be installed. And part (G) requires a receptacle outlet in a basement in addition to any receptacle outlet(s) that may be provided as the required receptacle(s) to serve a laundry area or other designated equipment such as a whole-house vacuum system in the basement. One receptacle in the basement at the laundry area located there may *not* serve as *both* the required “laundry” receptacle and the required “basement” receptacle. A separate receptacle has to be provided for each requirement to satisfy the Code rules.

210.52(G) requires that at least one receptacle outlet be provided in each portion of the basement that is “unfinished” in a one- or a two-family house, in addition to any required for a basement laundry or other dedicated use (Fig. 210-53). In other words, if a finished section of a basement results in two noncontiguous unfinished sections in different parts of a basement, then both of those unfinished sections must have a receptacle installed on a general-purpose branch circuit. It calls for at least one receptacle in an attached garage of a one- or two-family house. But for a detached garage, the rule simply requires that one receptacle outlet must be installed in the detached garage *if*—for

some reason other than the **NEC**—electric power is run to the garage, such as where the owner might desire it or some local code might require it (Fig. 210-54). The rule itself does not require that electric power be run to a detached garage to supply a receptacle there. Effective with the 2011 **NEC**, the same rule also applies to detached accessory buildings.

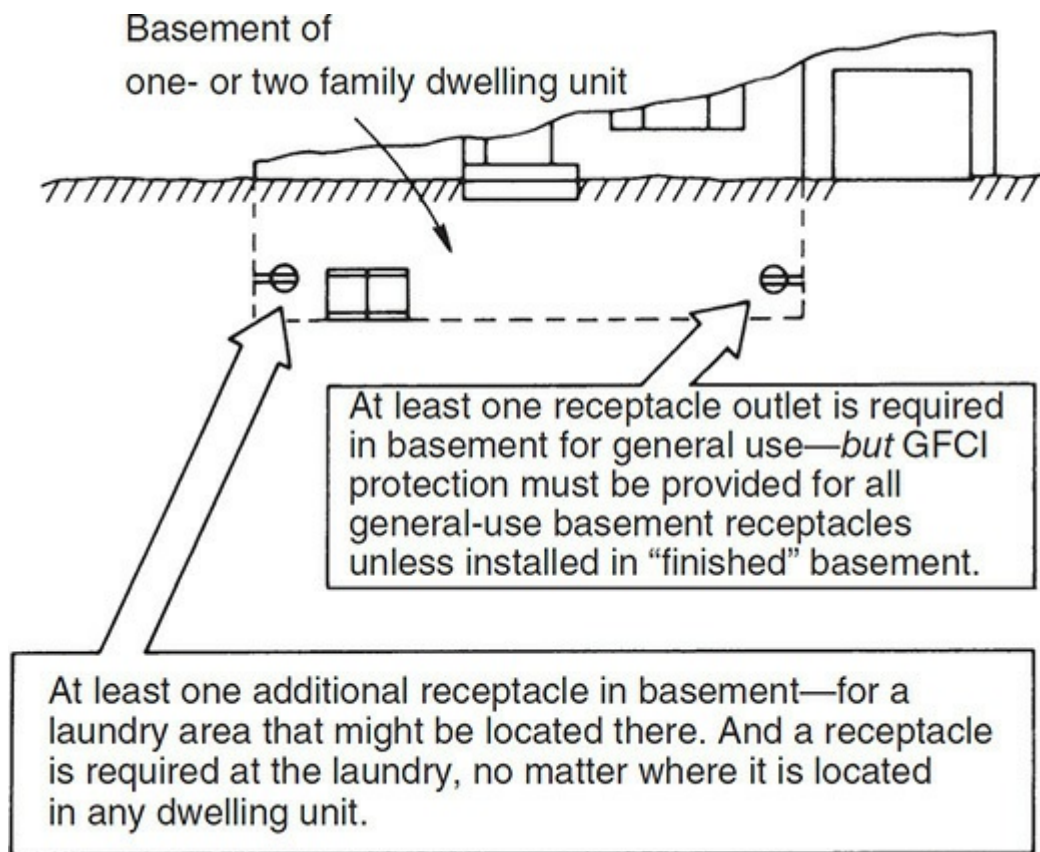

Fig. 210-53. Only one basement receptacle is required (in addition to any for the laundry), but *all* general-purpose receptacles in *unfinished* basements must be GFCI protected. As of the 2017 **NEC**, this rule also applies to two-family houses. [Sec. 210.52(G).]

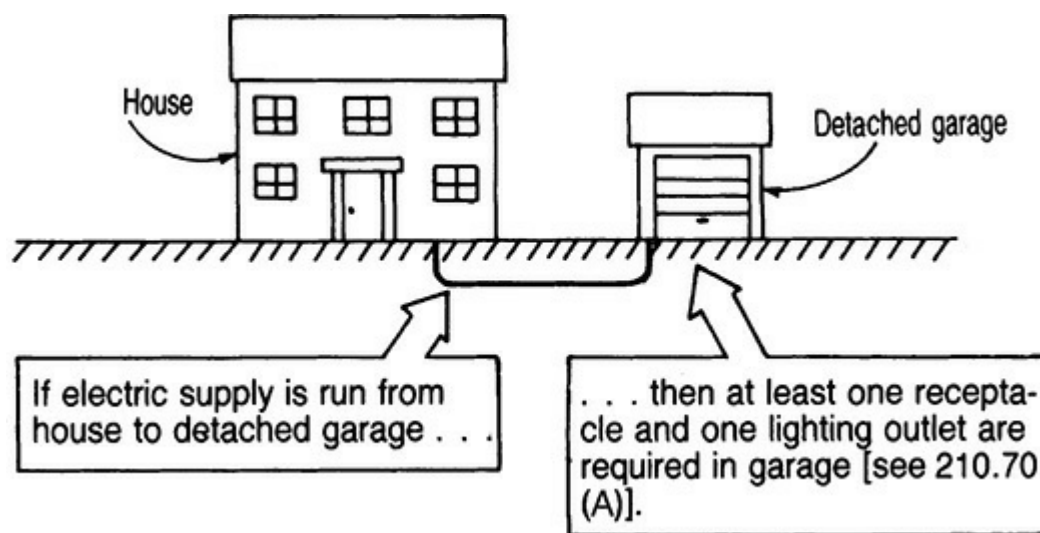

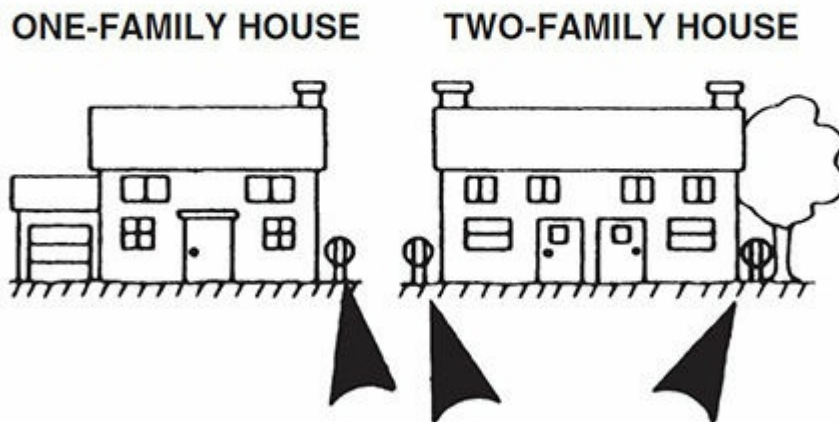

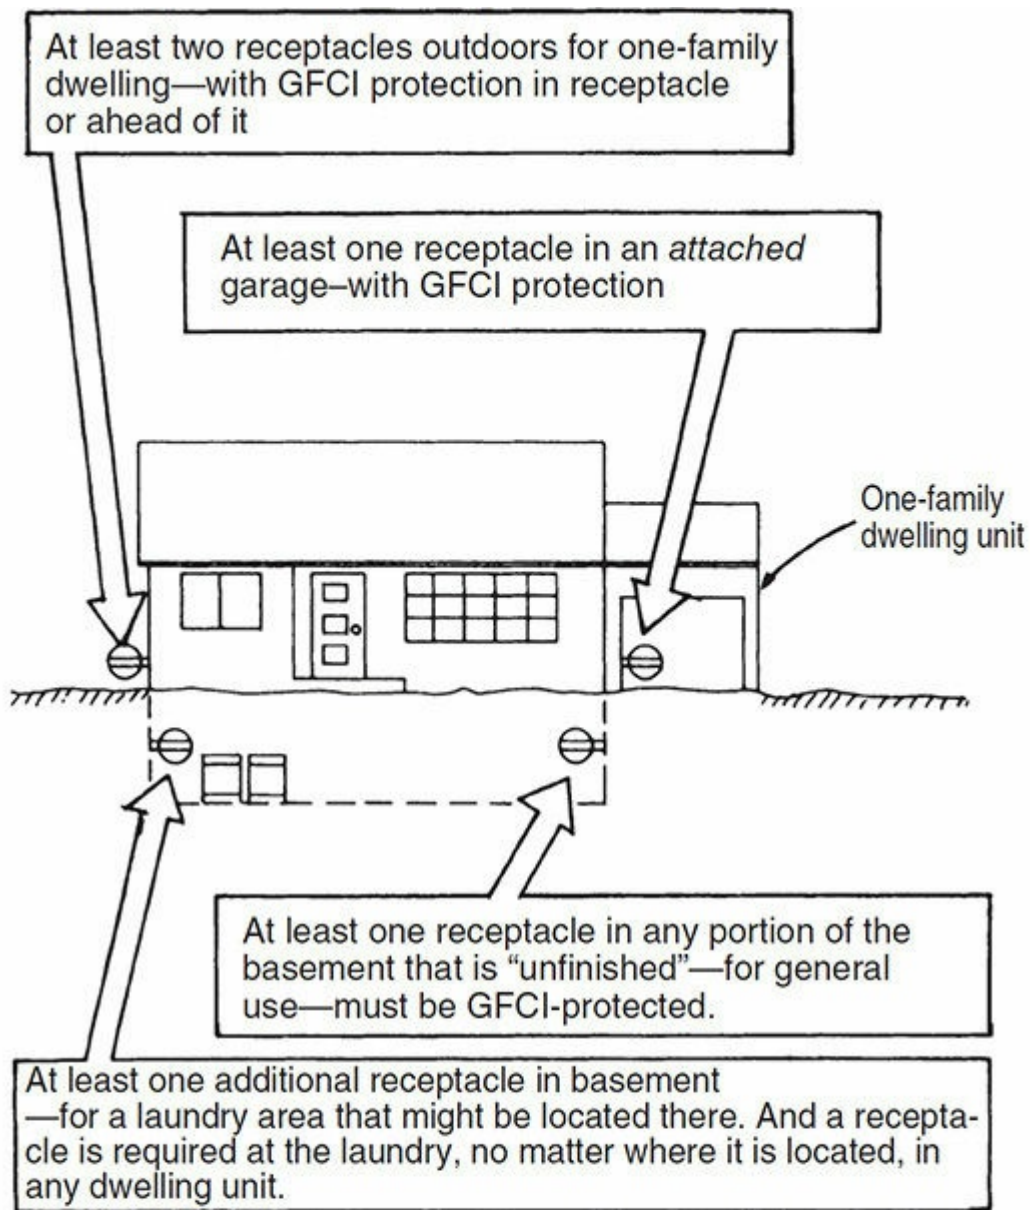

Fig. 210-54. Detached garage may be required to have a receptacle and lighting outlet. [Sec. 210.52(G).]

The 2014 **NEC** required a receptacle outlet for each vehicle space, but did not specify a location.

The 2017 **NEC** has closed this loophole by requiring placement “in each vehicle bay” and not over 5½ ft above the floor, matching the height limit in 210.52(4). As now covered in 210.11(C)(4), at least one circuit must be dedicated to these outlets (with an outdoor receptacle also permitted). [Figure 210-55](#) shows some of the required receptacles.

At least two receptacles must be installed outdoors—one at the front and one at the back—for a one-family dwelling and for each dwelling unit of a two-family dwelling at grade level—with GFCI protection in or ahead of each receptacle.

Fig. 210-55. These specific receptacles are required for dwelling occupancies. [Sec. 210.52(E), (F), and (G).]

In part **(H)**, a receptacle outlet is required in any dwelling-unit hallway that is 10 ft (3.0 m) or more in length. This provides for connection of plug-in appliances that are commonly used in halls—lamps, vacuum cleaners, and so forth. The length of a hall is measured along its centerline. Although 210.52(H) calls for one receptacle outlet for each dwelling-unit hallway that is 10 ft (3.0 m) or more in length, part **(H)** does not specify location or require more than a single receptacle outlet. However, good design practice would dictate that a convenience receptacle should be provided for each 10 ft (3.0 m) of hall length. And they should be located as close as possible to the middle of the hall. Note that the rule applies within dwelling units only, and therefore does not apply to a common hallway of a multifamily building or a hotel, although it would be obviously good design to provide receptacles in those other buildings.

Part **(I)**, as of the 2011 **NEC**, requires receptacle coverage in foyers. Foyers, or entrance hallways, have been previously considered as hallways and only a single receptacle outlet has been enforceable, and then only if the total length was 10 ft (3.0 m) or longer. This new paragraph only applies to foyers that are not “part” of a hallway qualifying as such under 210.52(H), and which exceed 60 sq ft (5.6 sq m) in area. It also does not apply to entrance areas that are part of a room otherwise covered in 210.52(A). [Figure 210-56](#) shows a foyer that qualifies under this new provision.

Fig. 210-56. Receptacles are required for large foyers. [Sec. 210.52(I).]

If a foyer qualifies under this rule, at least one receptacle outlet must be installed in each wall space 3 ft (900 mm) or wider. This measurement includes contiguous wall space unbroken at the floor line by doorways, door-side windows that extend to the floor, and similar openings.

210.60. Guest Rooms, Guest Suites, Dormitories, and Similar Occupancies. The number of receptacles in a guest room of a hotel or motel, or an equivalent sleeping room of a dormitory or similar location, must be determined by the every-12-ft rule of 210.52(A) but *may* be located where convenient for the furniture layout. In other words, first lay out the room on paper as though 210.52(A) applied as written, and count the receptacles that result. Then, shift the receptacles if desired to accommodate permanent furniture arrangements, but do not decrease the total number. In addition, make sure that no fewer than two of the receptacle outlets are readily accessible. If a receptacle outlet falls behind the bed, install some means of assuring that when the bed is moved

against the wall, any cords plugged into the receptacle are not damaged (a wet-location “in-use” cover might suffice), or locate the receptacle low enough so as to be out of the way. Where “permanent provisions for cooking” are installed in guest rooms or suites, the installation must satisfy the rule of 210.17 and be wired just as if it were an individual dwelling unit within a multifamily dwelling.

210.62. Show Windows. The rule here calls for one receptacle in a show window for each 3.7 m (12 ft), or major fraction thereof, of length (measured horizontally) to accommodate portable window signs and other electrified displays (Fig. 210-57). The receptacles (125-V, 15- or 20-A, single phase) must be installed within 450 mm (18 in.) of the top of the window to count.

For a 20-ft-long store show window, a minimum of two receptacles must be installed, one for each 12 linear ft or major fraction thereof of show window length.

Fig. 210-57. Receptacles are required for show windows in stores or other buildings. (Sec. 210.62.)

210.63. Heating, Air-Conditioning, and Refrigeration Equipment Outlet. A general-purpose 125-V receptacle outlet must be installed within 25 ft (7.5 m) of heating, air-conditioning, and refrigeration equipment. Although the 1999 NEC limited application of this rule to equipment located on rooftops *and* in attics and crawl spaces (Fig. 210-58), the maintenance receptacle required by this rule must be provided wherever the equipment is installed, and now the rule applies wherever the equipment is located. The receptacles must be on the same level as the equipment, which is occasionally an issue on discontinuous rooftops where a “nearby” receptacle within 7.5 m (25 ft) as the crow flies in actuality requires a ladder to reach. Common sense would dictate that an additional receptacle need not be installed where there is another properly rated receptacle within 25 ft and on the same level as the equipment. For example, if one of the outdoor receptacles installed at a dwelling unit falls within 7.5 m (25 ft) of this equipment, an additional receptacle need not be installed. The service receptacle must not be connected to the load side of the disconnect switch for the equipment for obvious reasons. Note that the rule does not apply to pure

ventilating equipment (the “V” in the familiar acronym “HVAC”) and it also does not apply to evaporative coolers (the so-called “swamp coolers”) at single- and two-family dwellings.

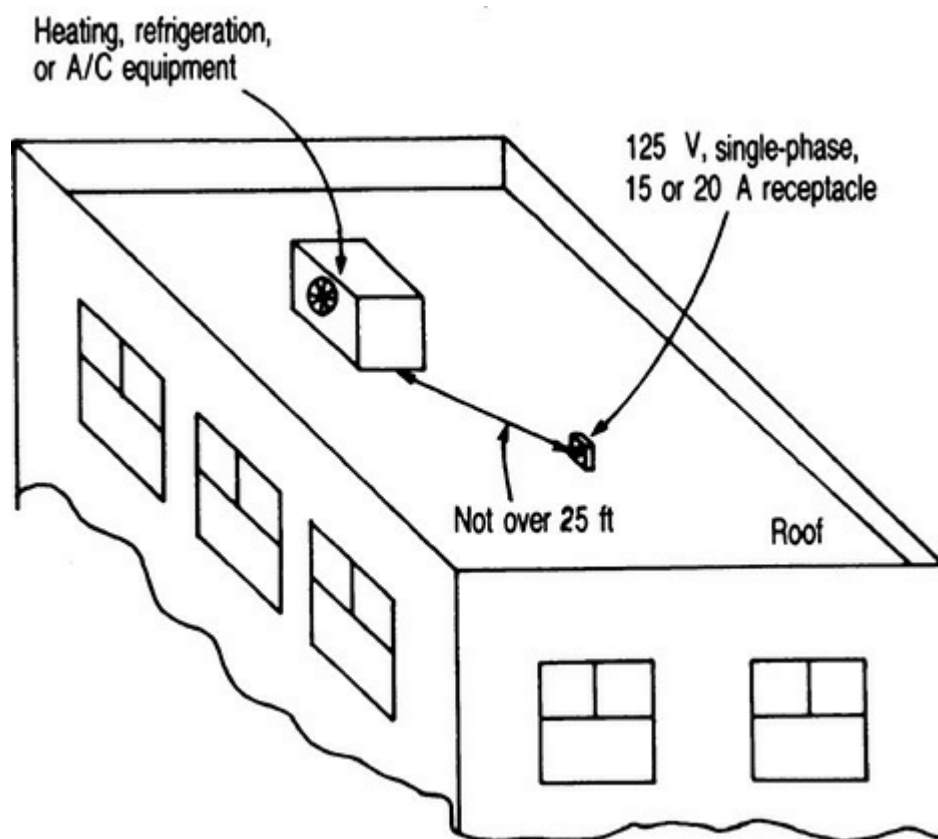

Fig. 210-58. Maintenance receptacle outlet required for rooftop mechanical equipment as well as for such equipment in all other locations—indoors and outdoors. (Sec. 210.63.)

210.64. Electrical Service Areas. In other than one- and two-family dwellings, at least one general-purpose receptacle outlet must be provided in an accessible location within 25 ft and located in the same room as the service equipment. This will allow for orderly connections of monitoring equipment for data analysis and other purposes in such areas. As of the 2017 **NEC**, this requirement is waived for service equipment operating above 120 volts to ground at electric irrigation machinery and at natural and artificial bodies of water.

210.70. Lighting Outlets Required. The basic rule of part (A)(1) requires at least one wall-switch-controlled lighting outlet in habitable rooms and in bathrooms of dwelling units. The 2017 **NEC** added language to clarify that kitchens are also included. The rule of part (A)(2) calls for wall-switch-controlled lighting outlets in halls, stairways, attached garages, “detached garages with electric power,” and at outdoor entrances and exits in dwelling units.

The rule of 210.70(A)(1) basically requires that a “wall-switched-controlled” lighting outlet be provided in every room that would be required to be provided with a receptacle outlet as defined in 210.52(A). While that requirement constitutes the basic rule, a wall-switch-controlled receptacle will satisfy Exception No. 1 to 210.70(A)(1) where used in every “habitable room” except the kitchen—which, like the bathrooms in dwelling units, must *always* have a wall-switch-controlled lighting outlet. Other areas of dwelling units are covered in part 210.70(A)(2), while storage and equipment space are governed by part (A)(3).

The word *bathrooms* is in the basic rule because various building codes do not include bathrooms

under their definition of “habitable rooms.” So the word “bathroom” was needed to ensure that the rule covered bathrooms. The rule does not stipulate that the required “lighting outlets” must be ceiling lighting outlets; they also may be wall-mounted lighting outlets (Fig. 210-59).

EXCEPTION:

Wall-switched receptacle(s) may be used instead of a lighting outlet in habitable rooms other than kitchens and bathrooms.

Fig. 210-59. Lighting outlets required in dwelling units. (Sec. 210.70.)

Two exceptions are given to the basic requirements in **(A)(1)**. Exception No. 1 notes that in rooms other than kitchens and bathrooms, a wall-switch-controlled receptacle outlet may be used instead of a wall-switch-controlled lighting outlet. The receptacle outlet can serve to supply a portable lamp, which would give the necessary lighting for the room.

Part **(A)(1)**, Exception No. 2, indicates two conditions under which the use of an occupancy sensor is permitted to control any of the required lighting outlets designated in the basic rule: (1) where used in addition to the required wall switch and (2) where the sensor is equipped with manual override and is mounted at the “customary” switch location. Notice that the literal wording only permits such control for “lighting outlets.” Therefore, even though it is not entirely clear, it must be assumed that occupancy sensor control of a receptacle outlet—installed in accordance with the first exception to this section—is *not* permitted. In addition, occupancy sensors are generally rated not to exceed specified loads, and a receptacle load is not controlled, which would likely result in a listing violation [110.3(B)]. Note that 404.14(E) imposes a similar reservation on dimmer switches.

In 210.70(A)(2)(a), the Code calls for wall-switched lighting outlets for all those “other” areas in dwellings. Specifically, hallways and stairways must be provided with at least one wall-switch-controlled lighting outlet.

Part **(A)(2)(1)** also requires a wall-switch-controlled lighting outlet in every *attached* garage of a dwelling unit (such as a one-family house). But, for a *detached* garage of a dwelling unit, a switch-controlled lighting outlet is required *only* if the garage is provided with electric power—whether the provision of power is done as an optional choice or is required by a local code. Note that the **NEC** rule here does not itself require running power to the detached garage for the lighting outlet, but simply says that the lighting outlet must be provided *if* power is run to the garage.

Part **(A)(2)(2)** requires that outdoor entrances for personnel that afford grade-level access at dwelling unit garages be provided with an exterior lighting outlet. The second sentence clarifies that “a vehicle door in an attached garage is *not* considered as an outdoor entrance.” This makes it clear that the Code does not require such a light outlet at any garage door that is provided as a vehicle entrance because the lights of the car provide adequate illumination when such a door is being used during darkness. But the wording of this sentence does suggest that a rear or side door that is provided for personnel entry to an attached garage would be “considered as an outdoor entrance” because the note excludes only “vehicle” doors. Such personnel entrances from outdoors to the garage would seem to require a wall-switched lighting outlet.

At least one lighting outlet must be installed in every attic, underfloor space, utility room, and basement if it is used for storage or if it contains equipment requiring servicing. In such cases, the lighting outlet must frequently be controlled by a wall switch, but not always. The rule specifically allows a pull-chain lampholder or luminaire, provided it is reachable (“at least one point of control”) at the usual point of entry. However, for equipment requiring servicing, the lighting outlet must also be located at or near the equipment. If the equipment is at the point of entry, or if there is not such equipment and the space is only used for storage, then the pull chain at the entry will do. However, if there is such equipment and it is remote from the entry, then a wall switch is the only practical method because the luminaire or lampholder will be over at the equipment.

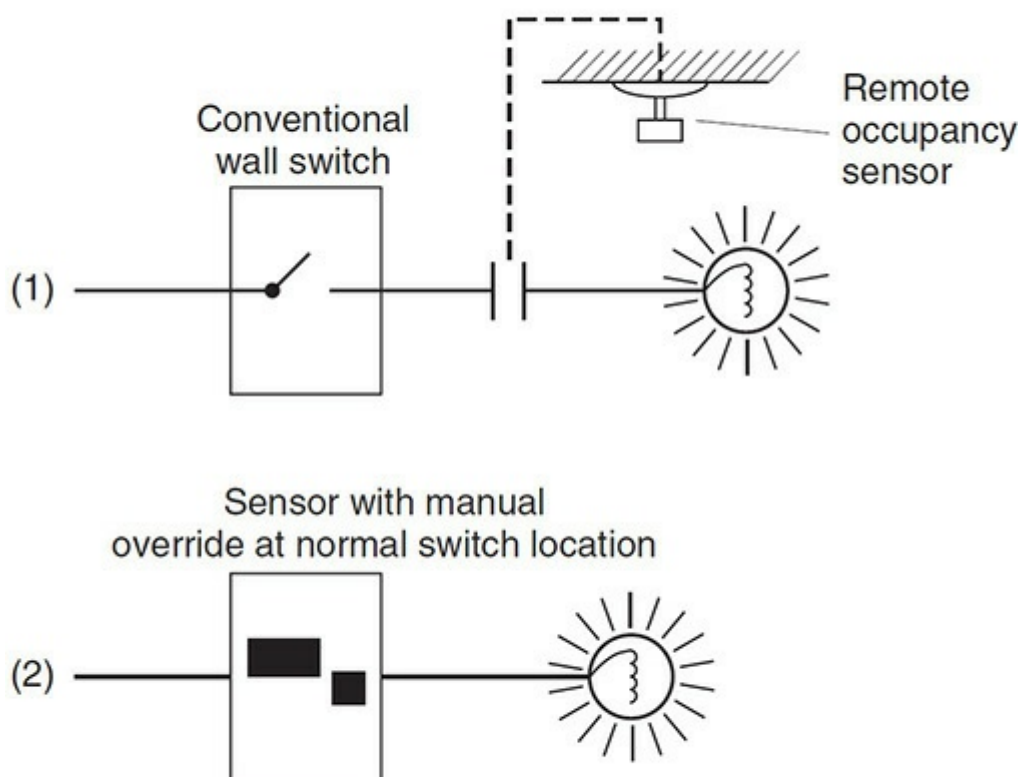

Part **(A)(2)(3)** requires that stairways between levels that have six or more risers have wall switch control from both ends of the stairway, with additional control required if the stairway includes a landing with an “entryway” between floor levels, as is common with split-level houses. The “entryway” provision closes a loophole in the top-and-bottom rule that would otherwise have no

wall switch control over the stairway lighting available to an occupant returning through the front door. Note that this rule applies even to a stairway connecting to an unfinished attic, and therefore a three-way switch loop or some other control must be arranged at both ends of the attic stair in this case. The 2017 **NEC** added the limitation that a conventional dimmer switch cannot be used at one end of a stair. If left in the fully dimmed position, the switch at the other end of the stair becomes non-functional. However, dimming is permitted if it can be controlled from both locations.

Where using any occupancy sensor for control of lighting, the use of a sensor that fails in the “on” position would be preferable to one that fails “off” or one that fails “as is.” Such a fail-safe feature on any sensor is not required but is preferable because control of the lighting outlet can be provided from the conventional wall switch or manual override until such time as the sensor can be replaced (Fig. 210-60). But, in the exception to (A)(2)(1, 2, and 3), the Code states that “in hallways, stairways, and at outdoor entrances remote, central, or automatic control of lighting shall be permitted.” This latter recognition appears to accept remote, central, or automatic control as an alternative to the wall switch control mentioned in the basic rules.

210.70(A)(1), Exception No. 2

Required outlets may be controlled by occupancy sensors.
Such control may be provided by either:

It is clear that a receptacle outlet installed in accordance with Exception No. 1 to Sec. 210.70(A) is *not* permitted to be controlled by such means.

Fig. 210-60. Occupancy sensor control for lighting outlets in dwellings must be as shown here. Either a sensor and a conventional wall switch or a sensor with a manual override installed at the “customary” wall-switch location must be provided. Remember, the rule here only applies to dwellings.

210.70(B) notes that at least one wall-switch-controlled lighting outlet is to be provided for guest rooms in hotels, motels, or similar occupancies. As in the case of conventional dwelling units, exceptions provide for wall switch control of receptacles in other than bathrooms, and in kitchens where provided (Fig. 210-61). In addition, the exceptions also allow for occupancy sensors on the same basis as for dwelling units generally.

Kitchen and all bathrooms—

Each must have at least one lighting outlet that is **wall-switch-controlled** (not pull-chain or switch in fixture or canopy)

Fig. 210-61. Switch-controlled lighting outlet in kitchen and bathroom of guest rooms and suites. [Sec. 210.70(A).]

Part (C) of 210.70 requires that either a lighting outlet containing a switch—such as the familiar pull-chain porcelain lampholder—or a wall-switch-controlled lighting outlet must be provided in attics or underfloor spaces, utility rooms, and basements—in *all occupancies* (including dwelling units). The lighting outlet must be located at or near the equipment to provide effective illumination. And the control wall switch must be installed at the point of entry to the space.

210.71. Meeting Rooms. As of the 2017 NEC, meeting rooms equal in size or smaller than 1000 sq ft must comply with a mandatory convenience receptacle placement provision. Larger rooms need not comply, but the evaluation must be carried out with any relocatable partitions so arranged as to create the smallest possible room size. The informational notes provide some helpful context, by explaining the intended coverage involves seated gatherings of conferees, typically using portable electronic equipment along with projectors and the like. Panel meetings of the National Electrical Code Committee are excellent examples of such activities. Rooms styled as auditoriums, schoolrooms, and coffee shops are specifically cited as not the intended application of this new section. [Figure 210-62](#) shows the process at work in a 4000 sq ft conference wing of a hotel.

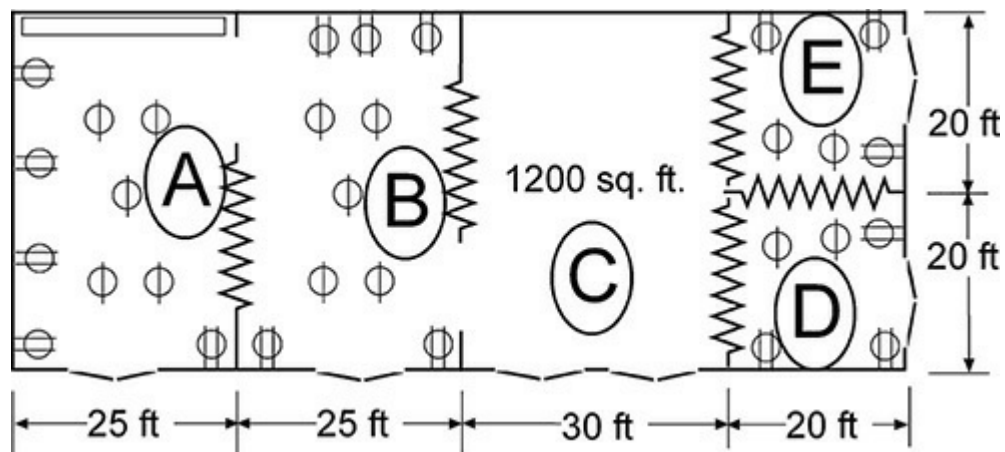

Fig. 210-62. A 4000 sq ft conference area. The receptacle count is based on the relocatable partitions being closed to minimize floor areas. The left room “A” has fixed cabinets in the back without work surfaces, and therefore has its receptacle census reduced [210.52(A)(4)]. Room “B” has the receptacles on the rear fixed wall repositioned to accommodate a design decision by the owner. Both Room “A” and that room are 1000 sq ft, and have the full complement of floor receptacles (shown as single receptacles for the purposes of this illustration; four plus a major fraction means five required). Room “C” is too large to be subject to the requirement. Smaller rooms “D” and “E” follow the customary procedures (210.71).

The process considers both fixed walls and the open floor as candidates for receptacles. For the fixed walls, in a similar procedure to hotel rooms, this section requires that a total number of receptacles be determined as though the normal residential rules in 210.52(A) were being applied, and then a number of receptacle outlets at least equal to that be installed. And, also comparable to hotel rooms, the specific locations of those receptacles can be located according to the design objectives of the owner. Any floor of a conference room must also be populated if it is at least 12 ft wide, and at least 215 sq ft in extent, in this case with floor receptacles. Here, the total number is determined by dividing the floor area in square feet by 215, with any major fractions rounded up. The positioning of floor receptacles is left as a design choice, but they must always be at least 6 ft from a fixed wall to be counted as satisfying the requirements.

ARTICLE 215. FEEDERS

215.1. Scope. *Feeders* are the conductors that carry electric power from the service equipment (or generator switchboard, where power is generated on the premises) to the overcurrent protective devices for branch circuits supplying the various loads. *Subfeeders* originate at a distribution center other than the service equipment or generator switchboard and supply one or more other distribution panelboards, branch-circuit panelboards, or branch circuits. Code rules on feeders apply also to all subfeeders for the simple reason that all subfeeders meet the definition of a feeder, and for this reason the **NEC** does not recognize the term (Fig. 215-1). Its use is being gradually phased out of this book.

Fig. 215-1. Article 215 applies only to those circuits that conform to the **NEC** definition of “feeder.” (Sec. 215.1.)

As a matter of good design, for the given circuit voltage, feeders and subfeeders must be capable of carrying the amount of current required by the load, plus any current that may be required in the future. Selection of the size of a feeder depends on the size and nature of the known load computed from branch-circuit data, the anticipated future load requirements, and voltage drop. However, the **NEC** does not require owners and installers to be wise about the future, and a feeder that will carry the load connected to it as determined by Art. 220 is **NEC** compliant. Section 90.1(B) clearly states that an **NEC**-compliant installation will be “essentially free from hazard, but not necessarily efficient, convenient, or adequate for good service or future expansion of electrical use.”

Article 215 deals with the determination of the minimum sizes of feeder conductors necessary for safety. Overloading of conductors may result in insulation breakdowns due to overheating; overheating of switches, busbars, and terminals; the blowing of fuses and consequent overfusing; excessive voltage drop; and excessive copper losses. Thus, the overloading will in many cases create a fire risk and is sure to result in very unsatisfactory service.

215.2. Minimum Rating and Size. The actual maximum load on a feeder depends upon the total load connected to the feeder and the demand factor(s) as established by the rules in parts III, IV, and V of Art. 220.

From an engineering viewpoint, there are two steps in the process of predetermining the maximum load that a feeder will be required to carry: first, a reasonable estimate must be made of the probable connected load; and, second, a reasonable value for the demand factor must be assumed. From a survey of a large number of buildings, the average connected loads and demand factors have been ascertained for lighting and small appliance loads in buildings of the more common classes of occupancy, and these data are presented in parts III, IV, and V of Art. 220 as minimum requirements. That is, it is not permissible to assume any demand factor that would result in a calculated load that is less than the Code-prescribed minimum. However, given that calculations in accordance with the **NEC** provide for no future growth or additional loading, providing capacity for less than the Code-prescribed minimum represents poor design and is a violation of the **NEC**.

The load is specified in terms of volt-amperes per square foot for certain occupancies. These loads are here referred to as standard loads, because they are minimum standards established by the Code in order to ensure that the service, feeder, and branch-circuit conductors will have sufficient carrying capacity for safety.

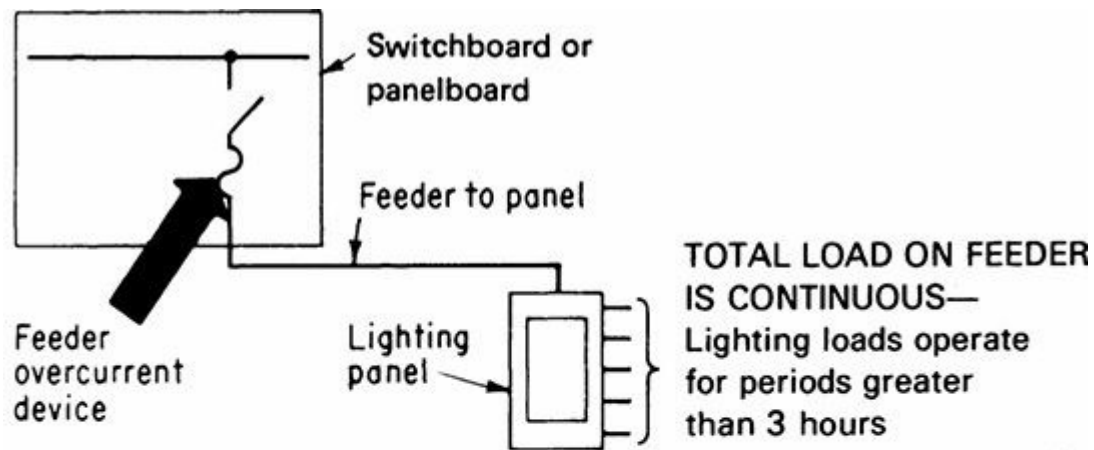

Calculating Feeder Load

The key to accurate determination of required feeder conductor capacity in amperes is effective calculation of the total load to be supplied by the feeder. Feeders and subfeeders are sized to provide sufficient power to the circuits they supply. For the given circuit voltage, they must be capable of carrying the amount of current required by the load, plus any current which may be required in the future. The size of a feeder depends upon known load, future load, and voltage drop.

The minimum load capacity which must be provided in any feeder or subfeeder can be determined by considering **NEC** requirements on feeder load. As presented in Sec. 215.2, these rules establish the minimum load capacity to be provided for all types of loads.

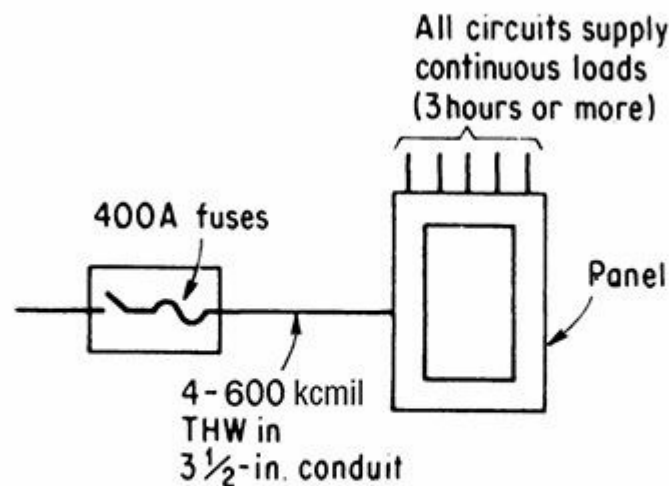

The first sentence of 215.2(A)(1) requires feeder conductors to have ampacity at least equal to the sum of loads on the feeder, as determined in accordance with Art. 220. And 215.3 gives rules on the rating of any feeder protective device.

If an overcurrent protective device for feeder conductors is not UL-listed for continuous operation at 100 percent of its rating, the load on the device must not exceed the noncontinuous load plus 125 percent of the continuous load. 215.3 applies to feeder overcurrent devices—CBs and fuses in switch assemblies—and requires that the rating of any such protective device must generally never be less than the amount of noncontinuous load of the circuit (that amount of current that will not be flowing for 3 h or longer) plus 125 percent of the amount of load current that will be continuous (flowing steadily for 3 h or longer) ([Fig. 215-2](#)).

FEEDER OVERCURRENT DEVICES AND CONDUCTORS must be rated not less than 125% of the continuous load *and* the feeder conductors must be sized so they have an ampacity such that they are properly protected by the rating of the feeder CB or fuses, as required by 240.4. Another way of saying that is "the continuous load must not exceed 80% of the rating of the protection."

EXAMPLE: For this feeder, with conductors rated at 420 A, (smallest size at least 125% of the continuous load), the maximum continuous load permitted for a conventional fused switch is 80% of the 400-A fuse rating [$400 \times 0.8 = 320\text{A}$].

Rating of fuses must be at least equal to 125% times the continuous load and the 400-A rating is proper protection for conductors with an ampacity of 420 A. But, the load must be limited to 320 A to prevent overheating of OC device.

Fig. 215-2. Feeders must generally be loaded to no more than 80 percent for a continuous load. [Sec. 215.2(A)(1).]

For any given load to be supplied by a feeder, after the minimum rating of the overcurrent device is determined from the preceding calculation (noncontinuous plus 125 percent of continuous), then a suitable size of feeder conductor must be selected. For each ungrounded leg of the feeder (the so-called phase or line legs of the circuit), the conductor must have a table ampacity in the 75°C column that is at least equal to the amount of noncontinuous current plus the amount of continuous current, from the **NEC** tables of ampacity [Tables 310.15(B)(16) through 310.15(B)(21)].

Although the rules of 210.19 and 215.2 are aimed at limiting the load on the circuit protective device, the conductor's ampacity also must be based on the nature of the load. Just as is required for the overcurrent device, the conductor's ampacity must not be less than the noncontinuous load plus 125 percent of the continuous load, *except* where derating—either for the number of conductors, 310.15(B)(3)(a), or elevated ambient temperature, which must be derated by the factor shown in the Ambient Temperature Correction Factors in Tables 310.15(B)(2)(a) or 310.15(B)(2)(b) as applicable—is needed. In those cases, the conductor's table ampacity in the 75°C column must be not less than the sum of noncontinuous plus 125 percent of the continuous load *before* any derating is applied. *And*, after derating *is* applied, the conductor's ampacity must be such that the overcurrent device protects the conductor as required or permitted by 240.4.

Note that the conductor size increase previously described applies only to the ungrounded or phase conductors because they are the ones that must be properly protected by the rating of the protective device. A neutral or grounded conductor of a feeder does not have to be increased; its size must simply have ampacity sufficient for the neutral load as determined from 220.61.

The exceptions for 215.2(A) and 215.3 note that a CB or fused switch that is UL-listed for continuous operation at 100 percent of its rating may be loaded right up to a current equal to the device rating. Feeder ungrounded conductors must be selected to have ampacity equal to the noncontinuous load plus the continuous load—without applying the 1.25 multiplier. The neutral conductor is sized in accordance with 220.61, which permits reduction of neutral size for feeders loaded over 200 A that do not supply electric-discharge lighting, data processing equipment, or other “nonlinear loads” that generate high levels of harmonic currents in the neutral.

Feeders run with differing ampacities between source and load A new Exception No. 2 to 215.2(A)(1)(a) in the 2017 **NEC** modifies this requirement in the event the feeder conductors change size between source and load. Normally, this is never done; the process of installing a pull box and splicing and re-splicing conductors between line and load ends is generally not cost-effective. However, there are instances where it is extremely advantageous, and even required under some conditions. The remainder of the coverage in this book on Article 215 assumes that this exception is not being used because it usually isn't; however, it is now a live option.

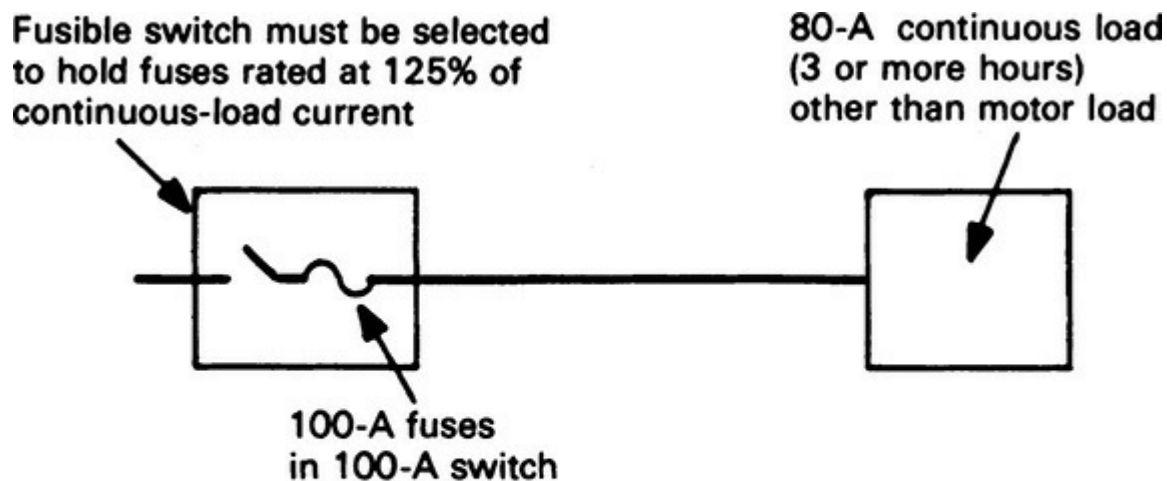

One example is when Type MI cable, with its inherent fire resistance characteristics, is used between source and load. Sec. 700.10(D)(1)(2) requires a 2-hour fire resistance rating for emergency circuit feeders under the occupancy conditions specified in 700.10(D), and Type MI cable is often used for this purpose. Now, the ampacity of MI cable is essentially limited only by the melting point of copper because its insulation is magnesium oxide, which is a refractory compound with a melting point far higher than copper. This is why 332.80 essentially allows free-air ampacities or better for this wiring, and the MI cable industry has step-up connectors that allow for the direct termination of small MI conductors into connectors that allow for integral connections to larger conductor tails. Another example is cablebus, which is also allowed free-air ampacities by 370.80 and is essentially designed for large-capacity industrial feeders. There have also been a number of field installations done with custom Type MC cable constructions where the extreme length and units costs of a large-capacity industrial feeder supplying continuous loads justified the cost of running the greater length of the circuit with conductors sized to ampacity, and then extensions at each end provided to accommodate **NEC** rules for actual device terminations in 110.14(C).

The underlying principle is that wires have middles and ends, and the rules for one differ from the other. It is indeed possible to separate the two concepts in the process of wiring a feeder through the

medium of 110.14(C)(2). Unlike conventional device terminations that must be utilized in concert with the special rules governing the wire sizes permitted to land on them, connectors applied under this procedure are rated only by their own chemistry and design. Properly positioned and wired, these connectors allow an installer to marry one size wire that might be required at a termination with another size wire that works for the length of the run. Power distribution blocks, covered in 314.28(E) and 376.56(B), are extremely well suited to these applications. The terms of the exception assure that undersized conductors never enter the enclosure housing a terminating device. For complete details, please refer to the exhaustive discussion of ampacity calculation and wire selection that is in [Chap. 9](#) of this book, located at the coverage of Example D3(A).

Fuses for feeder protection The rating of a fuse is taken as 100 percent of rated nameplate current when enclosed by a switch or panel housing. But, because of the heat generated by many fuses, the maximum continuous load permitted on a fused switch is restricted by a number of NEMA, UL, and **NEC** rules to 80 percent of the rating of the fuses. Limitation of circuit-load current to *no more than* 80 percent of the current rating of fuses in equipment is done to protect the switch or other piece of equipment from the heat produced in the fuse element—and also to protect attached circuit wires from excessive heating close to the terminals. The fuse itself can actually carry 100 percent of its current rating continuously without damage to itself, but its heat is conducted into the adjacent wiring and switch components.

NEMA standards require that a fused, enclosed switch be marked, as part of the electrical rating, “Continuous Load Current Not to Exceed 80 Percent of the Rating of Fuses Employed in Other Than Motor Circuits” ([Fig. 215-3](#)). That derating compensates for the extra heat produced by continuous operation. Motor circuits are excluded from that rule, but a motor circuit is required by the **NEC** to have conductors rated at least 125 percent of the motor full-load current—which, in effect, limits the load current to 80 percent of the conductor ampacity and limits the load on the fuses rated to protect those conductors. But, the UL *Electrical Construction Materials Directory* does recognize fused bolted-pressure switches and high-pressure butt-contact switches for use at 100 percent of their rating on circuits with available fault currents of 100,000, 150,000, or 200,000 rms symmetrical A—as marked ([Fig. 215-4](#)). (See “Fused Power Circuit Devices” in that UL publication.)

Circuit conductors must be sized so that they have ampacity of at least 100-A protection before derating and be properly protected by the protective device selected in accordance with 215.2(A).

Fig. 215-3. For branch circuit or feeder, fuses in enclosed switch must be limited for continuous duty. [Sec. 215.2(A)(1).]

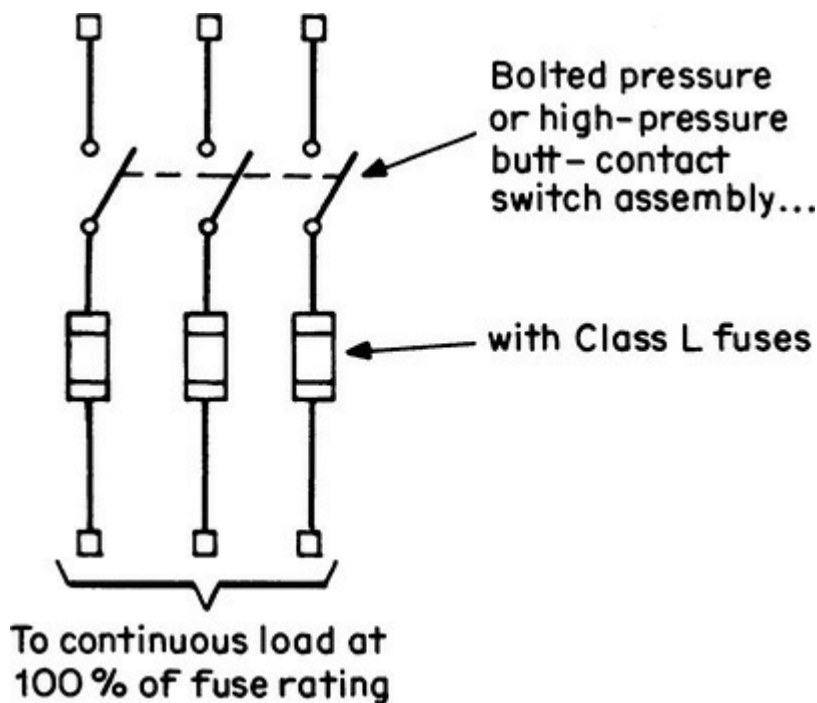

Fig. 215-4. Some fused switches and CBs may be used at 100 percent rating for continuous load. [Sec. 215.2(A)(1) Exception No. 1.]

Manual and electrically operated switches designed to be used with Class L current-limiting fuses rated 601 to 4000 A, 600 V ac are listed by UL as “Fused Power Circuit Devices.” This category covers bolted-pressure-contact switches and high-pressure, butt-type-contact switches suitable for use as feeder devices or service switches if marked “Suitable for Use As Service Equipment.” Such devices “have been investigated for use at *100 percent of their rating* on circuits having available fault currents of 100,000, 150,000, or 200,000 rms symmetrical amperes” as marked.

CB for feeder protection The nominal or theoretical continuous-current rating of a CB generally is taken to be the same as its trip setting—the value of current at which the breaker will open, either instantaneously or after some intentional time delay. But, as described previously for fuses, the real continuous-current rating of a CB—the value of current that it can safely and properly carry for periods of 3 h or more—frequently is reduced to 80 percent of the nameplate value by codes and standards rules.

The UL *Electrical Construction Materials Directory* contains a clear, simple rule in the instructions under “Circuit Breakers, Molded-Case.” It says:

Unless otherwise marked, circuit breakers should not be loaded to exceed 80 percent of their current rating, where in normal operation the load will continue for three or more hours.

A load that continues for 3 h or more is a *continuous* load. If a breaker is marked for *continuous* operation, it may be loaded to 100 percent of its rating and operate continuously.

There are some CBs available for continuous operation at 100 percent of their current rating, but they must be used in the mounting and enclosure arrangements established by UL for 100 percent rating. Molded-case CBs of the 100 percent continuous type are made in ratings from 225 A up.

Information on use of 100-percent-rated breakers is given on their nameplates.

Figure 215-5 shows two examples of CB nameplate data for two types of UL-listed 2000-A, molded-case CBs that are specifically tested and listed for continuous operation at 100 percent of their 2000-A rating—*but* only under the conditions described on the nameplate. These two typical nameplates clearly indicate that ventilation may or may not be required. Because most switchboards have fairly large interior volumes, the “minimum enclosure” dimensions shown on these nameplates (45 by 38 by 20 in.) usually are readily achieved. *But*, special UL tests must be performed if these dimensions are not met. Where busbar extensions and lugs are connected to the CB within the switchboard, the caution about copper conductors does not apply, and aluminum conductors may be used.

EXAMPLE 1

EXAMPLE 2

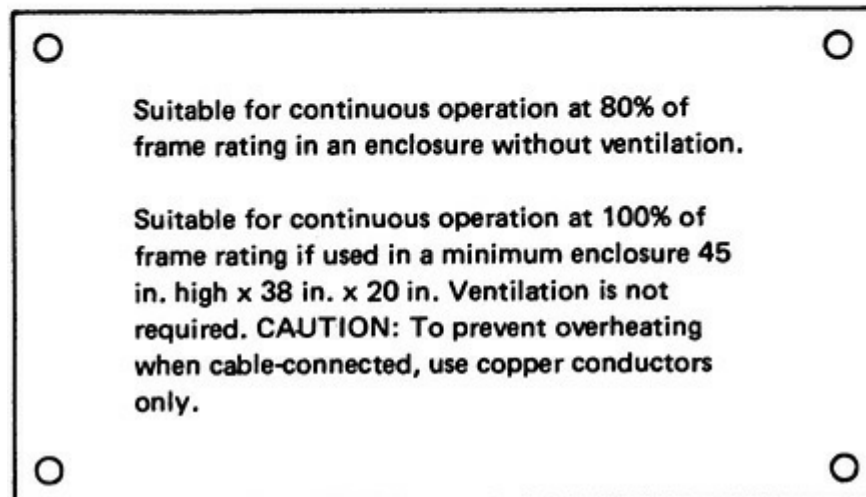

Fig. 215-5. Nameplates from CBs rated for 100 percent continuous loading. [Sec. 215.2(A)(1) Exception No. 1.]

If the ventilation pattern of a switchboard does not meet the ventilation pattern and the required enclosure size specified on the nameplate, the CB must be applied at 80 percent rating. Switchboard manufacturers have UL tests conducted with a CB installed in a specific enclosure, and the enclosure may receive a listing for 100-percent-rated operation even though the ventilation pattern or overall enclosure size may not meet the specifications. In cases where the breaker nameplate specifications

are not met by the switchboard, the customer would have to request a letter from the manufacturer certifying that a 100-percent-rated listing has been received. Otherwise, the breaker must be applied at 80 percent.

To realize savings with devices listed by UL at 100 percent of their continuous-current rating, use must be made of a CB manufacturer's data sheet to determine the types and ampere ratings of breakers available that are 100-percent-rated, along with the frame sizes, approved enclosure sizes, and the ventilation patterns required by UL, if any.

It is essential to check the instructions given in the UL listing to determine *if* and under what conditions a CB (or a fuse in a switch) is rated for continuous operation at 100 percent of its current rating.

A Comparison: 100-Percent-Rated versus Non-100-Percent-Rated OC Devices

OCPD (overcurrent protective device) rating For the purpose of comparison, let's consider a feeder supplying an 800-A fluorescent lighting load connected line-to-neutral, assumed to be operating continuously, and supplied from a circuit made up of three sets of parallel conductors, with each set run in a separate raceway (Fig. 215-6).

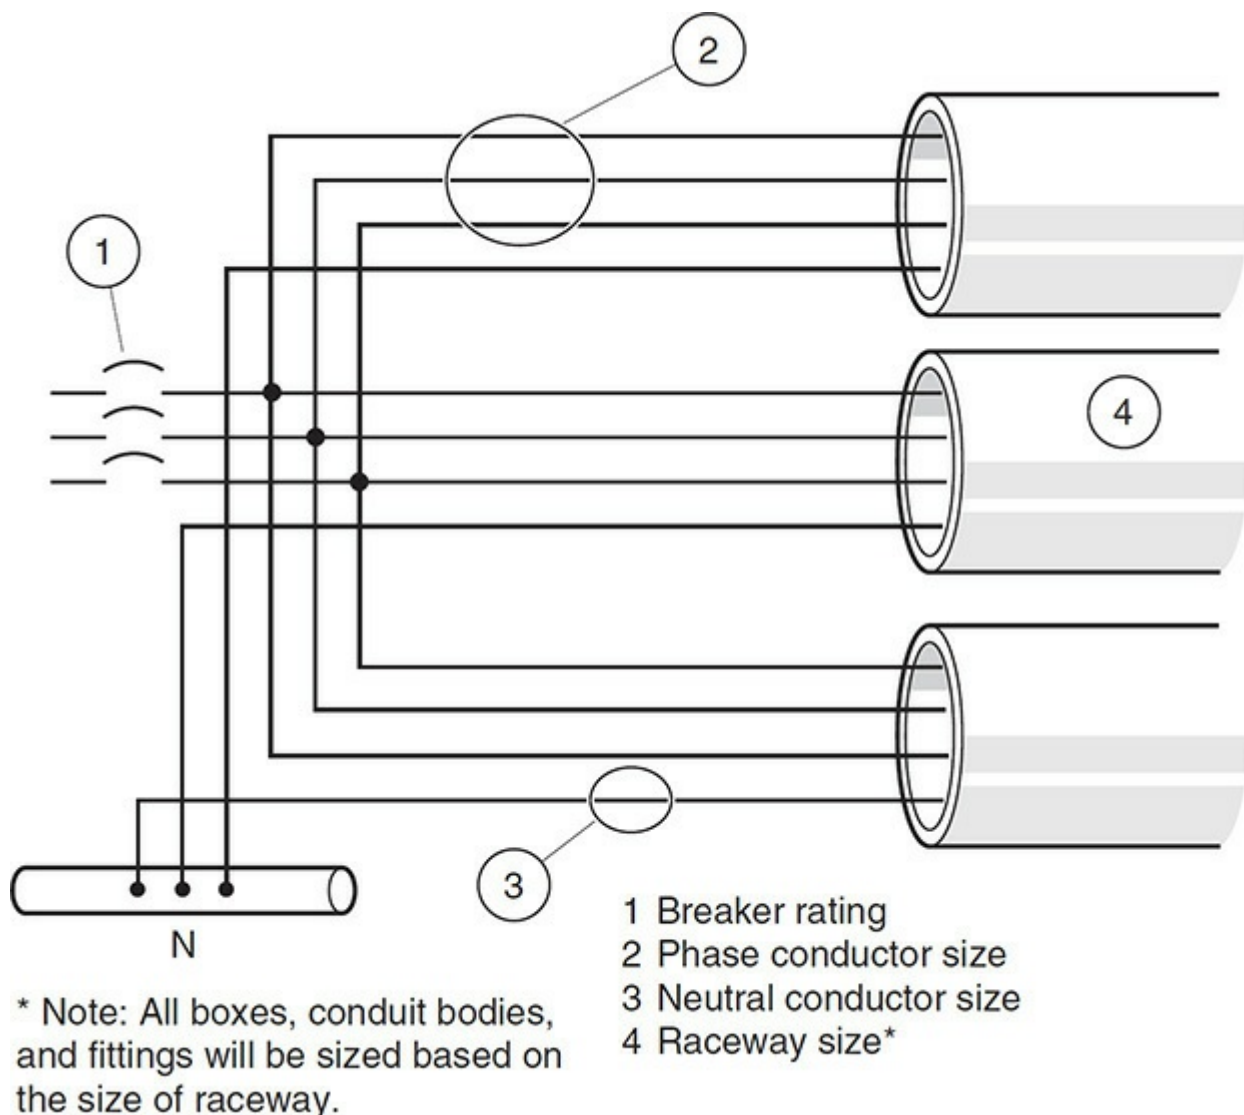

Fig. 215-6. The decision to use or not use a 100-percent-rated device will affect the size/rating of

these circuit components.

Non-100-percent-protected circuit As indicated, the rules of 215.3 call for a non-100-percent-rated OCPD to be rated not less than the sum of noncontinuous load (in this case 0 A) plus 125 percent of the continuous load, or 1000 A ($800 \text{ A} \times 1.25$), which means a minimum rating of 1000 A ($0 \text{ A} + 1000 \text{ A}$).

100-percent-protected circuit The rating required for a 100-percent-rated breaker to protect this lighting feeder need be no greater than the actual connected lighting load. Therefore, an 800-A, 100-percent-rated breaker would fully satisfy all applicable rules.

Phase Conductor Sizing

Non-100-percent-protected circuit Another disadvantage to using the non-100-percent-rated breaker is the Code-mandated procedure that must be used to establish the minimum acceptable conductor size for such circuits. As previously indicated, the conductors used with the 1000-A non-100-percent-rated breaker to supply the 800-A lighting load must also have additional capacity. And that capacity must be determined by the method prescribed in 215.2(A)(1)(a). The 2014 **NEC** has made this procedure somewhat more straightforward at the expense of some technical accuracy in certain cases. There are two independent calculations, which reflect a core principle, namely, that any wire has a middle and two ends. The rules that apply to the end of a wire are influenced by how connected devices and equipment tend to react to conductor operating temperatures and to the effect of continuous loads. Working from the default temperature assumption in 110.14(C)(1)(b) of 75°C and applying 215.2(A)(1)(a), we have a minimum size based on 100% of the noncontinuous load plus 125% of the continuous load, evaluated under the 75°C column in Table 310.15(B)(16).

The rules that apply to the middle of a wire reflect how ambient temperatures and mutual conductor-heating change conductor ampacity, because they change the conditions of use. Whether the load is continuous or not, and how the conductor size affects termination performance and heating is irrelevant to this calculation as this is the middle of the wire and the very definition of ampacity already assumes continuous load conditions. This is why 215.2(A)(1)(b) is an independent calculation. Take the connected load and then upsize to counteract any effects of mutual heating and increased ambient temperatures. Then, as covered in the parent language in 215.2(A)(1), size the wire to accommodate the worst case.

The 2014 **NEC** language works very well when the same size and type of wire lands on the line and load-side equipment and also runs between both ends without changing size or other ratings. This covers the overwhelming majority of installations. However, for very large and long feeders, at a certain price point it becomes cost-effective to place a pull box near both ends and decrease the feeder size between the pull boxes. Sec. 110.14(C)(2) expressly recognizes pressure connectors that can make such splices, limited only by the temperature rating of the connector, and in this regard full 90°C connectors are readily available. This makes it technically feasible, and entirely justified in terms of engineering principles, to leave a fully sized conductor heat sink in effect at each end, and then reduce the size of the middle of the wire (between the pull boxes) and rely on the increased ampacity resulting from a permitted higher operating temperature. The simplified wording in the 2014 **NEC** has inadvertently complicated this procedure to the point where an inspector would need to apply Sec. 90.4. There are a few other considerations in this regard.

- Where deratings are required, it is permissible that the derated ampacity be less than the sum of noncontinuous load plus 125 percent of the continuous load. But the conductors must always be properly protected by the OCPD, as required by Sec. 240.4.
- If the derated ampacity is *not* properly protected in accordance with 240.4 by the rating of the overcurrent device selected, then the next larger size of conductor must be evaluated. However, that evaluation can be limited to just the conductor's ampacity because the concern for satisfying 215.2(A)(1) was addressed when the previously considered smaller conductor was evaluated.
- The final point cannot be repeated too much. Remember which temperature column in Table 310.15(B)(16) must be used in satisfying the rule of Sec. 215.2(A)(1). As most are aware, Table 310.15(B)(16) has three different columns identified as 60°C, 75°C, and 90°C, under which are listed different insulating materials and the corresponding ampacity for each conductor size. Because current directly equates with heat, the higher-temperature-rated insulations are permitted to carry more current. Even though it is permissible to use the 90°C values for derating purposes, it must be remembered that for the requirement given in Sec. 215.2(A)(1) the ampacity value shown in the 75°C column of Table 310.15(B)(16) must be used! Where 90°C insulation (e.g., THHN) is used, it is still permissible to use the 90°C ampacity for the purposes of derating, as has long been recognized, but such practice is *not* permitted in selecting the minimum conductor size to supply continuous loads. Do not confuse the two rules.

To repeat, every conductor has a middle and two ends. The rules that apply to determining whether a wire will overheat in use involve an entirely separate set of calculations from those that determine how a termination will behave, and whether the wire as connected will have a sufficient heat sink capability so the connected OCPD will function as its manufacturer and UL tested it. At the end of this book, in conjunction with the discussion of Annex D, Example D3(a), we will tie all of these rules together in one place. The procedures that follow here will be consistent with that discussion, but focus on this concrete example of the cost comparison between 100 percent and conventional OCPDs.

For our example, we must first select a conductor that has a 75°C ampacity in Table 310.15(B)(16) which when multiplied by 3 (the number of conductors that will be paralleled to make up each phase) equals at least 1000 A.

In Table 310.15(B)(16), we see that at 75°C, three 400-kcmil copper conductors (335 A each, for a total of 1005 A) are adequate to satisfy the rule of 215.2(A)(1). However, because the load is fluorescent lighting, the rule of 310.15(B)(5)(c) would require us to count the neutral conductor as a current-carrying conductor. And 310.15(B)(3)(a) would call for an 80 percent derating of the Table 310.15(B)(16) ampacity because there are now more than three current-carrying conductors in the raceway. As indicated, if THHN (90°C-rated) insulation is used, then the derating may be applied against the 90°C ampacity for 400-kcmil copper. Multiplying the 90°C ampacity of 400 kcmil (380 A) times 3 gives us 1140 A. But, when that value is derated by 80 percent to satisfy 310.15(B)(3)(a) for more than three current-carrying conductors, we end up with an ampacity of only 912 A. According to the rule of 240.4(C), where the OCPD is rated at more than 800 A, the conductor's ampacity may *not* be less than the rating of the OC device. The conductor's ampacity must be equal to, or greater than, the rating of the OC device used. Therefore, because the derated ampacity of the 400-kcmil THHN copper conductors is less than 1000 A, it is *not* properly protected by the 1000-A-rated device. To supply this load, the next larger size of conductor (500 kcmil) must be evaluated—but *only* for ampacity. That's because we have already established that the 400-kcmil copper

conductor satisfies 215.2(A). And, if the smaller 400-kcmil conductors were adequately sized, then so should the larger 500s.

To determine the ampacity of the THHN-insulated, 500-kcmil copper conductors under these conditions of use, because we're using THHN conductors, we can apply the 80 percent derating against the 90°C ampacity value for 500-kcmil copper. Multiply the 430-A table value times the number of conductors (3) and derate by 80 percent. Or,

$$\begin{aligned}\text{Derated ampacity} &= (430 \text{ A/wire} \times 3 \text{ wires/phase}) \times 0.80 \\ &= 1290 \text{ A/phase} \times 0.80 \\ &= 1032 \text{ A}\end{aligned}$$

Therefore, the minimum size permitted for the phase conductors protected by the non-100-percent-rated device is THHN-insulated 500-kcmil copper.

100-percent-protected circuit As indicated by the exception to 215.2(A), the overcurrent device and the conductor size need only be adequate for the load to be served. Therefore, just as the CB need only be rated for 800 A, the circuit conductors need only be rated for 800 A. Where a 100-percent-rated OCPD is used, the basic rule in 215.2(A)(1) does *not* apply. Therefore, all we're really concerned with is conductor ampacity. That is, we must select a conductor with a table ampacity that when multiplied by 3 (number of conductors per phase) and derated by 80 percent (because there are still more than three current-carrying conductors in each raceway) is still equal to or greater than 800 A.

From Table 310.15(B)(16), we select a THHN-insulated 350-kcmil copper conductor with a 90°C table ampacity of 350 A. (*Remember:* The table ampacity shown in the 90°C column may be used in applying deratings to 90°C-insulated conductors.) As before, multiply the table value by 3 and derate by 80 percent, or:

$$\begin{aligned}\text{Derated ampacity} &= (350 \text{ A/wire} \times 3 \text{ wires/phase}) \times 0.80 \\ &= 1050 \text{ A/phase} \times 0.80 \\ &= 840 \text{ A}\end{aligned}$$

Therefore, the use of three THHN-insulated 350-kcmil copper conductors per phase would satisfy all rules regarding the minimum acceptable conductor size permitted for circuiting a 100-percent-rated 800-A device supplying this fluorescent lighting load.

Neutral Conductor Sizing

Non-100-percent-protected circuit It is worth noting that the rules given in 215.2(A) do *not* affect the sizing of the neutral. That is, because the neutral conductor does not generally connect to the CB, there is no need to be concerned with the nature of the load (i.e., continuous or a combination of continuous and noncontinuous). Remember, neutral sizing must satisfy the rules of 220.61. And, in that section, there is no requirement for additional capacity in the neutral where the load to be supplied is a continuous load. However, it certainly seems as if common sense should be applied to

the sizing of the neutral for the non-100-percent-protected circuit. Furthermore, effective with the 2008 **NEC**, there is now express language [215.2(A)(1) Exception No. 2] that specifically exempts a feeder neutral from the upsizing rules at terminations, provided it runs from busbar to busbar and does not land on an OCPD.

The 2005 **NEC** introduced an additional wrinkle in sizing neutrals on these systems. The neutral must have sufficient ampacity to safely carry a line-to-neutral short circuit without damaging itself or blowing open. This rule is now in its own numbered paragraph, at 215.2(A)(2). In this case, the neutral must have a size that is not smaller than the required size of an equipment grounding conductor for the system, as determined by Table 250.122. As we have seen when we looked at conduit fill for nonmetallic conduit, the required size is 2/0 AWG for this load if a 125 percent OCPD were used (1000 A) and 1/0 if the 100 percent OCPD (800 A) is used. Since the total neutral capacity will be 3 times a 350-kcmil conductor, this will not be a factor in this case. This issue has significance in instances where the overwhelming majority of the load is line-to-line, resulting in calculated neutral sizes that may be very small, to the point of not being able to handle a short circuit.

Note also that although 250.122(F) normally requires equipment grounding conductors in each parallel raceway to qualify independently as fully rated and sized conductors based on the full rating of the OCPD, this special provision in 215.2(A)(2) waives this rule and allows the three neutrals to be considered in terms of their collective ampacity as a group. In addition, 310.10(H)(1) sets the minimum size for paralleled conductors at 1/0 AWG, so in installations such as this that sets yet another floor under the minimum sizing on grounded circuit conductors generally. Again, for this installation with three sets of 350-kcmil neutral conductors, compliance with both these rules is not in doubt. However, because this is an **NEC Handbook**, the topic must be considered.

100-percent-protected circuit As was just indicated, whether a 100-percent-rated CB or a non-100-percent-rated CB is used, the Code permits the neutral conductor for both circuits to be the same size. For the example at hand, a neutral conductor of 350-kcmil, THHN-insulated copper conductor would be acceptable regardless of the type of CB used.

Raceway size As has long been the rule, the minimum acceptable size of raceway must be based on the amount of space occupied by the circuit conductors. And in no case may the cross-sectional area of the enclosed conductors exceed 40 percent of the raceway's cross-sectional area where three or more conductors are run within the raceway, as indicated in [Chap. 9](#) of the **NEC**.

Non-100-percent-protected circuit In accordance with Note 6 to the tables in [Chap. 9](#), where a mix of conductor sizes is to be run, conduit fill must be determined by using the specific dimensions given for conductors and raceway fill in Tables 5 and 5A and Table 4, respectively.

The phase conductors are 500 kcmil and the neutral is 350 kcmil. From Table 5, we take the square-inch area of a 500-kcmil THHN, which is 0.7073 sq in. That value is multiplied by 3, which is the number of phase conductors in each raceway. The product of that multiplication is then added to the Table 5 value given for the 350-kcmil THHN neutral conductor (0.5242 sq in.) as follows:

$$\begin{aligned}\text{Total area} &= (0.7073 \text{ sq in.} \times 3) + 0.5242 \text{ sq in.} \\ &= 2.1219 \text{ sq in.} + 0.5242 \text{ sq in.} \\ &= 2.6461 \text{ sq in.}\end{aligned}$$

Next, using the data given for the individual raceways in Table 4, we can determine the minimum acceptable size of raceway. Moving down the 40 percent-fill column of each raceway's table we find the size that is equal to, or greater than, 2.6461 sq in. The minimum size permitted for this combination of conductors in the common metal raceways—rigid metal conduit, intermediate metal conduit, or electrical metallic tubing—is 3 in. in each case.

To determine the minimum size of nonmetallic conduit, add the square-inch area of a No. 2/0 grounding conductor—from Table 5, if insulated, or from Table 8, if bare—to the 2.6461 sq in. total just determined. Then go to Table 4 and find the minimum size raceway that has a square-inch value in the 40 percent-fill column that is equal to, or greater than, the total of this combination.

100-percent-protected circuit As covered in Note 1 to the tables of [Chap. 9](#), where all the conductors are of the same size and have the same insulation, the data given in the tables of App. C are permitted to be used.

For rigid metal conduit, Table C8 shows that the minimum-size pipe permitted to contain four 350-kcmil THHN insulated conductors is metric designator 78 (trade size 3), which may contain five such 350s. However, Table C4 covering IMC permits four 350-kcmil THHN conductors in a single metric designator 63 (trade size 2½) raceway. And Table C1 also recognizes four 350-kcmil THHN conductors in metric designator 63 (trade size 2½) EMT.

Summary The choice we have to supply this 800 A of fluorescent lighting is between:

1. 1000-A CB/500-kcmil phase conductors/metric designator 78 (trade size 3) conduit
2. 800-A CB/350-kcmil phase conductors/metric designator 63 (trade size 2½) conduit (where IMC or EMT are used)

If larger raceway is used, then larger fittings, boxes, and so forth will also be required. If nonmetallic raceway is used, the equipment grounding conductor would be required to be larger in the 1000-A circuit (2/0 versus 1/0). And in either case, the labor costs will rise.

In addition to those economic realities, a check of one manufacturer's pricing indicates that the 100-percent-rated 800-A CB is actually *less expensive* than the non-100-percent-rated 1000-A device, primarily because of the jump in frame size. That is, the 1000-A CB has a 1200-A frame size while the 800-A breaker has an 800-A frame. The larger frame sizes are generally more robust. That is, they are designed to be capable of withstanding greater electrical stresses than the smaller frame sizes. As a result, the larger frame size will require more material, engineering, production costs, and so forth; therefore, a greater price is charged. There is an immediate savings to be realized simply by selecting the 800-A, 100-percent-rated device.

The final benefit that should be realized is the elimination of the need for equipment ground fault protection (GFPE). Remember Sec. 215.10 would require any feeder disconnect rated 1000 A or more on a 480Y/277-V system to be provided with equipment ground fault protection of the type required at services. Of course, this protection is *not* required where such equipment protection is provided ahead of the feeder disconnect, as long as that GFP has not been desensitized by a connection between ground and neutral on the line side of the disconnect, such as at the output of a separately derived system (e.g., a transformer). A 2008 **NEC** revision to 215.10 Exception No. 2 now expressly covers this point, and disallows any GFPE on the line side of a transformer from being considered as protecting any load side feeders.

One last thing to remember is that the exception to 215.2(A)(1) requires that the conductors used with 100-percent-rated OC devices must have an ampacity at least equal to the sum of continuous and noncontinuous loads. In the preceding example, the conductor size selected satisfies this requirement because of its 840-A ampacity, which includes all required deratings. If the conductor had a final ampacity of, say, 760 A, it would still satisfy the rules of 240.4 because the circuit is not rated over 800 A. *But*, the exception to this rule requires a minimum ampacity—as covered in 310.15 and the accompanying tables—that is *not less than* the total load supplied.

It certainly seems as if 100-percent-rated devices are the way to go in this particular case. Such an approach will allow maximum utilization and will do so at lower cost! (See [Fig. 215-7.](#))

Load: 800-A fluorescent lighting

Makeup: Three parallel sets of conductors
in three separate conduits

Non-100-percent-rated circuit

- Breaker: 1000 A
- Phase conductors: 500 kcmil (3/phase)
- Neutral conductors: 350 kcmil (1/pipe)
- Raceway size* (IMC): 3 in.

100-percent-rated circuit

- Breaker: 800 A
- Phase conductors: 350 kcmil (3/phase)
- Neutral conductors: 350 kcmil (1/pipe)
- Raceway size* (IMC): 2-1/2 in.

* All pullboxes, junction boxes, conduit bodies, etc., must be based on the raceway size.

Fig. 215-7. Non-100-percent-rated circuit versus 100-percent-rated circuit.

As shown in [Fig. 215-8](#), the rule of part (A)(3) of this section requires that the ampacity of feeder conductors must be at least equal to that of the service conductors where the total service current is carried by the feeder conductors. In the case shown, No. 4 TW aluminum is taken as equivalent to No. 6 TW copper and has the same ampacity (55 A).

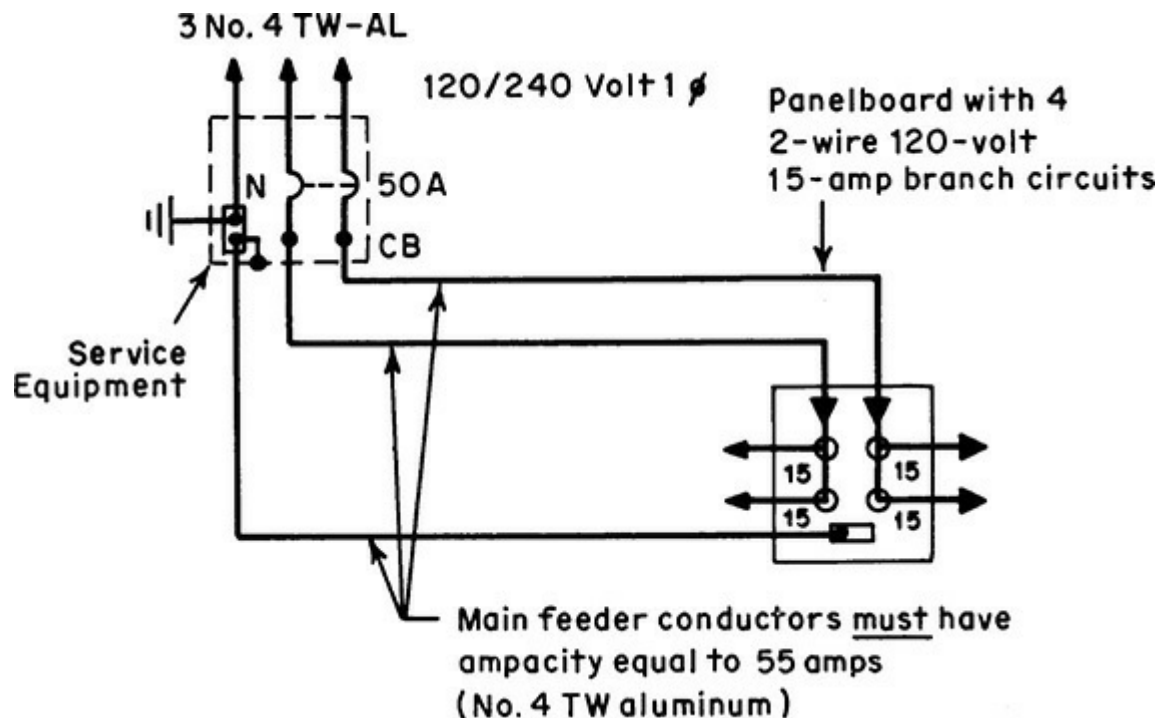

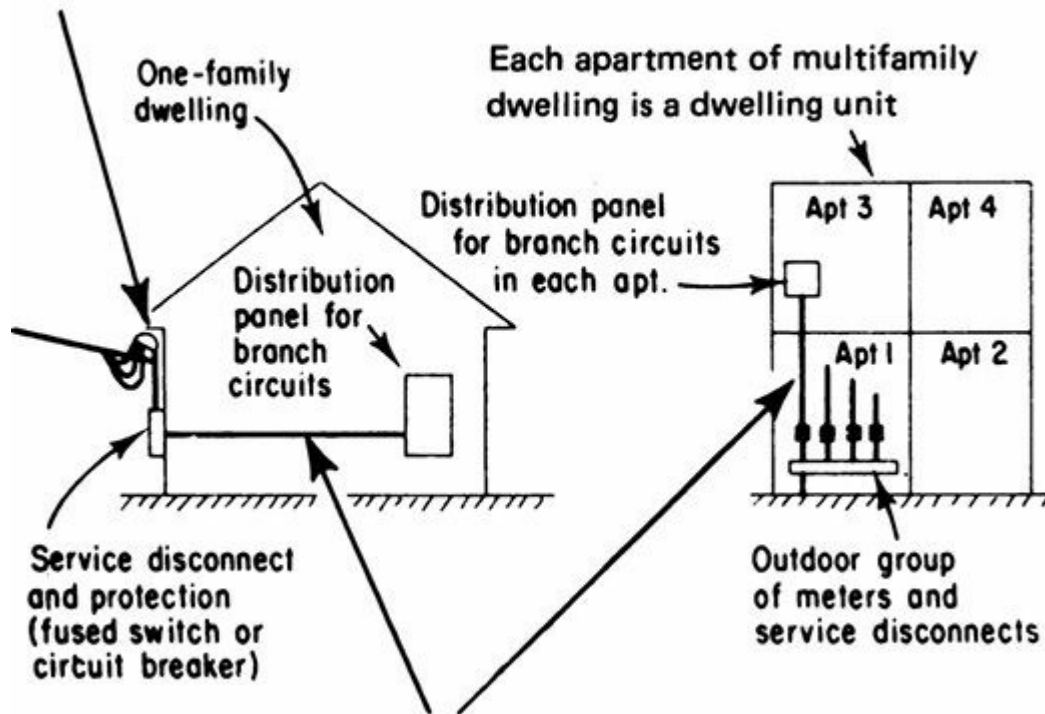

Fig. 215-8. Feeder conductors must not have ampacity less than service conductors. [Sec. 215.2(A)(3).]

In this section, part (A)(4) formerly noted that it was never necessary for feeder conductors at mobile homes or “individual dwelling units” to be larger than the service-entrance conductors (assuming use of the same conductor material and the same insulation). In particular, this was aimed at those cases where the size of service-entrance conductors for a dwelling unit is selected in accordance with the higher-than-normal ampacities permitted by 310.15(B)(7) for services to

residential occupancies. If a set of service conductors for an individual dwelling unit is brought in to a single service disconnect (a single fused switch or CB) and load and the service conductors are sized for the increased ampacity value permitted by 310.15(B)(7), diversity on the load-side feeder conductors gives them the same reduced heat-loading that enables the service conductors to be assigned the higher ampacity. This rule simply extended the permission of 310.15(B)(7) to those feeders and was applicable for any such feeder for a dwelling unit (a one-family house or an apartment in a two-family or multifamily dwelling) or for a mobile-home feeder ([Fig. 215-9](#)). Since 310.15(B)(7) now clearly covers such feeders, the 2014 **NEC** deleted this rule.

If 310.15(B)(7) is used to assign higher ampacity to the service-entrance conductors . . .

. . . then these feeder conductors may also be assigned the higher ampacities of 310.15(B)(7) (for instance, No. 2/0 copper THW is rated at 200 amps instead of 175 amps). (They do not have to be larger than the service conductors.)

Or, a multi family dwelling might be fed like this —

Fig. 215-9. Feeder conductors need not be larger than service-entrance conductors when higher ampacity is used. [Sec. 215.2(A)(3).]

Informational note No. 2 in 215.2(A)(1) comments on voltage drop in feeders. It should be carefully noted that with extremely few and very specific exceptions the **NEC** does not establish any mandatory rules on voltage drop for either branch circuits or feeders. The references to 3 and 5 percent voltage drops are purely advisory—that is, recommended maximum values of voltage drop.

The Code normally does not consider excessive voltage drop to be unsafe.

The voltage-drop note suggests not more than 3 percent for feeders supplying power, heating, or lighting loads. It also provides for a maximum drop of 5 percent for the conductors between the service-entrance equipment and the connected load. If the feeders have an actual voltage drop of 3 percent, then only 2 percent is left for the branch circuits. If a lower voltage drop is obtained in the feeder, then the branch circuit has more voltage drop available, provided that the total drop does not exceed 5 percent. For any one load, the total voltage drop is made up of the voltage drop in the one or more feeders plus the voltage drop in the branch circuit supplying that load.

Again, however, values stated in the informational note on voltage drop are recommended values and are not intended to be enforced as a requirement.

Voltage drop should always be carefully considered in sizing feeder conductors, and calculations should be made for peak load conditions. For maximum efficiency, the size of feeder conductors should be such that voltage drop up to the branch-circuit panelboards or point of branch-circuit origin is not more than 1 percent for lighting loads or combined lighting, heating, and power loads and not more than 2 percent for power or heating loads. Voltage drop in most cases is a design concern only, and the applicable design specification may impose lower limits of voltage drop. Voltage-drop limitations are shown in Fig. 215-10 for NEC levels and better levels of drop, as follows:

1. For combinations of lighting and power loads on feeders and branch circuits, use the voltage-drop percentages for lighting load (at left in Fig. 215-10).

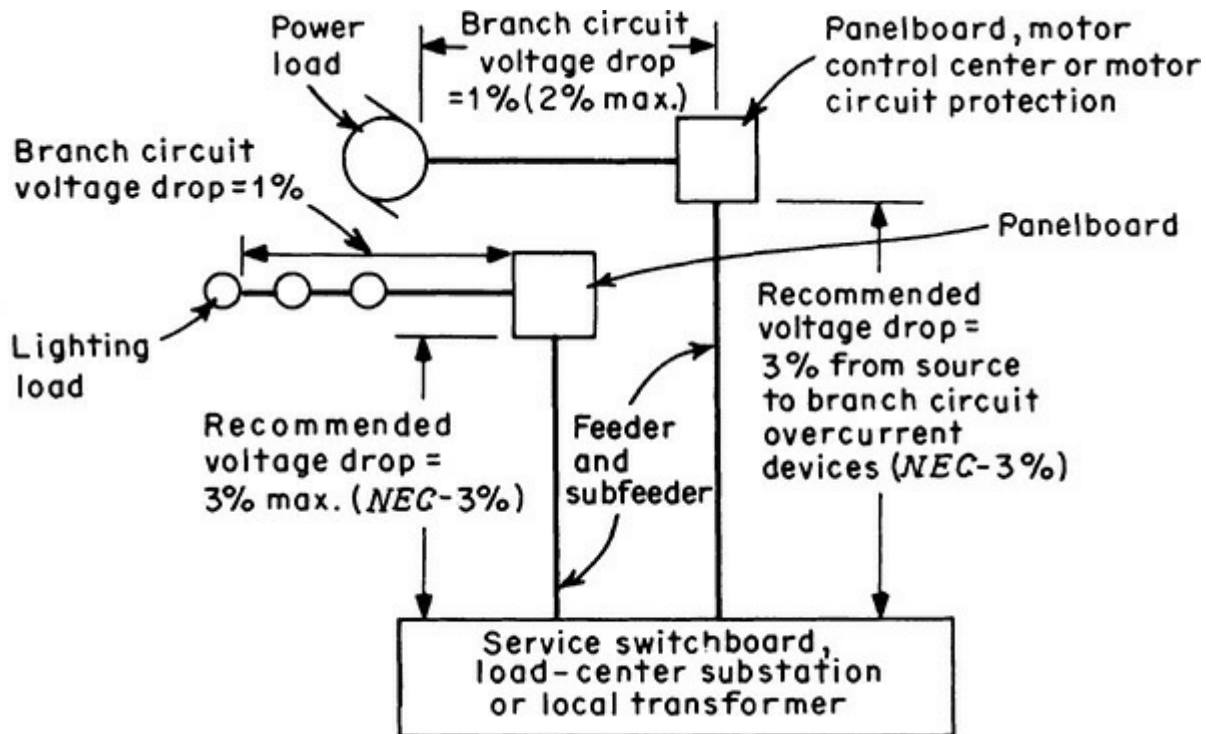

Fig. 215-10. Recommended basic limitations on voltage drop. (Sec. 215.2, informational note No. 2.)

2. The word *feeder* here refers to the overall run of conductors carrying power from the source to the point of final branch-circuit distribution, including feeders, subfeeders, sub-subfeeders, and so forth. As previously noted, the prefix “sub” is no longer correct code terminology.
3. The voltage-drop percentages are based on nominal circuit voltage at the source of each voltage level. Indicated limitations should be observed for each voltage level in the

distribution system.

There are many cases in which the previously mentioned limits of voltage drop (1 percent for lighting feeders, etc.) should be relaxed in the interests of reducing the prohibitive costs of conductors and conduits required by such low drops. In many installations a 5 percent drop in feeders is not critical or unsafe—such as in apartment houses.

Voltage-drop tables and calculators are available from a good number of electrical equipment manufacturers. Voltage-drop calculations vary according to the actual circuit parameters (e.g., ac or dc, single- or multiphase, power factor, circuit impedance, line reactance, types of enclosures [nonmetallic or metallic], length and size of conductors, and conductor material [copper, copper-clad aluminum, or aluminum]).

Calculations of voltage drop in any set of feeders can be made in accordance with the formulas given in the electrical design literature, such as those shown in [Fig. 215-11](#). From this calculation, it can be determined if the conductor size initially selected to handle the load will be adequate to maintain voltage drop within given limits. If it is not, the size of the conductors must be increased (or other steps taken where conductor reactance is not negligible) until the voltage drop is within prescribed limits. Many such graphs and tabulated data on voltage drop are available in handbooks and from manufacturers. [Figure 215-12](#) shows an example of excessive voltage drop—over 10 percent in the feeder.

**Two-wire, single-phase circuits
(inductance negligible)**

$$V = \frac{2k \times L \times I}{d^2} = 2R \times L \times I$$

$$d^2 = \frac{2k \times L \times I}{V}$$

V = drop in circuit voltage (volts)

R = resistance per ft of conductor (ohms/ft)

I = current in conductor (amperes)

**Three-wire, single-phase circuits
(inductance negligible)**

$$V = \frac{2k \times L \times I}{d^2}$$

V = drop between outside conductors (volts)

I = current in more-heavily loaded outside conductor (amps)

**Three-wire, three-phase circuits
(inductance negligible)**

$$V = \frac{2k \times L \times I}{d^2} \times 0.866$$

V = voltage drop of 3-phase circuit

**Four-wire, three-phase balanced circuits
(inductance negligible)**

Lighting loads

Voltage drop between one outside conductor and neutral equals one-half of drop calculated by formula above for 2-wire circuits.

Motor loads

Voltage drop between any two outside conductors equals 0.866 times the drop determined by formula above for two-wire circuits.

In the above formulas:

L = one-way length of circuit (ft)

d² = cross-section area of conductor (circular mils)

k = resistivity of conductor metal (cir mil-ohms/ft)

= 12 for circuits loaded to more than 50%
of allowable circuit capacity

= 11 for circuits loaded less than 50%

= 18 for aluminum or copper-clad aluminum
conductors

Example: 230-V two-wire heating circuit. Load is 24 A. Circuit size is No. 10 AWG copper, and the one-way circuit length is 200 ft.

$$VD = \frac{24 \times 200 \times 24}{10,380} = \frac{115,200}{10,380} = 11$$

An 11-V drop on a 230-V circuit is about a 5 percent drop (11/230 = 0.0478). No. 8 AWG copper conductors would be needed to reduce the voltage drop to 3 percent on the branch circuit and allow 2 percent more on the feeder.

Fig. 215-11. Calculating voltage drop in feeder circuits. (Sec. 215.2, informational note No. 2.)

1. No. 10 copper conductor has a resistance of 1.018 ohms per 1000 ft (Table 8, Chapter 9).
2. The two 500-ft lengths of circuit conductors total 1000 ft and have a resistance of 1.018 ohms.
3. Voltage Drop = load current x conductor resistance
= 24 amps x 1.018 ohms = 24.43 volts
4. $\frac{24.43}{240} = 10.2\%$ VOLTAGE DROP—NEC SUGGESTS MAX. 3%

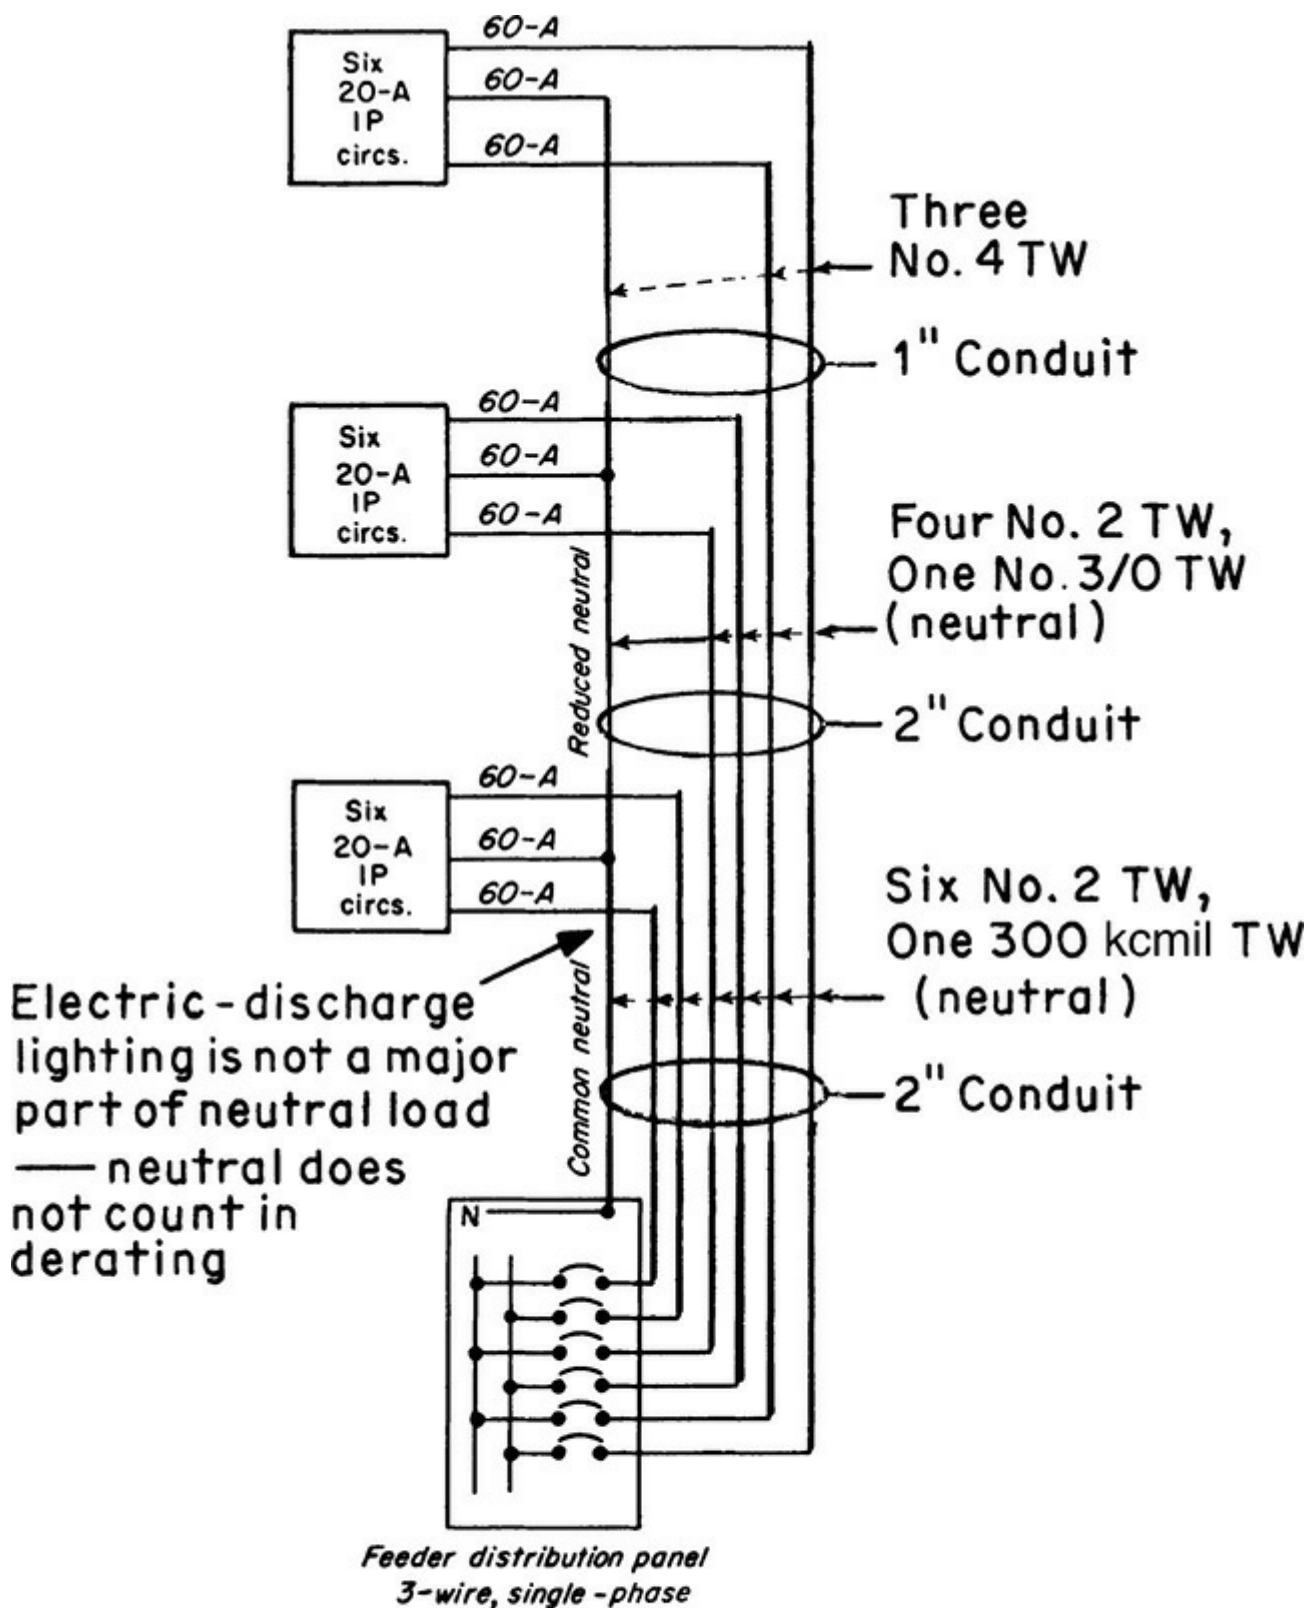

Fig. 215-12. Feeder voltage drop should be checked. (Sec. 215.2, informational note No. 2.)

215.2(B). Feeders Over 600 V. This part of the section covers medium-voltage feeders, for which the ampacity rules are far different. The basic rule is that the ampacity of a medium-voltage feeder supplying transformers must match the sum of the primary ratings of the transformers supplied. If such a feeder also supplies utilization equipment, then the minimum ampacity is the sum of any transformer primaries supplied plus the utilization load taken at 125 percent of its maximum design loading based on the maximum current that would be drawn at any one time, thereby allowing for noncoincident loads. If, however, a facility has engineering staff with documented training and experience working with medium-voltage power systems, and they exercise supervision over the monitoring, maintenance, and service required for the system, then the engineering staff may alter the sizing of the feeder conductors that are to be installed. Because the majority of the **NEC** is adjusting upwards the threshold for applying high-voltage rules from 600 V to 1000V, 215.3 Exception No. 2 has been modified so only circuits at or over 1000V move into Part X of Art. 240.

215.4. Feeders with Common Neutral Conductor. A frequently discussed Code requirement is that of 215.4, covering the use of a common neutral with more than one set of feeders. This section says that a common neutral feeder may be used for two or three sets of 3-wire feeders or two sets of 4-wire feeders. It further requires that all conductors of feeder circuits employing a common neutral feeder must be within the same enclosure when the enclosure or raceway containing them is metal.

A common neutral is a single neutral conductor used as the neutral for more than one set of feeder conductors. It must have current-carrying capacity equal to the sum of the neutral conductor capacities if an individual neutral conductor were used with each feeder set. [Figure 215-13](#) shows a typical example of a common neutral, used for three-feeder circuits. A common neutral may be used only with feeders. It may never be used with branch circuits, except outdoors as covered in 225.7. A

single neutral of a multiwire branch circuit is not a “common neutral.” It is the neutral of only a single circuit, even though the circuit may consist of 3 or 4 wires. A feeder common neutral is used with more than one feeder circuit.

Note: Conductor sizes conform to reduced carrying capacities for more than three conductors in conduit.

Fig. 215-13. Example of three feeder circuits using a single, “common neutral”—with neutral size

reduced as permitted. (Sec. 215.4.)

215.5. Diagrams of Feeders. This is the code section that authorizes the inspection community to request, and to insist on if necessary, feeder diagrams and load calculations, stipulations of demand factors applied, and recitations of wire sizes and insulation types, etc.

215.7. Ungrounded Conductors Tapped from Grounded Systems. Refer to 210.19 for a discussion that applies as well to feeder circuits as to branch circuits.

215.9. Ground-Fault Circuit-Interrupter Protection for Personnel. A ground-fault circuit interrupter may be located in the feeder and protect all branch circuits connected to that feeder. In such cases, the provisions of 210.8 and Art. 590 on temporary wiring will be satisfied and additional *downstream* ground-fault protection on the individual branch circuits would not be required. It should be mentioned, however, that downstream ground-fault protection is more desirable than ground-fault protection in the feeder because less equipment will be deenergized when the ground-fault circuit interrupter opens the supply in response to a line-to-ground fault.

As shown in Fig. 215-14, if a ground-fault protector is installed in the feeder to a panel for branch circuits to outdoor residential receptacles, this protector will satisfy the **NEC** as the ground-fault protection required by 210.8 for such outdoor receptacles.

215.10. Ground-Fault Protection of Equipment. This section mandates equipment ground-fault protection for every feeder disconnect switch or circuit used on a 480Y/277-V, 3-phase, 4-wire feeder where the disconnect is rated 1000 A or more, as shown in Fig. 215-15. This is a very significant Code requirement for ground-fault protection of the same type that has long been required by 230.95 for every *service* disconnect rated 1000 A or more on a 480Y/277-V service.

Fig. 215-14. GFCI in feeder does satisfy as protection for branch circuits. (Sec. 215.9.)

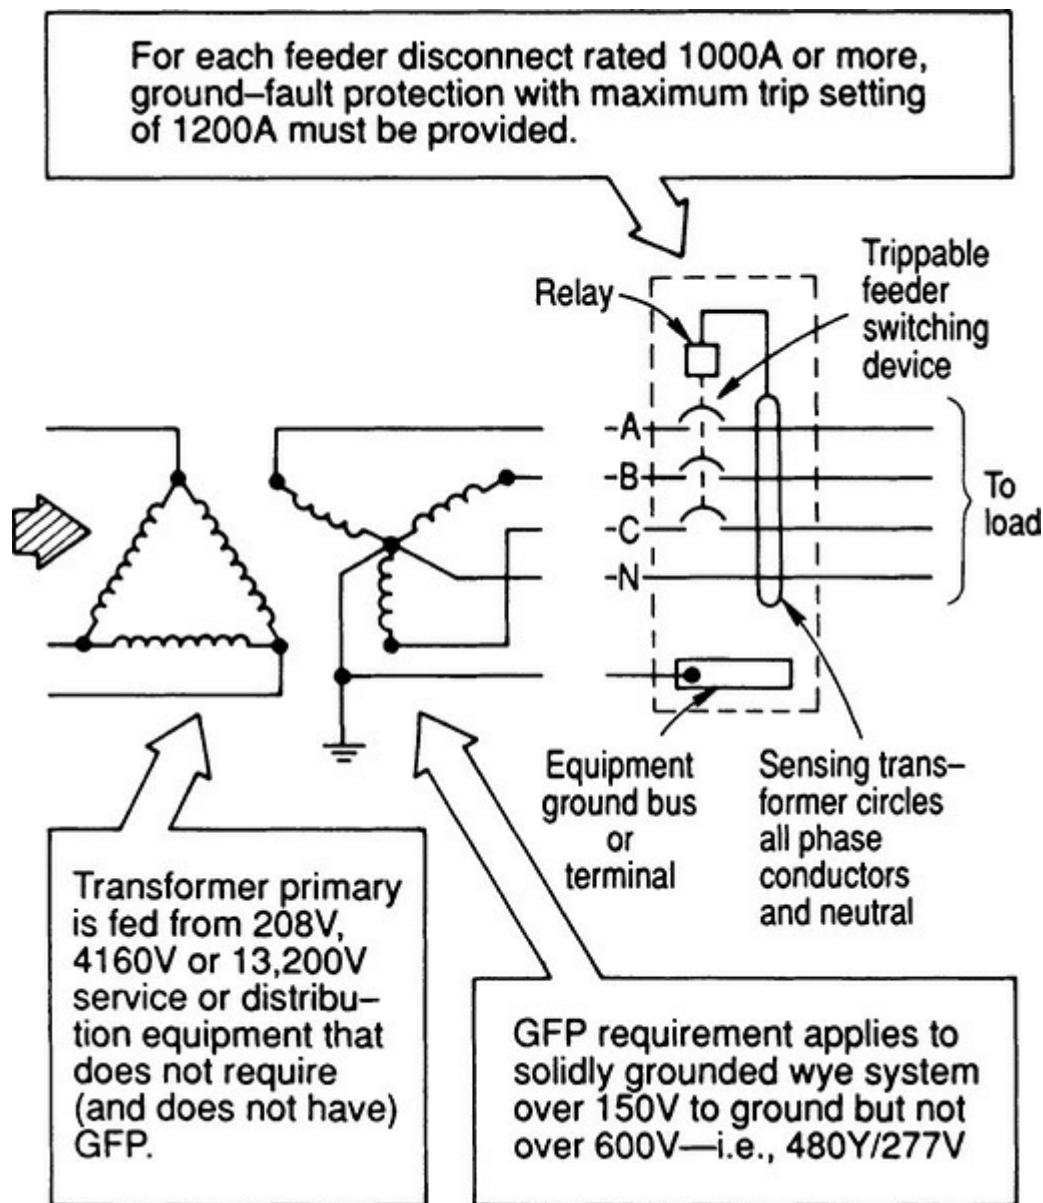

Fig. 215-15. A 480Y/277-V feeder disconnect rated 1000 A or more must have ground-fault protection (GFP) if there is not GFP on its supply side. (Sec. 215.10.)

As indicated by Exception No. 1, GFPE of equipment may be omitted for “continuous industrial” processes, but only if “additional” or “increased” hazards will result where a process is shut down in a nonorderly manner. An example of this principle at work is 695.6(G), which forbids the application of GFPE to a fire pump circuit. Since Chap. 6 provisions automatically vary the requirements of Chap. 1 through 4 per 90.3, the former Exception No. 2 in this location that excluded fire pump disconnects from the need for equipment GFPE has been deleted as unnecessary.

Exception No. 2 notes that feeder ground-fault protection is not required on a feeder disconnect if equipment ground-fault protection is provided on the supply (line) side of the feeder disconnect and, as noted previously, this exception does not apply when a transformer is interposed between the GFPE and the large feeder to be protected.

The substantiation submitted as the basis for the addition of this new rule stated as follows:

Substantiation: The need for ground-fault equipment protection for 1000 amp or larger 277/480 grounded system is recognized and required when the service equipment is 277/480 volts. This proposal will require the same needed protection when the service equipment is not 277/480 volts. Past proposals attempted to require these feeders be treated as services in order to achieve this protection, but treating a feeder like a service created many other concerns. This proposal only addresses the feeder equipment

ground-fault protection needs when it is not provided in the service equipment.

As noted, this rule calls for this type of feeder ground-fault protection when ground-fault protection is not provided on the supply side of the feeder disconnect, such as where a building has a high-voltage service (say, 13,200 V) or has, say, a 208Y/120-V service with a load-side transformer stepping-up the voltage to 480Y/277 V—because a service at either one of these voltages (e.g., 13.2 kV and 208Y/120 V) is not required by 230.95 to have GFP. The wording of this exception also prohibits GFPE on the supply side of a transformer from qualifying as protecting conductors on its load side for any other reason, such as instances where a one-to-one isolating transformer is used to supply feeder conductors where the applied voltage and current require GFPE under this section.

215.11. Circuits Derived from Autotransformers. This section recognizes application of autotransformers for supplying a feeder to a panelboard or group of overcurrent devices. This is the same permission given for branch circuits (see 210.9), and with comparable exceptions.

215.12. Identification for Feeders. The rules in parts (A), (B), and (C) of this section present the same requirements for feeder conductors that are given for branch circuits in 210.5. See 210.5 for a discussion of these rules. Note that this section has been correlated with the changes in 210.5 made in the 2014 **NEC** to systematically cover dc distributions.

ARTICLE 220. BRANCH-CIRCUIT, FEEDER, AND SERVICE LOAD CALCULATIONS

220.1. Scope. The revision of this article in the 2005 edition of the Code provides a more logical and coherent approach for establishing the minimum rating of conductors used as branch circuits, feeders, and service conductors. Better arrangement and segregation of rules applying to branch circuits from those that apply to feeders and/or service conductors and vice versa has reduced confusion and made the intent of the Code more understandable. The same Code-making panel (CMP 2) has jurisdiction over Arts. 210, 215, and 220. The article reorganization in 2005 followed an earlier reassignment of provisions among these three articles with the objective that Art. 220 should only address how to calculate a load, whether expressed in amperes of current on a wire or in terms of volt-amperes of power required for some portion of an electrical system. For this reason, the discussion that follows will only address load calculations. How to translate those results into an appropriate wire selection is a task left to other locations in the **NEC** and in this book, particularly at the end where Annex D, Example D3(a) is covered. The load calculation examples in Annex D, including D3(a), are also under the jurisdiction of CMP 2, so the examples should correlate with procedures in Art. 220.

The general rules related to calculating branch-circuit feeder and service conductors are presented in Part I and these sections apply across the board. The rules for calculating the minimum ratings and sizes for branch circuits are given in Part II, while those for feeders and service conductors are covered in Part III. Part IV covers the alternate methods of calculating feeder loads in certain cases. Part V provides procedures for calculating minimum sizes of feeders and service conductors supplying a farm.

All the calculations and design procedures covered by Art. 220 involve mathematical manipulation of units of voltage, current, resistance, and other measures of electrical conditions or characteristics.

220.5. Calculations. NEC references to voltages vary considerably. The Code contains references to 120, 125, 115/230, 120/240, and 120/208 V. Standard voltages to be used for the calculations that have to be made to observe the rules of Art. 220 are 120, 120/240, 208Y/120, 240, 480Y/277, 480, 600Y/347, and 600 V. But use of lower voltage values (115, 230, 440, etc.) as denominators in calculations would not be a Code violation because the higher current values that result would ensure Code compliance because of greater capacity in circuit wires and other equipment. Nevertheless, the approach in this book will be to always use the standard values. If a circuit is to be oversized for design reasons, which is often an excellent idea, it is preferable to add the allowance for future growth openly, instead of hiding that decision by using a bogus voltage. Remember that for the majority of loads a decreased voltage results in decreased load current, which is why electric utilities, when faced with demand they cannot cope with, reduce voltage (brownout).

In all electrical systems, there is a normal, predictable spread of voltage values over the impedances of the system equipment. It has been common practice to assign these basic levels to each nominal system voltage. The highest value of voltage is that at the service entrance or transformer secondary, such as 480Y/277 V. Then considering a voltage drop due to impedance in the circuit conductors and equipment, a “nominal” mid-system voltage designation would be 460Y/265. Variations in “nominal” voltages have come about because of (1) differences in utility-supply voltages throughout the country, (2) varying transformer secondary voltages produced by different and often uncontrolled voltage drops in primary feeders, and (3) preferences of different engineers and other design authorities. Although an uncommon voltage system within the United States, the reference to 600Y/347V is one of many additions that were made to the 1996 NEC that attempt to harmonize the NEC with the Canadian Electrical Code.

Because the NEC is produced by contributors from all over the nation and of varying technical experiences, it is understandable that diversity of designations would creep in. As with many other things, we just have to live with problems until we solve them.

To standardize calculations, Annex D covering the examples at the end of the code book also specifies that nominal voltages of 120, 120/240, 240, and 208/120 V are to be used in computing the ampere load on a conductor. The reason for this is the plain wording of 220.5(A).

In some places, the NEC adopts 115 V as the basic operating voltage of equipment designed for operation at 110–125 V. That is indicated in Tables 430.248 to 430.251. References are made to “rated motor voltages” of 115, 230, 460, 575, and 2300 V—all values over 115 are integral multiples of 115. The last note in Tables 430.249 and 430.250 indicates that motors of those voltage ratings are applicable on systems rated 110–120, 220–240, 440–480, and 550–600 V. Although the motors can operate satisfactorily within those ranges, it is better to design circuits to deliver rated voltage. These Code voltage designations for motors are consistent with the trend over recent years for manufacturers to rate equipment for corresponding values of voltage. These voltages are used in the motor rules for historical reasons and nowhere else in the Code.

In this context, the issue of significant figures needs to be addressed. Many calculations involve dividing volt-amperes by volts to get amperes, or something comparable. Usually, such a calculation will result in some form of infinitely repeating decimal. Given today’s calculators, work with these machines is simple and potentially misleading due to the illusion of precision. Load calculations are not an exact science. The inherent nature of large-scale electrical power systems is such that three significant figures is probably more than can actually be relied on as having any meaning whatsoever. The newest example in Annex D, Example D3(a), squarely addresses this issue for the first time,

stating “For reasonable precision, volt-ampere calculations are carried to three significant figures only.” The example goes on to state that “Where loads are converted to amperes, the results are rounded to the nearest whole ampere” and due reference is made to 220.5(B).

Rounding to the nearest whole ampere is fully in accordance with these concepts and fully validated statistical procedures. Some numbers go up a little and others go down; there is no real decrease in safety or ultimate results. The majority of tax calculations are now being done as whole dollar calculations for the same reasons. Sec. 220.5(B) specifically authorizes the process for load calculations, with results of 0.5 and up resulting in the number to the left of the decimal increasing by one, and results of less than 0.5 being discarded.

220.12. Lighting Load for Specified Occupancies. Article 220 gives the basic rules on calculation of loads for branch circuits and feeders. The task of calculating a branch-circuit load and then determining the size of circuit conductors required to feed that load is common to all electrical system calculations. Although it may seem to be a simple matter (and it usually is), there are many conditions which make the problem confusing (and sometimes controversial) because of the **NEC** rules that must be observed.

Code Table 220.12 lists certain occupancies (types of buildings) for which a minimum general lighting load is specified in volt-amperes per square meter (square foot). In each type of building, there must be adequate branch-circuit capacity to handle the total load that is represented by the product of volt-amperes per square foot times the square-foot area of the building. For instance, if one floor of an office building is 40,000 sq ft in area, that floor must have a total branch-circuit capacity of 3700 m^2 ($40,000 \text{ ft}^2$) times 39 VA/m^2 ($3\frac{1}{2} \text{ VA/ft}^2$) (Code Table 220.12) for general lighting. Note that the total load to be used in calculating required circuit capacity must never be taken at less than the indicated volt-amperes per unit area times the area for those occupancies listed. Of course, if the branch-circuit load for lighting is determined from a lighting layout of specific fixtures of known volt-ampere rating, the load value must meet the previous volt-amperes-per-unit area minimum; and if the load from a known lighting layout is greater, then the greater volt-ampere value must be taken as the required branch-circuit capacity.

Note that the bottom of Table 220.12 requires a minimum general lighting load of 6 VA/m^2 ($\frac{1}{2} \text{ VA/ft}^2$) to cover branch-circuit and feeder capacity for halls, corridors, closets, and all stairways. Likewise, an additional 3 VA/m^2 ($\frac{1}{4} \text{ VA/ft}^2$) must be provided for storage areas.

As indicated in 220.12, when the load is determined on a volt-amperes-per-unit area basis, open porches, garages, unfinished basements, and unused areas are not counted as part of the area for dwelling unit calculations. Also note that area calculations must be made using the *outside* dimensions of the “building, apartment, or other area involved.”

When fluorescent or HID lighting is used on branch circuits, the presence of the inductive effect of the ballast or transformer creates a power factor consideration. Determination of the load in such cases must be based on the total of the volt-ampere rating of the units and not on the wattage of the lamps.

Based on extensive analysis of load densities for general lighting in office buildings, Table 220.12 requires a minimum unit load of only $3\frac{1}{2} \text{ VA/sq ft}$ —rather than the previous unit value of 5—for “office buildings” and for “banks.”

A footnote at the bottom of the table requires compliance with 220.14(K) for banks and office buildings. That rule establishes the minimum load capacity required for receptacles in such

occupancies. The rule in 220.14(K) calls for capacity to be provided based on the larger of the following: 11 VA/m² (1 VA/ft²) or the actual connected number of receptacles at 1.5 A apiece. In those cases where the actual number of receptacles is not known at the time feeder and branch-circuit capacities are being calculated, it seems that a unit load of 4½ VA/sq ft must be used, and the calculation based on that figure will yield minimum feeder and branch-circuit capacity for both general lighting and all general-purpose receptacles that may later be installed.

Of course, where the actual number of general-purpose receptacles is known, the general lighting load is taken at 3½ VA/sq ft for branch-circuit and feeder capacity, and each strap or yoke containing a single, duplex, or triplex receptacle is taken as a load of 180 VA to get the total required branch-circuit capacity, with the demand factors of Table 220.44 applied to get the minimum required feeder capacity for receptacle loads. Again, where the actual connected known receptacle load is less than 1 VA/sq ft, then a value of 1 VA/sq ft must be added to the total.

The 2014 **NEC** added an exception to this rule, which may be the beginning of more extensive changes. For the first time an Art. 220 load, in this case for lighting, can be based on something external to the **NEC**. In this case the local energy code results can be used if the building was designed and constructed to meet those requirements. This process is conditioned on a power monitoring system being in place that watches the entire “general lighting load of the building” and generates an alarm if that load exceeds the value in the energy code. In addition, if you decide to use this exception, the demand factors in Table 220.42 are off limits.

Until this exception was added, the system load had to be figured strictly by Art. 220 procedures. This has far-reaching effects, because 210.11(B) requires the electrical system upstream of branch-circuit panelboards to fully accommodate Art. 220 results; only the number of branch circuits actually installed can be reduced to match the connected load. Facility engineers have complained for generations that they had to provide feeder and service capacity far in excess of realistic demand, and the electric utilities routinely scoff at **NEC** generated demand results. The mandated alarm systems should be easily capable of being programmed to record actual demand. Assuming the sky does not fall, look for public input going forward aimed at further adjustments of Art. 220 results based on this experience. The 2017 **NEC**, as predicted, added to this direction through a second exception here. Now, if a bank or office building is designed and constructed in accordance with a local building code that limits the lighting density to not over 1.2 VA/ft², a reduction from table lighting loads in those categories by 1 VA/ft² can be applied.

220.14. Other Loads—All Occupancies. This section covers rules on providing branch-circuit capacity for loads other than general lighting and designates specific amounts of load that must be allowed for each outlet. This rule establishes the minimum loads that must be allowed in computing the minimum required branch-circuit capacity for general-use receptacles and “outlets not used for general illumination.” 220.14(D) requires that the actual volt-ampere rating of a recessed lighting fixture be taken as the amount of load that must be included in branch-circuit capacity. This permits local and/or decorative lighting fixtures to be taken at their actual load value rather than having them be taken as “other outlets,” which would require a load allowance of “180 volt-amperes per outlet”—even if each such fixture were lamped at, say, 25 W. Or, in the case where a recessed fixture contained a 300-W lamp, allowance of only 180 VA would be inadequate. Note that these loads are not the general lighting loads addressed in 220.12 and included in volt-ampere per unit area calculations, but rather specialized lighting that may apply in certain applications as described.

Similarly, sign and outline lighting must also be considered separately. Such lighting is *not* part of the general lighting load and therefore must be accounted for as indicated in the specific sections that cover those types of equipment. In this case Art. 600 has a mandatory minimum circuiting allowance that must be built in to most commercial load calculations. Of course, if the actual load is known to be larger, then the larger number enters the load calculation.

Receptacle Outlets

The last sentence of 220.14(I) calls for “each single or each multiple receptacle *on one yoke*” to be taken as a load of “not less than 180 volt-amperes”—in commercial, institutional, and industrial occupancies. The rule requires that every general-purpose, single or duplex or triplex convenience receptacle outlet in nonresidential occupancies be taken as a load of 180 VA, and that amount of circuit capacity must be provided for each such outlet (Fig. 220-1). Code intent is that each individual device yoke—whether it holds one, two, or three receptacles—is a load of 180 VA. This rule makes clear that branch-circuit and feeder capacity must be provided for receptacles in nonresidential occupancies in accordance with loads calculated at 180 VA per receptacle yoke.

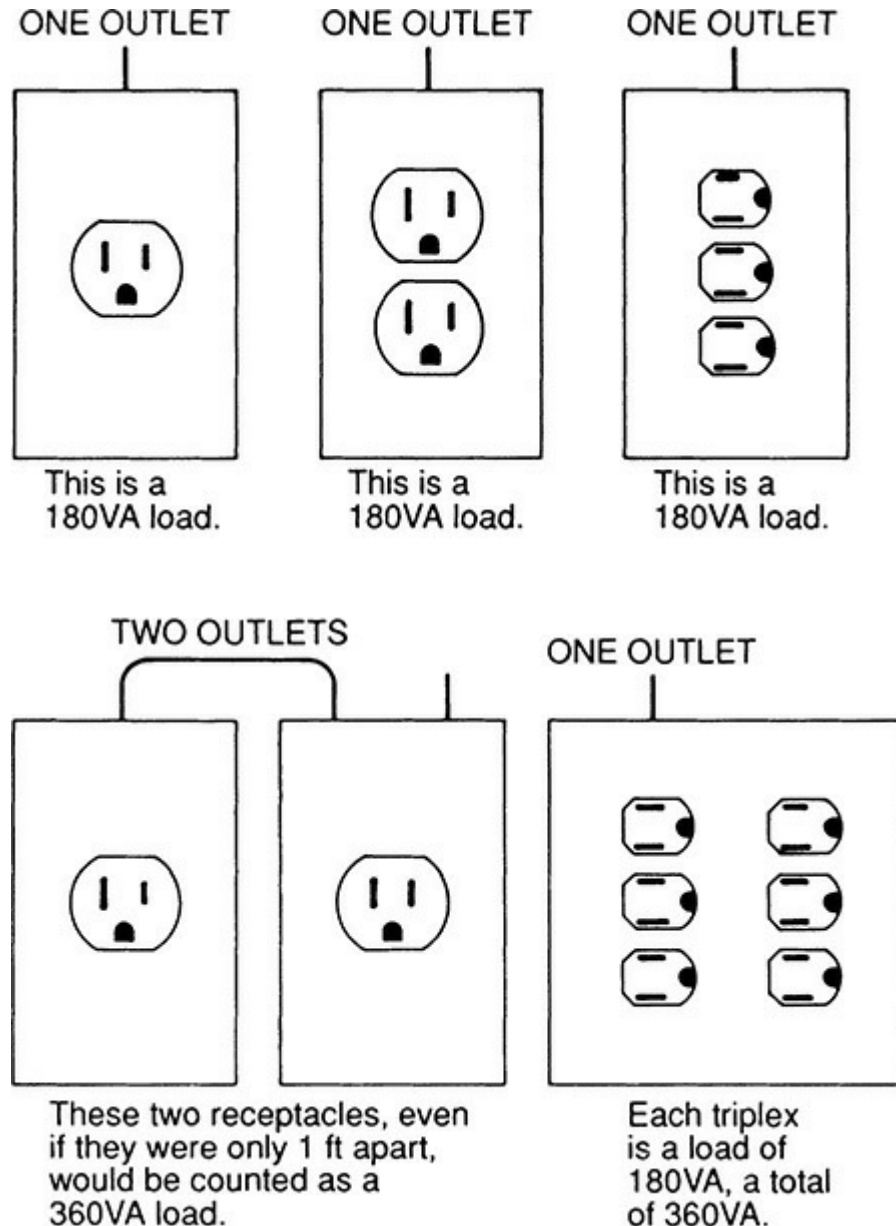

Fig. 220-1. Classification of single, duplex, and triplex receptacles. [Sec. 220.14(I).]

If a 15-A, 120-V circuit is used to supply *only* receptacle outlets, then the maximum number of general-purpose receptacle outlets that may be fed by that circuit is

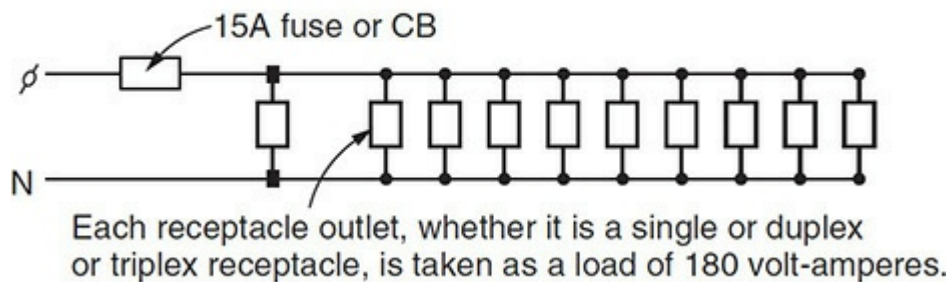

$$15 \text{ A} \times 120 \text{ V} + 180 \text{ VA or 10 receptacle outlets}$$

For a 20-A, 115-V circuit, the maximum number of general-purpose receptacle outlets is

$$20 \text{ A} \times 120 \text{ V} + 180 \text{ VA or 13 receptacle outlets}$$

See [Fig. 220-2](#).

15A, 120V CIRCUIT—Maximum of 10 receptacle outlets

20A, 120V CIRCUIT—Maximum of 13 receptacle outlets

Fig. 220-2. Number of receptacles per circuit, nonresidential occupancy. As shown in the drawing, there is one yoke per outlet. Where multiple yokes are installed at an outlet, the 180-VA requirement applies per yoke. [Sec. 220.14(I).]

Although the Code gives the previously described data on maximum permitted number of receptacle outlets in commercial, industrial, institutional, and other nonresidential installations, there are no such limitations on the number of receptacle outlets on residential branch circuits. There are reasons for this approach.

In 210.52, the Code specifies where and when receptacle outlets are required on branch circuits. Note that there are no specific requirements for receptacle outlets in commercial, industrial, and institutional installations other than for store show windows in 210.62 and equipment for conditioned air and refrigeration in 210.63. There is the general rule that receptacles do have to be installed where flexible cords are used. In nonresidential buildings, if flexible cords are not used, there is no *requirement* for receptacle outlets. They have to be installed only where they are needed, and the number and spacing of receptacles are completely up to the designer. But because the Code takes the position that receptacles in nonresidential buildings only have to be installed where needed for connection of specific flexible cords and caps, it demands that where such receptacles are installed,

each must be taken as a load of 180 VA.

A different approach is used for receptacles in dwelling-type occupancies. The Code simply assumes that cord-connected appliances will always be used in all residential buildings and requires general-purpose receptacle outlets of the number and spacing indicated in 210.52 and 210.60. These rules cover one-family houses, apartments in multifamily houses, guest rooms in hotels and motels, living quarters in dormitories, and so forth. But because so many receptacle outlets are required in such occupancies and because use of plug-connected loads is intermittent and has great diversity of load values and operating cycles, the Code notes at the bottom of Table 220.12 that the loads connected to such receptacles are adequately served by the branch-circuit capacity required by 210.11, and no additional load calculations are required for such outlets.

In dwelling occupancies, it is necessary to first calculate the total “general lighting load” from 220.12 and Table 220.12 (at 33 VA/m² [3 VA/ft²] for dwellings or 22 VA/m² [2 VA/ft²] for hotels and motels, including apartment houses without provisions for cooking by tenants) and then provide the minimum required number and rating of 15-A and/or 20-A general-purpose branch circuits to handle that load as covered in 210.11(A). As long as that basic circuit capacity is provided, any number of lighting outlets may be connected to any general-purpose branch circuit, up to the rating of the branch circuit if loads are known. The lighting outlets should be evenly distributed among all the circuits. Although residential lamp wattages cannot be anticipated, the Code method covers fairly heavy loading.

When the preceding Code rules on circuits and outlets for general lighting in dwelling units, guest rooms of hotels and motels, and similar occupancies are satisfied, general-purpose convenience receptacle outlets may be connected on circuits supplying lighting outlets; or receptacles only may be connected on one or more of the required branch circuits; or additional circuits (over and above those required by Code) may be used to supply the receptacles. But no matter how general-purpose receptacle outlets are circuited, *any number* of general-purpose receptacle outlets may be connected on a residential branch circuit—with or without lighting outlets on the same circuit.

And when small-appliance branch circuits are provided in accordance with the requirements of 210.11(C)(1), *any number* of small-appliance receptacle outlets may be connected on the 20-A small-appliance circuits—but *only* receptacle outlets may be connected to these circuits and only in the specified rooms.

210.52(A) applies to spacing of receptacles connected on the 20-A small-appliance circuits, as well as spacing of general-purpose receptacle outlets. That section, therefore, establishes the *minimum* number of receptacles that must be installed for greater convenience of use.

220.14(H) requires branch-circuit capacity to be calculated for multioutlet assemblies (prewired surface metal raceway with plug outlets spaced along its length). Part **(H)(2)** says that each 300-mm (1-ft) length of such strip must be taken as a 180-VA load when the strip is used where a number of appliances are likely to be used simultaneously. For instance, in the case of industrial applications on assembly lines involving frequent, simultaneous use of plugged-in tools, the loading of 180 VA/ft must be used. Part **(H)(1)** allows loading of 180 VA for each 1.5-m (5-ft) section in commercial or institutional applications of multioutlet assemblies when use of plug-in tools or appliances is not heavy. [Figure 220-3](#) shows an example of the more intensive load calculation.

Fig. 220-3. Calculating required branch-circuit capacity for multioutlet assembly. [Sec. 220.14(H).]

Part (G) permits branch-circuit capacity for the outlets required by 210.62 for show windows to be calculated, as shown in Fig. 220-4—instead of using the load-per-outlet value (180 VA) from part (I) of 220.14.

Fig. 220-4. Alternate method for calculating show-window circuit capacity. [Sec. 220.14(G).]

As noted by 220.14(B), 220.54 is permitted to be used in calculating the size of branch-circuit conductors for household clothes dryers; this results in a load of 5000 VA being used for a household electric dryer when the actual dryer rating is not known. This is essentially an exception to 220.14(A), which specifies that the “ampere rating of appliance or load served” shall be taken as the branch-circuit load for an outlet for a specific appliance. A comparable calculation applies to a household cooking appliance; here again the number from Part III if the article on feeders is allowed to be used for a branch circuit. For household ranges, this correlates with 210.21(B)(4) that bases the range receptacle ampere rating on a single range demand load as given in Table 220.55, and that configuration also correlates with the rating of the branch-circuit overcurrent device through 210.20(D).

Part III. Feeder and Service Load Calculations

220.42. General Lighting. For general illumination, a feeder must have capacity to carry the total load of lighting branch circuits determined as part of the lighting design and not less than a minimum branch-circuit load determined on a volt-amperes-per-unit-area basis from the table in 220.12.

Demand factor permits sizing of a feeder according to the amount of load that operates simultaneously.

Demand factor is the ratio of the maximum amount of load that will be operating at any one time on a feeder to the total connected load on the feeder under consideration. This factor is frequently less than 1. The sum of the connected loads supplied by a feeder is multiplied by the demand factor to determine the load which the feeder must be sized to serve. This load is termed the *maximum demand* of the feeder:

$$\text{Maximum demand load} = \text{connected load} \times \text{demand factor}$$

Tables of demand and diversity factors have been developed from experience with various types of load concentrations and various layouts of feeders and subfeeders supplying such loads. Table 220.42 of the **NEC** presents common demand factors for feeders to general lighting loads in various types of buildings (Fig. 220-5).

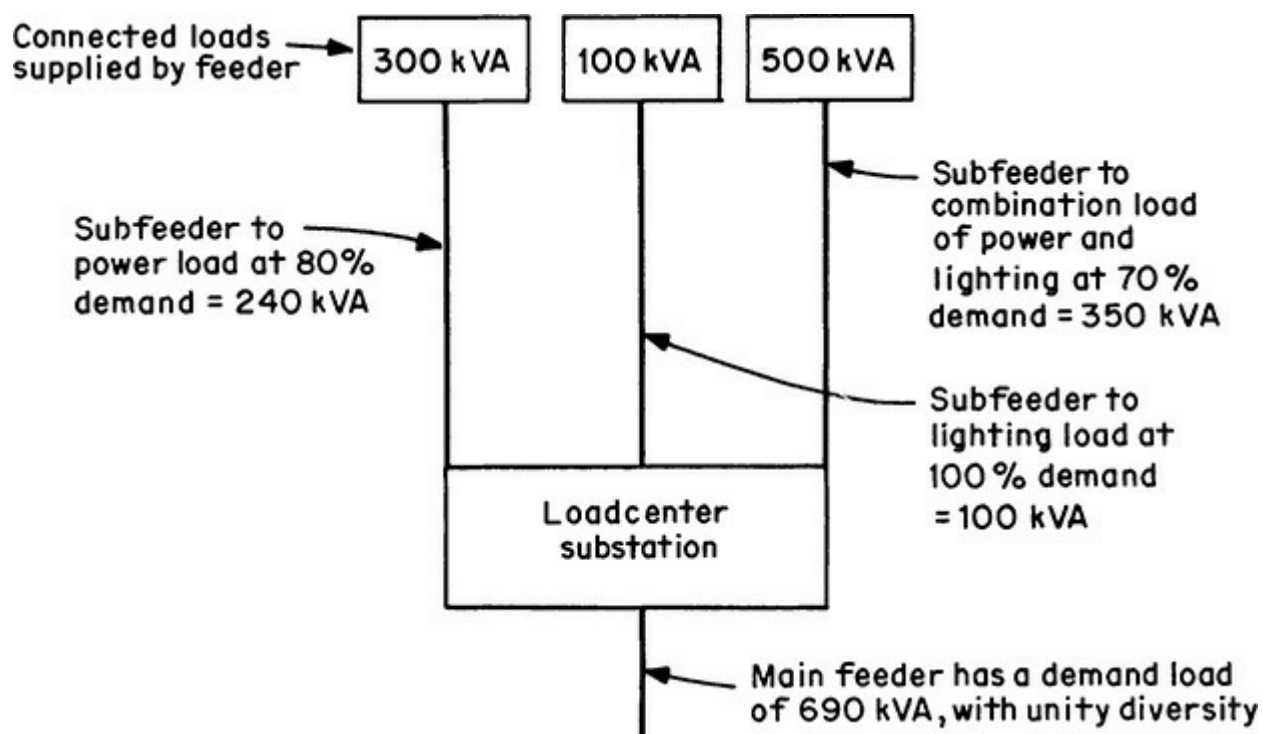

Fig. 220-5. How demand factors are applied to connected loads. (Sec. 220.42.)

The demand factors given in Table 220.42 may be applied to the total branch-circuit load to get required feeder capacity for lighting (but must not be used in calculating branch-circuit capacity). Note that a feeder may have a capacity of less than 100 percent of the total branch-circuit load for only the types of buildings designated in Table 220.42, that is, for dwelling units, hospitals, hotels, motels, and storage warehouses. In all other types of occupancies, it is assumed that *all* general

lighting will be operating at the same time, and each feeder in those occupancies must have capacity (ampacity) for 100 percent of the volt-amperes of branch-circuit load of general lighting that the feeder supplies.

example If a warehouse feeder fed a total branch-circuit load of 20,000 VA of general lighting, the minimum capacity in that feeder to supply that load must be equal to 12,500 VA plus 50 percent times (20,000 – 12,500) VA. That works out to be 12,500 plus 0.5×7500 or 16,250 VA.

But, the note to Table 220.42 warns against using any value less than 100 percent of branch-circuit load for sizing any feeder that supplies loads that will all be energized at the same time.

220.43. Show-Window and Track Lighting. In providing minimum required capacity in feeders, a load of 150 VA must be allowed for each 2 ft (600 mm) or fraction thereof of lighting track. That amount of load capacity must be provided in feeders and service conductors (see [Fig. 220-6](#)) in nonresidential installations and would have to be added in addition to the general lighting load in volt-amperes per square foot from **NEC** Table 220.12. For residential applications, track lighting is considered to be included in the 33 VA/m² (3 VA/ft²) calculations and no additional load need be added.

1. According to 220.43(B), the feeder must have capacity equal to 75 VA/300 mm (/1 ft) [150 VA/600 mm (/2 ft)]. Therefore, each phase conductor must have capacity for:
 $8 \text{ tracks} \times 6.0 \text{ m (20 ft)/ track} = \text{minimum VA capacity}$
 $12,000 \text{ VA} = \text{minimum VA capacity}$
 This is all line-to-neutral load; to find amperes, divide by 120 V
 $12,000 \text{ VA} \div 120 \text{ V} = 100 \text{ A}$

2. Due to the continuous nature of the load, the minimum rating of the overcurrent protective device must be sized to accept 125% of this load: $100 \text{ A} \times 1.25 = 125 \text{ A}$.

3. The conductors must have a similar rating where terminating on an overcurrent device, evaluated under the 75°C column of Table 310.15(B)(16). No. 1AWG THHN (130 A) will work.

4. If the luminaires are HIDs, the neutral will be current carrying per 310.15(B)(5)(c) and mutual conductor heating in the raceway must be evaluated, based on the 90°C column of Table 310.15(B)(16), taken at 80% per 310.15(B)(3)(a): $150 \text{ A} \times 0.8 = 120 \text{ A}$; this is permitted because the 125A OCPD protects the conductor per 240.4(B), and the load (100 A) does not exceed the actual ampacity (120 A).

Fig. 220-6. A single-circuit lighting track must be taken as a load of 150 VA for each 2 ft (610 mm) or fraction thereof, divided among the number of circuits. For a 2-circuit lighting track, each 2-ft (610-mm) length is a 75-VA load for each circuit. For a 3-circuit track, each 2-ft (610-mm) length is a 50 VA load for each circuit. (Sec. 220.43.)

A new exception as of the 2011 **NEC** grants relief from this loading requirement if the total load that will be carried by the track is limited by a device designed for this purpose, the reduced load can be used to design the feeder capacity. The substantiation for this proposal documented an instance where the track load calculated under the usual provisions of 220.43(B) resulted in a feeder load of 11,250 VA. However, the applicable energy code set an upper limit of 4500 W. Differences like this produce significant changes in transformer and feeder sizing. For this reason, the original proposal requested a blanket exception allowing energy code limits to replace those in the **NEC**. This was another in a very long and continuing line of proposed changes involving complaints about excessive load capabilities arising in building electrical designs from Art. 220 results. Refer to the discussion

of the new (in the 2014 **NEC**) 220.12 Exception for the latest chapter in this process.

The panel compromised and agreed to allow for a reduction in the calculated load, but only if an actually installed device permanently restricted the load that could be connected to the track. This final load may or may not have any relation to the applicable energy code, and could result from a simple design preference on the part of the owner. When such a device is installed, its upper let-through loading is now permitted to be the track lighting contribution to Art. 220 feeder load for the system. The limiting device can be as simple as the branch-circuit overcurrent device actually installed, or a supplementary overcurrent device installed for this purpose.

If show-window lighting is supplied by a feeder, capacity must be included in the feeder to handle 200 VA per linear 300 mm (1 ft) of show-window length. Note that on the feeder level, the 200 VA per 300 mm (1 ft) is the only allowable calculation, unlike the branch circuit calculations that can be done either this way or on the basis of the receptacles actually in use taken at 180 VA each.

220.44. Receptacle Loads—Other Than Dwelling Units. This rule permits two possible approaches in determining the required feeder ampacity to supply receptacle loads in “other than dwelling units,” where a load of 180 VA of feeder capacity must be provided for all general-purpose 15- and 20-A receptacle outlets. (In dwelling units and in guest rooms of hotels and motels, no feeder capacity is required for 15- or 20-A general-purpose receptacle outlets. Such load is considered sufficiently covered by the load capacity provided for general lighting.) But in other than dwelling units, where a load of 180 VA of feeder capacity must be provided for all general-purpose 15- and 20-A receptacle outlets, a *demand factor* may be applied to the total calculated receptacle load as follows. Wording of this rule makes clear that *either* Table 220.42 or Table 220.44 may be used to apply demand factors to the total load of 180-VA receptacle loads when calculating required ampacity of a feeder supplying receptacle loads connected on branch circuits.

In other than dwelling units, the branch-circuit load for receptacle outlets, for which 180 VA was allowed per outlet, may be added to the general lighting load and may be reduced by the demand factors in Table 220.42. That is the basic rule of 220.44 and, in effect, requires any feeder to have capacity for the total number of receptacles it feeds and requires that capacity to be equal to 180 VA (per single or multiple receptacle) times the total number of receptacles (yokes)—with a reduction from 100 percent of that value permitted only for the occupancies listed in Table 220.42.

Because the demand factor of Table 220.42 is shown as 100 percent for “All Other” types of occupancies, the basic rule of 220.44 as it appeared prior to the 1978 **NEC** required a feeder to have ampacity for a load equal to 180 VA times the number of general-purpose receptacle outlets that the feeder supplied. That is no longer required. Recognizing that there is great diversity in use of receptacles in office buildings, stores, schools, and all the other occupancies that come under “All Others” in Tables 220.42, 220.44 contains a table to permit reduction of feeder capacity for receptacle loads on feeders. Those demand factors apply to *any* “nondwelling” occupancy.

The amount of feeder capacity for a typical case where a feeder, say, supplies panelboards that serve a total of 500 receptacles is shown in [Fig. 220-7](#).

Take the total number of general-purpose receptacle outlets fed by a given feeder. . .

. . . multiply the total by 180 volt-amperes
[required load of 220.3(B) (9) for each receptacle]. . .

$$500 \times 180 \text{ VA} = 90,000 \text{ VA}$$

Then apply the demand factors from Table 220.13:

First 10 k VA or less @ 100% demand	=	10,000 VA
Remainder over 10 kVA @ 50% demand		
= (90,000 – 10,000) × 50%		
= 80,000 × 0.5	=	40,000 VA
Minimum demand-load total =		50,000 VA

Therefore, the feeder must have a capacity of 50 kVA for the total receptacle load. Required minimum ampacity for that load is then determined from the voltage and phase-makeup (single- or 3-phase) of the feeder.

Fig. 220-7. Table 220.13 permits demand factor in calculating feeder demand load for general-purpose receptacles. (Sec. 220.44.)

Although the calculation of Fig. 220-7 cannot always be taken as realistically related to usage of receptacles, it is realistic relief from the 100-percent-demand factor, which presumed that all receptacles were supplying 180-VA loads simultaneously.

220.50. Motors. Any feeder that supplies a motor load or a combination load (motors plus lighting and/or other electrical loads) must satisfy the indicated **NEC** sections of Art. 430. Feeder capacity for motor loads is usually taken at 125 percent of the full-load current rating of the largest motor supplied, plus the sum of the full-load currents of the other motors supplied. However, 430.26 allows the application of demand factors in certain cases as determined by the inspector.

Specifically, 430.26 operates by “special permission,” which is the written permission from the authority enforcing the code. Some authorities recommend that no demand factor be used in determining the size of circuit to install so that the additional current capacity, thus allowed in the circuit, will give some spare capacity for growth. On the other hand, as noted in the discussion at 220.12 Exception, one of the major and repeated areas of discussion by the Code-making panel responsible for load calculations involves the repeated and well-documented oversizing of industrial feeders in this area. Electric utilities know how much power they provide to their customers, and it too often does not compare well with load calculations run without appropriate demand factors. The express allowance for the judicious use of demand factors in the **NEC** for these loads is something

that well deserves careful consideration. The factors given in Div. 12 of our sister book, the *American Electricians' Handbook*, are an excellent place to start.

220.51. Fixed Electric Space Heating. Capacity required in a feeder to supply fixed electrical space-heating equipment is determined on the basis of a load equal to the total connected load of heaters on all branch circuits served from the feeder. Under conditions of intermittent operation or where all units cannot operate at the same time, permission may be granted for use of less than a 100 percent demand factor in sizing the feeder. 220.82, 220.83, and 220.84 permit alternate calculations of electric heat load for feeders or service-entrance conductors (which constitute a service feeder) in dwelling units. But reduction of the feeder capacity to less than 100 percent of connected load must be authorized by the local electrical inspector. Feeder load current for heating must not be less than the rating of the largest heating branch circuit supplied.

220.52. Small-Appliance and Laundry Loads—Dwelling Unit. For a feeder or service conductors in a single-family dwelling, in an individual apartment of a multifamily dwelling with provisions for cooking by tenants, or in a hotel or motel suite with cooking facilities or a serving pantry, at least 1500 VA of load must be provided for each 2-wire, 20-A small-appliance circuit (to handle the small appliance load in kitchen, pantry, and dining areas) that is actually installed. The total small-appliance load determined in this way may be added to the general lighting load, and the resulting total load may be reduced by the demand factors given in Table 220.42.

Note that in a major clarification, the 2008 **NEC** changed the verb in this rule from “required by 210.11(C)(1)” to “covered by 210.11(C)(1).” A key point of contention for a very long time has been whether 3000 VA based on two small appliance branch circuits was all that was needed to put into a load calculation, even if many more were actually installed in a given dwelling unit. The theory behind this was that 210.11(C)(1) requires only two such circuits. The opposing viewpoint noted that 210.11(C)(1) actually mandated “two or more” such circuits, so all that were provided should be counted in the load calculation. By changing the word, it is now clear that although only two such circuits are required, if you choose to install more, the load calculation must include every one that is in place, taken at 1500 VA each. The same change was made in (B) following, so if multiple laundry circuits are provided, each will enter the load calculation at 1500 VA.

A feeder load of at least 1500 VA must be added for each 2-wire, 20-A laundry circuit installed as covered by 210.1(C)(2). And that load may also be added to the general lighting load and subjected to the demand factors in Table 220.42.

220.53. Appliance Load—Dwelling Unit(s). For fixed appliances (fastened in place) other than ranges, clothes dryers, air-conditioning equipment, and space-heating equipment, feeder capacity in dwelling occupancies must be provided for the sum of these loads; but, if there are at least four such fixed appliances, the total load of four or more such appliances may be reduced by a demand factor of 75 percent (**NEC** 220.53). Wording of this rule makes clear that a “fixed appliance” is one that is “fastened in place.”

As an example of application of this Code provision, consider the following calculation of feeder capacity for fixed appliances in a single-family house. The calculation is made to determine how much capacity must be provided in the service-entrance conductors (the service feeder):

Water heater	2500 W	240 V =	10.4
Kitchen disposal	½ hp	120 V = 9.8 A + 25% =	12.3
Furnace motor	¼ hp	120 V =	5.8 A
Attic fan	¼ hp	120 V = 5.8 A	0.0 A
Water pump	½ hp	240 V =	4.9 A

Load in amperes on each ungrounded leg of feeder = 33.4 A

To comply with 430.24, 25 percent is added to the full-load current of the ½-hp, 120-V appliance motor because it is the highest-rated motor in the group. Since it is assumed that the load on the 120/240-V feeder will be balanced and each of the ¼-hp motors will be connected to different ungrounded conductors, only one is counted in the preceding calculation. Except for the 120-V motors, all the other appliance loads are connected to both ungrounded conductors and are automatically balanced. Since there are four or more fixed appliances in addition to a range, clothes dryer, etc., a demand factor of 75 percent may be applied to the total load of these appliances. Seventy-five percent of 33.4 = 25 A, which is the current to be added to that computed for the lighting and other loads to determine the total current to be carried by the ungrounded (outside) service-entrance conductors.

The preceding demand factor may be applied to similar loads in two-family or multifamily dwellings.

220.54. Electric Clothes Dryers— Dwelling Unit(s). This rule prescribes a minimum demand of 5 kVA for 120/240-V electric clothes dryers in determining branch-circuit and feeder sizes. Note that this rule applies only to “household” electric clothes dryers, and not to commercial applications. This rule is helpful because the ratings of electric clothes dryers are not usually known in the planning stages when feeder calculations must be determined (Fig. 220-8).

Fig. 220-8. Feeder load of 5 kVA per dryer must be provided if actual load is not known. (Sec. 220.54.)

When sizing a feeder for one or more electric clothes dryers, a load of 5000 VA or the nameplate rating, whichever is larger, shall be included for each dryer—subject to the demand factors of Table 220.54 when the feeder supplies a number of clothes dryers, as in an apartment house. At one time this table periodically generated paradoxical load calculations; for some load brackets, adding additional clothes dryers actually decreased the calculated load for the feeder. This has been corrected, and now adding a clothes dryer always results in at least some additional load capacity required in the feeder.

220.55. Electric Cooking Appliances in Dwelling Units and Household Cooking Appliances Used in Instructional Programs. Feeder capacity must be allowed for household electric cooking appliances rated over 1¾ kW, in accordance with Table 220.55 of the Code. Feeder demand loads for a number of cooking appliances on a feeder may be obtained from Table 220.55.

Note 4 to Table 220.55 permits sizing of a branch circuit to supply a single electric range, a wall-mounted oven, or a counter-mounted cooking unit in accordance with that table. That table is also used in sizing a feeder (or service conductors) that supplies one or more electric ranges or cooking units. Note that 220.55 and Table 220.55 apply only to such cooking appliances in a “dwelling unit” and do not cover commercial or institutional applications, although ranges in vocational school kitchens are covered.

Figure 220-9 shows a typical NEC calculation of the minimum demand load to be used in sizing the branch circuit to the range. The same value of demand load is also used in sizing a feeder (or service conductors) from which the range circuit is fed. Calculation is as follows:

Fig. 220-9. Minimum amp rating of branch-circuit conductors for a 12-kW range. (Sec. 220.55.)

A branch circuit for the 12-kW range is selected in accordance with Note 4 of Table 220.55, which says that the branch-circuit load for a range may be selected from the table itself. Under the heading “Number of Appliances,” read across from “1.” The maximum demand to be used in sizing the range circuit for a 12-kW range is shown under the heading “Maximum Demand” to be not less than 8 kW. The minimum rating of the range-circuit ungrounded conductors will be

$$\frac{8000 \text{ W}}{240 \text{ V}} = 33.3 \text{ A or } 33 \text{ A}$$

NEC Table 310.15(B)(16) shows that the minimum size of copper conductors that may be used is 8 AWG (TW—40 A, THW—45 A, XHHW or THHN—50 A). No. 8 AWG is also designated in 210.19(A)(3) as the minimum size of conductor for any range rated 8¾ kW or more because the circuit must be at least rated 40 A.

The overload protection for this circuit of No. 8 TW conductors would be *40-A fuses or a 40-A circuit breaker*. If THW, THHN, or XHHW wires are used for the circuit, they must be taken as having an ampacity of not more than 40 A and protected at that value. That requirement follows from the UL rule that conductors up to No. 1 AWG size must be used at the 60°C ampacity for the size of conductor, regardless of the actual temperature rating of the insulation—which may be 75°C or 90°C. Similarly, 110.14(C)(1)(a) brings the same listing limitations into the **NEC** itself. The ampacity used must be that of TW wire of the given size unless both the overcurrent device at the beginning of the circuit and the range receptacle at the end of the circuit, if used, are marked to allow for 75°C connections.

Although the two hot legs of the 120/240-V, 3-wire circuit must be not smaller than No. 8, Exception No. 2 to Sec. 210.19(A)(3) permits the neutral conductor to be smaller, but it specifies that it must have an ampacity not less than 70 percent of the rating of the branch-circuit CB or fuse and may never be smaller than No. 10.

For the range circuit in this example, the neutral may be rated

$$70\% \times 40 \text{ A (rating of branch-circuit protection)} = 28 \text{ A}$$

This calls for a No. 10 neutral.

[Figure 220-10](#) shows a more involved calculation for a range rated over 12 kW. [Figure 220-11](#) shows two units that total 12 kW and are taken at a demand load of 8 kW, as if they were a single range. [Figure 220-12](#) shows another calculation for separate cooking units on one circuit. And a feeder that would be used to supply any of the cooking installations shown in Figs. 220-9 through [220-12](#) would have to include capacity equal to the demand load used in sizing the branch circuit.

Refer to *NEC* Table 220.55.

1. Column C applies to ranges rated not over 12 kW, but this range is rated 16.6 kW.
2. Note 1, below the Table, tells how to use the Table for ranges over 12 kW and up to 27 kW. For such ranges, the maximum demand in Column C must be increased by 5% for each additional kW of rating (or major fraction) above 12 kW.
3. This 16.6-kW range exceeds 12 kW by 4.6 kW.
4. 5% of the demand in Column C for a single range is 400 watts (8000 watts \times 0.05).
5. The maximum demand for this 16.6-kW range must be increased above 8 kW by 2000 watts:
400 watts (5% of Column C) \times 5 (4 kW + 1 for the remaining 0.6 kW)
6. The required branch circuit must be sized, therefore, for a total demand load of 8000 watts + 2000 watts = 10,000 watts
7. Required size of branch circuit—

$$\text{Amp rating} = \frac{10,000 \text{ W}}{240 \text{ V}} = 42 \text{ A}$$

USING 60C CONDUCTORS, AS REQUIRED BY 110.14(C)(1)(a), THE UNGROUNDED BRANCH CIRCUIT CONDUCTORS WOULD CONSIST OF 6 AWG CONDUCTORS. THIS IS THE DEFAULT; 75C CONNECTIONS ARE PERMITTED AS COVERED IN 110.14(C)(1)(a)(3).

Fig. 220-10. Sizing a branch circuit for a household range over 12 kW. (Sec. 220.55.)

Fig. 220-11. Two units treated as a single-range load. (Sec. 220.55.)

1. Note 4 of Table 220.55 says that the branch-circuit load for a counter-mounted cooking unit and not more than two wall-mounted ovens, all supplied from a single branch circuit and located in the same room, shall be computed by adding the nameplate ratings of the individual appliances and treating this total as a single range.

2. Therefore, the three appliances shown may be considered to be a single range of 18-kW rating (6 kW + 6 kW + 6 kW).

3. From Note 1 of Table 220.55, such a range exceeds 12 kW by 6 kW and the 8-kW demand of Column C must be increased by 400 watts (5% of 8000 watts) for each of the 6 additional kilowatts above 12 kW.

4. Thus, the branch-circuit demand load is—

$$8000 \text{ WATTS} + (6 \times 400 \text{ WATTS}) = 10,400 \text{ WATTS}$$

A 50-AMP CIRCUIT IS REQUIRED.

Fig. 220-12. Determining branch-circuit load for separate cooking appliances on a single circuit. (Sec. 220.55.)

A feeder supplying more than one range (rated not over 12 kW) must have ampacity sufficient for the maximum demand load given in Table 220.55 for the number of ranges fed. For instance, a feeder to 10 such ranges would have to have ampacity for a load of 25 kW.

Other Calculations on Electric Cooking Appliances

The following “roundup” points out step-by-step methods of wiring the various types of household electric cooking equipment (ranges, counter-mounted cooking units, and wall-mounted ovens) according to the **NEC**.

Tap Conductors

210.19(A)(3), Exception No. 2, gives permission to reduce the size of the neutral conductor of a 3-wire range branch circuit to 70 percent of the rating of the CB or fuses protecting the branch circuit. However, this rule does not apply to smaller taps connected to a 50-A circuit—where the smaller taps (none less than 20-A ratings) must all be the same size. Further, it does not apply when individual branch circuits supply each wall- or counter-mounted cooking unit and all circuit conductors are of the same size and less than No. 10.

210.19(A)(3), Exception No. 1, permits tap conductors, rated not less than 20 A, to be connected to 50-A branch circuits that supply ranges, wall-mounted ovens, and counter-mounted cooking units. These taps cannot be any longer than necessary for servicing. [Figure 220-13](#) illustrates the application of this rule.

NEC rules permit a 50-amp circuit to supply cooktops and ovens. Typical arrangement shows such a circuit. Junction box sizes are computed from Table 314.16(A) and Table 314.16(B) for No. 6 conductor combinations. Taps to each unit are No. 10.

Fig. 220-13. One branch circuit to cooking units. (Sec. 220.55.)

In 210.19(A)(3), Exception No. 1, the wording “no longer than necessary for servicing” encourages the location of circuit junction boxes as close as possible to each cooking and oven unit connected to 50-A circuits. A number of counter-mounted cooking units have integral supply leads about 36 in. (914 mm) long, and some ovens come with supply conduit and wire in lengths of 48 to 54 in. Therefore, a box should be installed close enough to connect these leads.

Feeder and Circuit Calculations

220.55 permits the use of Table 220.55 for calculating the feeder load for ranges and other cooking appliances that are individually rated more than 1 $\frac{3}{4}$ kW.

Note 4 of the table reads: “The branch-circuit load for one wall-mounted oven or one counter-mounted cooking unit shall be the nameplate rating of the appliance.” [Figure 220-14](#) shows a separate branch circuit to each cooking unit, as permitted.

Note 1: Individual br. circuits supplying single units are computed at 100% demand factor. (See Note 4 to Table 220.55)

Note 2: Equipment grounding conductors are computed according to Table 250.122

An 8-kW cooktop is supplied by an individual No. 8 (40-amp) branch circuit, and a No. 12 (20-amp) branch circuit supplies a 4-kW oven. Such circuits are calculated on the basis of the nameplate rating of the appliance. In most instances individual branch circuits cost less than 50-amp, multi-outlet circuits for cooking and oven units.

Fig. 220-14. Separate branch circuit to cooking units. (Sec. 220.55.)

Common sense dictates that there is no difference in demand factor between a single range of 12 kW and a wall-mounted oven and surface-mounted cooking unit totaling 12 kW. This is explained in the last sentence of Note 4 of Table 220.55. The mere division of a complete range into two or more units does not change the demand factor. Therefore, the most direct and accurate method of computing the branch-circuit and feeder calculations for wall-mounted ovens and surface-mounted cooking units within each occupancy is to total the kilowatt ratings of these appliances and treat this total kilowatt rating as a single range of the same rating. For example, a particular dwelling has an 8-kW, 4-burner, surface-mounted cooking unit and a 4-kW wall-mounted oven. This is a total of 12 kW, and the maximum permissible demand given in Column C of Table 220.55 for a single 12-kW range is 8 kW.

Similarly, it follows that if the ratings of a 2-burner, counter-mounted cooking unit and a wall-mounted oven are each 3.5 kW, the total of the two would be 7 kW—the same total as a small 7-kW range. Because the 7-kW load is less than $8\frac{3}{4}$ kW, Note 3 of Table 220.55 permits Column B of Table 220.55 to be used in lieu of Column C. The demand load is 5.6 kW (7 kW times 0.80). Range or total cooking and oven unit ratings less than $8\frac{3}{4}$ kW are more likely to be found in small apartment units of multifamily dwellings than in single-family dwellings.

Because the demand loads in Column C of Table 220.55 apply to ranges not exceeding 12 kW,

they also apply to wall-mounted ovens and counter-mounted cooking units within each individual occupancy by totaling their aggregate nameplate kilowatt ratings. Then if the total rating exceeds 12 kW, Note 1 to the table should be used as if the units were a single range of equal rating. For example, assume that the total rating of a counter-mounted cooking unit and two wall-mounted ovens is 16 kW in a dwelling unit. The maximum demand for a single 12-kW range is given as 8 kW in Column C. Note 1 requires that the maximum demand in Column C be increased 5 percent for each additional kilowatt or major fraction thereof that exceeds 12 kW. In this case 16 kW exceeds 12 kW by 4 kW. Therefore, 5 percent times 4 equals 20 percent, and 20 percent of 8 kW is 1.6 kW. The maximum feeder and branch-circuit demand is then 9.6 kW (8 kW plus 1.6 kW). A 9600-W load would draw exactly 40 A at 240 V, thereby just fitting on a circuit rated 40 A.

For the range or cooking unit demand factors in a multifamily dwelling, say a 12-unit apartment building, a specific calculation must be made, as follows:

1. Each apartment has a 6-kW counter-mounted cooking unit and a 4-kW wall-mounted oven. And each apartment is served by a separate feeder from a main switchboard. The maximum cooking demand in each apartment feeder should be computed in the same manner as previously described for single-family dwellings. Since the total rating of cooking and oven units in each apartment is 10 kW (6 kW plus 4 kW), Column C of Table 220.55 for one appliance should apply. Thus, the maximum cooking demand load on each feeder is 8 kW.
2. In figuring the size of the main service feeder, Column C should be used for 12 appliances. Thus, the demand would be 27 kW.

As an alternate calculation, assume that each of the 12 apartments has a 4-kW counter-mounted cooking unit and a 4-kW wall-mounted oven. This would total 8 kW per apartment. In this case, Column B of Table 220.55 can be used to determine the cooking load in each separate feeder. By applying Column B on the basis of a single 8-kW range, the maximum demand is 6.4 kW (8 kW times 0.80). Therefore, 6.4 kW is the cooking load to be included in the calculation of each feeder. Notice that this is 1.6 kW less than the previous example where cooking and oven units, totaling 10 kW, had a demand load of 8 kW. And this is logical, because smaller units should produce a smaller total kilowatt demand.

On the other hand, it is advantageous to use Column C instead of Column B for computing the main service feeder capacity for twelve 8-kW cooking loads. The reason for this is that Column B gives a higher result where more than five 8-kW ranges (or combinations) and more than twelve 7-kW ranges (or combinations) are to be used. In these instances, calculations made on the basis of Column B result in a demand load greater than that of Column C for the same number of ranges. As an example, twelve 8-kW ranges have a demand load of 30.72 kW (12 times 8 kW times 0.32) in applying Column B, but only a demand load of 27 kW in Column C. And in Column C the 27 kW is based on twelve 12-kW ranges. This discrepancy dictates use of Column B only on the limited basis previously outlined.

The reason for the higher demand factor for a smaller range is that the smaller appliances, while in use, have more of their current consuming functions in operation at the same time. This is the reason that the demand factors in Column A are never lower and usually higher for the same number of appliances listed in Column B. When the cooking function is subdivided over several appliances, as in this example, the effect is to create one large range, and collectively the appliances will behave as a larger range with its attendant effectively smaller demand factor in Column C. Note 3 gives the option of using either Column C or Columns A and/or B to make this calculation for this reason.

Branch-Circuit Wiring

Where individual branch circuits supply each counter-mounted cooking unit and wall-mounted oven, there appears to be no particular problem. Figure 220-14 gives the details for wiring units on individual branch circuits.

Figure 220-13 shows an example of how typical counter-mounted cooking units and wall-mounted ovens are connected to a 50-A branch circuit.

Several manufacturers of cooking units provide an attached flexible metal conduit with supply leads and a floating 4-in. octagon box as a part of each unit. These units are commonly called “prewired types.” With this arrangement, an electrician does not have to make any supply connections in the appliance. Where such units are connected to a 50-A circuit, the 4-in. octagon box is removed, and the flexible conduit is connected to a larger circuit junction box, which contains the 6 AWG circuit conductors.

On the other hand, some manufacturers do not furnish supply leads with their cooking units. As a result, the electrical contractor must supply the tap conductors to these units from the 50-A circuit junction box (see Fig. 220-13). In this case, connections must be made in the appliance as well as in the junction box. Figure 220-15 shows a single branch circuit supplying the same units, as shown in Fig. 220-13.

Same size and type of units as in Fig. 220-12,
but wired on individual circuits

Individual branch circuits supply the same units that appear in Fig. 220-12. With this arrangement, smaller branch circuits supply each unit with no JBs required. Although two additional fuse or CB poles are required in a panelboard, overall labor/material costs are less than the 50-amp circuit shown in Fig. 220-12. However, one disadvantage to individual circuits is that smaller size circuits will not handle larger units, which may be installed at a later date.

Fig. 220-15. Separate circuits have advantages. (Sec. 220.55.)

40-A Circuits

The NEC does recognize a 40-A circuit for two or more outlets, as noted in 210.23(C). Because an 8 AWG (40-A) circuit can supply a single range rated not over 16.4 kW, it can also supply counter- and wall-mounted units not exceeding the same total of 16.4 kW. The rating of 16.4 kW is determined as the maximum rating of equipment that may be supplied by a 40-A branch circuit, which has a capacity of 9600 W ($40 \text{ A} \times 240 \text{ V}$). From Note 1 to Table 220.55, a 15.4-kW load would require a demand capacity equal to 8000 W plus $[(16.4 \times 12) \times 0.05 \times 8000] = 8000 \text{ W}$ plus $4 \times 0.05 \times 8000 = 8000$ plus 1600 = 9600 W.

Figure 220-16 shows an arrangement of a 8-AWG (40-A) branch circuit supplying one 7.5-kW cooking unit and one 4-kW oven. Or individual branch circuits may be run to the units.

The NEC permits 40-amp circuits in lieu of 50-amp circuits where the aggregate nameplate rating of cooktops and ovens is less than 15.5 kW. Most ranges are less than 15.5 kW and so are most combinations of cooktops and ovens.

Fig. 220-16. A single 40-A circuit may supply units. (Sec. 220.55.)

220.56. Kitchen Equipment—Other than Dwelling Unit(s). Commercial electric cooking loads must comply with 220.56 and its table of feeder demand factors for commercial electric cooking equipment—including dishwasher booster heaters, water heaters, and other kitchen equipment. Space-heating, ventilating, and/or air-conditioning equipment is excluded from the phrase “other kitchen equipment.”

At one time, the Code did not recognize demand factors for such equipment. Code Table 220.56 is the result of extensive research on the part of electric utilities. The demand factors given in Table 220.56 may be applied to *all* equipment (except the excluded heating, ventilating, and air-conditioning loads) that is *either* thermostatically controlled *or* is used only on an intermittent basis. Continuously operating loads, such as infrared heat lamps used for food warming, would be taken at

100 percent demand and not counted in the “Number of Units” that are subject to the demand factors of Table 220.56.

The rule says that the minimum load to be used in sizing a feeder to commercial kitchen equipment must not be less than the sum of the largest two kitchen equipment loads. If the feeder load determined by using Table 220.56 on the total number of appliances that are controlled or intermittent and then adding the sum of load ratings of continuous loads like heat lamps is less than the sum of load ratings of the two largest load units—then the minimum feeder load must be taken as the sum of the two largest load units.

example Find the minimum demand load to be used in sizing a feeder supplying a 20-kW quick-recovery water heater, a 5-kW fryer, a dough mixer with a 3-phase 1½-hp, 208-V motor, and four continuously operating 250-W food-warmer infrared lamps—with a 208Y/120V, 3-phase, 4-wire supply.

Although the water heater, the fryer, and the four lamps are a total of 1 + 1 + 4, or 6, unit loads, the 250-W lamps may not be counted in using Table 220.56 because they are continuous loads. For the water heater and the fryer, Table 220-56 indicates that a 90 percent demand must be used where the “Number of Units of Equipment” is 3. The motor must be taken at 125 percent per 430.24, and based on Table 430.250 per 430.6(A)(1). The table current is 6.6 A, and 125 percent of that is 8.3 A.

To convert the motor load to volt-amperes, do the following multiplication:

$8.3 \text{ A} \times 208 \text{ V} \times \sqrt{3}$. Although this should be familiar to you, and it is the usual 1.732 term used in three-phase work all the time, remember that 208 V is simply the line-to-neutral voltage, also multiplied by the same term, thus the same multiplication can be written:

$8.3 \text{ A} \times 120 \text{ V} \times \sqrt{3} \times \sqrt{3}$. Since $\sqrt{3} \times \sqrt{3} = 3$, the multiplication is simply $8.3 \text{ A} \times 360 \text{ V}$. Working with 360 in 208Y/120V systems (and 831 in 480Y/277V systems) is much simpler and faster than using the square root of three and the line-to-line voltage.

Therefore, $8.3 \text{ A} \times 360 \text{ V} = 3 \text{ kVA}$, and feeder minimum load (kW = kVA) must then be taken as

Water heater @ 90%	18.0 kVA
Fryer @ 90%	4.5 kVA
Dough mixer @ 90%	+2.7 kVA
	25.2 kVA

Four 250-W lamps @ 100% +1.0 kVA = 26.2 kVA

Then, the feeder must be sized for a minimum current load of

$$\frac{26.2 \times 1000}{360} = 73 \text{ A}$$

The two largest equipment loads are the water heater and the dryer:

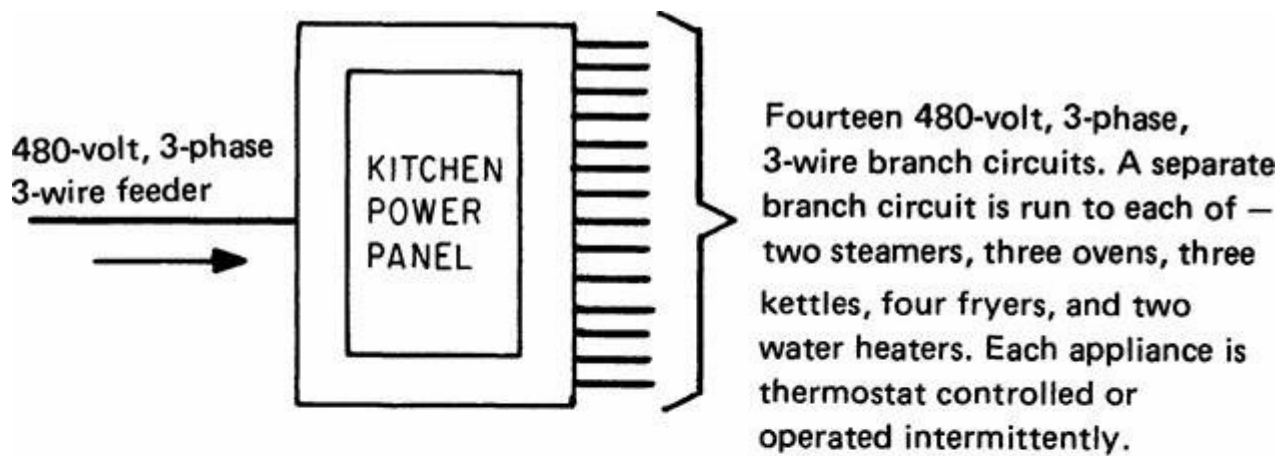

$$20 \text{ kVA} + 5 \text{ kVA} = 25 \text{ kVA}$$

and they draw

$$\frac{25 \times 1000}{360} = 69 \text{ A}$$

Therefore, the 73-A demand load calculated from Table 220.56 satisfies the last sentence of the rule because that value is “not less than” the sum of the largest two kitchen equipment loads. The feeder must be sized to have at least 73 A of capacity for this part of the total building load.

Figure 220-17 shows another example of reduced sizing for a feeder to kitchen appliances.

Kitchen panel supplies fourteen 480-volt, 3-phase, 3-wire branch circuits.

A separate branch circuit is run to each of—

- Two steamers,
- Three ovens,
- Three kettles,
- Four fryers, and
- Two water heaters

The 14 appliances make up a total connected load of 303.3 kVA

QUESTION:

Is a full-capacity feeder ($303.3 \text{ kVA} / 480 \times 1.73 = 366 \text{ amps}$) required here? Or can a demand factor be applied?

ANSWER:

Although it is possible that all of the appliances might operate simultaneously, it is not expected that they will all be operating at full connected load. Table 220.56 of the *NE Code* does permit use of a demand factor on a feeder for commercial electric cooking equipment (including dishwasher, booster heaters, water heaters and other kitchen equipment). As shown in the Table, for six or more units, a demand factor of 65% can be applied to the feeder sizing:

$$366 \text{ amps} \times 0.65 = 238 \text{ amps}$$

The feeder must have at least that much capacity, and that amp rating must be at least equal to or greater than the sum of the amp ratings of the two largest load appliances served. Capacity must be included in the building service entrance conductors for this load.

Fig. 220-17. Demand factor for commercial-kitchen feeder. (Sec. 220.56.)

220.60. Noncoincident Loads. When dissimilar loads (such as space heating and air cooling in a building) are supplied by the same feeder, the smaller of the two loads may be omitted from the total capacity required for the feeder if it is unlikely that the two loads will operate at the same time.

220.61. Feeder or Service Neutral Load. This section covers requirements for sizing the neutral conductor in a feeder, that is, determining the required ampere rating of the neutral conductor. The basic rule of this section says that the minimum required ampacity of a neutral conductor must be at least equal to the “feeder neutral load”—which is the “maximum unbalance” of the feeder load.

“The maximum unbalanced load shall be the maximum net computed load between the neutral and any one ungrounded conductor... .” In a 3-wire, 120/240-V, single-phase feeder, the neutral must have a current-carrying capacity at least equal to the current drawn by the total 120-V load connected between the more heavily loaded hot leg and the neutral. As shown in Fig. 220-18, under unbalanced conditions, with one hot leg fully loaded to 60 A and the other leg open, the neutral would carry 60 A and must have the same rating as the loaded hot leg. Thus No. 6 THW hot legs would require No. 6 THW neutral (copper).

Fig. 220-18. Neutral must be sized the same as hot leg with heavier load. (Sec. 220.61.)

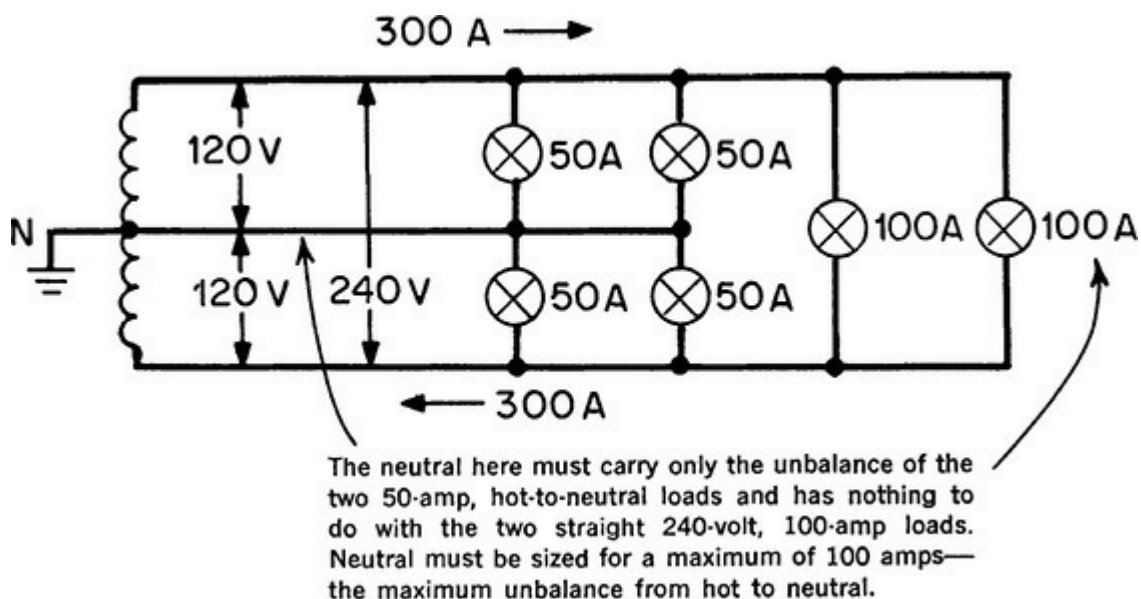

Fig. 220-19. Neutral sizing is not related to phase-to-phase loads. (Sec. 220.61.)

It should be noted that straight 240-V loads, connected between the two hot legs, do not place any

load on the neutral. As a result, the neutral conductor of such a feeder must be sized to make up a 2-wire, 120-V circuit with the more heavily loaded hot leg. Actually, the 120-V circuit loads on such a feeder would be considered as balanced on both sides of the neutral. The neutral, then, would be the same size as each of the hot legs if only 120-V loads were supplied by the feeder. If 240-V loads also were supplied, the hot legs would be sized for the total load; but the neutral would be sized for only the total 120-V load connected between one hot leg and the neutral, as shown in [Fig. 220-19](#).

But, there are qualifications on the basic rule of 220.61, as follows:

1. When a feeder supplies household electric ranges, wall-mounted ovens, counter-mounted cooking units, and/or electric dryers, the neutral conductor may be smaller than the hot conductors but must have a carrying capacity at least equal to 70 percent of the current capacity required in the ungrounded conductors to handle the load (i.e., 70 percent of the load on the ungrounded conductors). Table 220.56 gives the demand loads to be used in sizing feeders that supply electric ranges and other cooking appliances. Table 220.55 gives demand factors for sizing the ungrounded circuit conductors for feeders to electric dryers. The 70 percent demand factor may be applied to the minimum required size of a feeder phase (or hot) leg in order to determine the minimum permitted size of neutral, as shown in [Fig. 220-20](#).

From Table 220-19—DEMAND LOAD for 8 10-kW ranges = 23 kW

$$\text{LOAD ON EACH UNGROUNDED LEG} = \frac{23,000 \text{ W}}{230 \text{ V}} = 100 \text{ amps} \quad (\text{e. g., No. 1TW})$$

$$\text{Required minimum Neutral capacity} = 70\% \times 100 \text{ amps} = 70 \text{ amps} \quad (\text{e.g., No. 4TW})$$

Fig. 220-20. Sizing the neutral of a feeder to electric ranges. (Sec. 220.61.) This calculation uses 230 V because it generates a round number result; the more exact approach would use 240 V resulting in a load of 96 A resulting a neutral ampacity of 67 A.

2. For feeders of three or more conductors—3-wire, dc; 3-wire, single-phase; and 4-wire, 3-phase—a further demand factor of 70 percent may be applied to that portion of the unbalanced load in excess of 200 A. That is, in a feeder supplying only 120-V loads evenly divided between each ungrounded conductor and the neutral, the neutral conductor must be the same size as each ungrounded conductor up to 200-A capacity, but may be reduced from the size of the ungrounded conductors for loads above 200 A by adding to the 200 A only 70 percent of the amount of load current above 200 A in computing the size of the neutral. It should be noted that this 70 percent demand factor is applicable to the unbalanced load in excess of 200 A and not simply to the total load, which in many cases may include 240-V loads on 120/240-V, 3-

wire, single-phase feeders or 3-phase loads or phase-to-phase connected loads on 3-phase feeders. [Figure 220-21](#) shows an example of neutral reduction as permitted by 220.61.

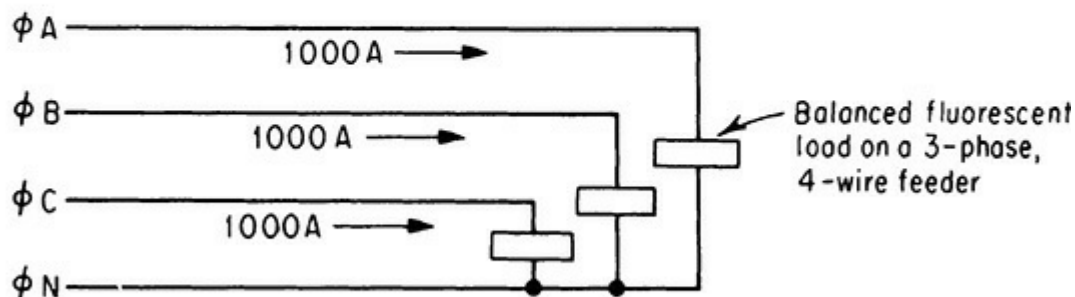

Fig. 220-21. Neutral may be smaller than hot-leg conductors on feeders over 200 A. (Sec. 220.61.)

WATCH OUT!

The size of a feeder neutral conductor may *not* be based on less than the current load on the feeder phase legs when the load consists of electric-discharge lighting, data-processing equipment, or similar equipment. The foregoing reduction of the neutral to 200 A plus 70 percent of the current over 200 A does not apply when all or most of the load on the feeder consists of electric-discharge lighting, electronic data-processing equipment, and similar electromagnetic or solid-state equipment. In a feeder supplying ballasts for electric-discharge lamps and/or computer equipment, there must not be a reduction of the neutral capacity for that part of the load which consists of discharge light sources, such as fluorescent mercury-vapor or other HID lamps. For feeders supplying only electric-discharge lighting or computers, the neutral conductor must be the same size as the phase conductors no matter how big the total load may be ([Fig. 220-22](#)). Full-sizing of the neutral of such feeders is required because, in a balanced circuit supplying ballasts or computer loads, neutral current approximating the phase current is produced by third (and other odd-order) harmonics developed by the ballasts. For large electric-discharge lighting or computer loads, this factor affects sizing of neutrals all the way back to the service. It also affects rating of conductors in conduit because such a feeder circuit consists of *four* current-carrying wires, which requires application of an 80 percent reduction factor. [See 310.15(B)(3)(a) and 310.15(B)(5)(c).]

EXAMPLE:

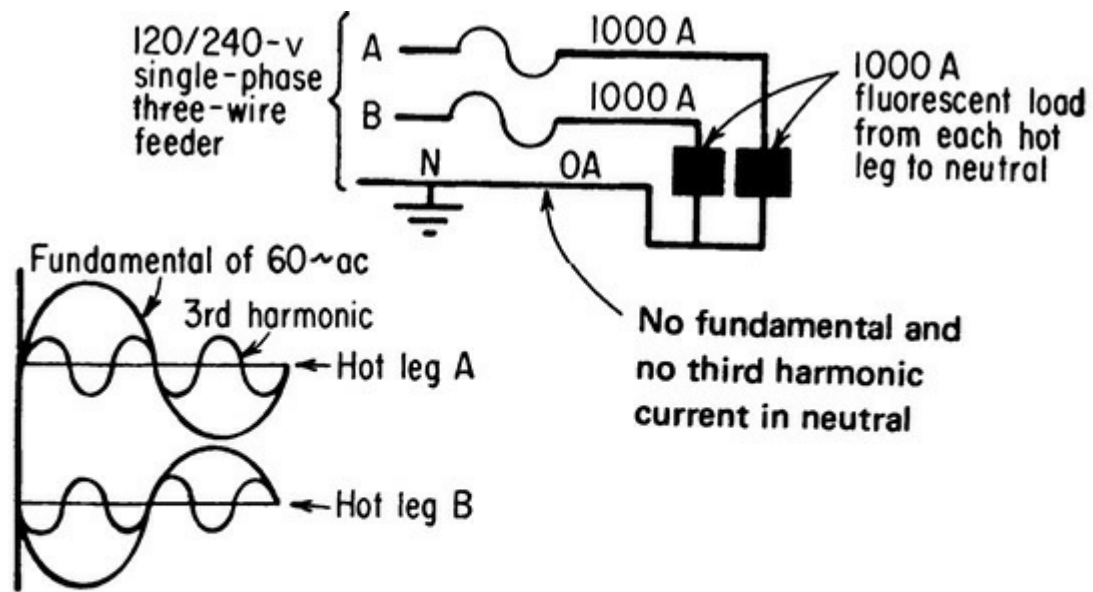

There must be no reduction in amp rating of this neutral. It must have 1000-amp rating like the phase conductors.

Fig. 220-22. Full-size neutral for feeders to ballast loads or computers. (Sec. 220.61.)

In the case of a feeder supplying, say, 200 A of fluorescent lighting and 200 A of incandescent, there can be no reduction of the neutral below the required 400-A capacity of the phase legs, because the 200 A of fluorescent lighting load cannot be used in any way to take advantage of the 70 percent demand factor on that part of the load in excess of 200 A.

It should be noted that the Code wording in 220.61 permits reduction in the size of the neutral when electric-discharge lighting and/or computers are used, if the feeder supplying the electric-discharge lighting load over 200 A happens to be a 120/240-V, 3-wire, single-phase feeder. In such a feeder, the harmonic currents in the hot legs are 180° out of phase with each other and, therefore, would not be additive in the neutral as they are in a 3-phase, 4-wire circuit. In the 3-phase, 4-wire circuit, the third harmonic components of the phase currents are in phase with each other and add together in the neutral instead of canceling out. [Figure 220-23](#) shows a 120/240-V circuit.

As shown, both the fundamental and harmonic currents are 180° out of phase and both cancel in the neutral. Under balanced conditions, the neutral current is zero.

Fig. 220-23. Harmonic loading on true single-phase distributions does not interfere with permitted size reductions over 200 A (220.61).

Figure 220-24 shows a number of circuit conditions involving the rules on sizing a feeder neutral.

1. Incandescent lighting only

Serving an incandescent load, each phase conductor must be rated for 1000 amps. But neutral only has to be rated for 200 amps plus $(70\% \times 800 \text{ amps})$ or $200 + 560 = 760 \text{ amps}$.

2. Electric discharge lighting only

Because load is electric discharge lighting, there can be no reduction in the size of the neutral. Neutral must be rated for 1000 amps, the same as the phase conductors, because the third harmonic currents of the phase legs add together in the neutral. This applies also when the load is mercury-vapor or other metallic-vapor lighting.

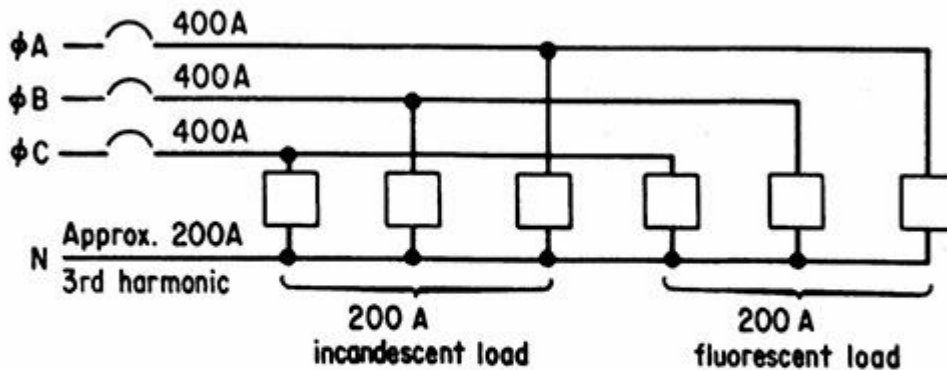

3. Incandescent plus motor load

Although 1000 amps flow on each phase leg, only 500 amps is related to the neutral. Neutral, then, is sized for 200 amps plus (70% x 300 amps) or $200 + 210 = 410$ amps. The amount of current taken for 3-phase motors cannot be "unbalanced load" and no capacity has to be provided for this in the neutral.

4. Electric discharge lighting plus motor load

Here, again, the only possible load that could flow on the neutral is the 800 amps flowing over each phase to the fluorescent lighting. But because it is fluorescent lighting there can be no reduction of neutral capacity below the 800-amp value on each phase. The 70% factor for that current above 200 amps DOES NOT APPLY in such cases.

5. Incandescent plus electric discharge lighting

Each phase leg carries a total of 400 amps to supply the incandescent load plus the fluorescent load. But because there can be no reduction of neutral capacity for the fluorescent and because the incandescent load is not over 200 amps, the neutral must be sized for the maximum possible unbalance, which is 400 amps.

Fig. 220-24. Sizing the feeder neutral for different conditions of loading. (Sec. 220.61.)

Part IV

This part of Art. 220 offers a number of alternative methods for establishing the minimum required current-carrying capacity of service or feeder conductors. Remember that each of the requirements

specified within each individual optional method must be satisfied.

220.82. Dwelling Unit. This section sets forth an optional method of calculating service demand load for a residence. This method may be used instead of the standard method as follows:

1. Only for a one-family residence or an apartment in a multifamily dwelling, or other “dwelling unit”
2. Served by a 120/240-V or 120/208-V 3-wire, 100-A or larger service or feeder
3. Where the total load of the dwelling unit is supplied by one set of service-entrance or feeder conductors that have an ampacity of 100 A or greater

This method recognizes the greater diversity attainable in large-capacity installations. It therefore permits a smaller size of service-entrance conductors for such installations than would be permitted by using the load calculations of 220.40 through 220.61.

In making this calculation, as described by 220.82(C), the heating load or the air-conditioning load may be disregarded as a “noncoincident load,” where it is unlikely that two dissimilar loads (such as heating and air conditioning) will be operated simultaneously. In the present **NEC**, 100 percent of the air-conditioning load is compared with only *40 percent* of the total connected load of four or more electric space heaters [220.82(C)(6)], and the lower value is omitted from the calculation. Or, where there are less than four separately controlled electric heating units, the 100 percent value of the air-conditioning load is compared with 65 percent of the load where the electric heating system has less than four separately controlled units.

example A typical application of the data and table of 220.82, in calculating the minimum required size of service conductors, is as follows:

A 1500-sq-ft (139.5-m²) house (excluding unoccupied basement, unfinished attic, and open porches) contains the following specific electric appliances:

- 12-kW range
- 2.5-kW water heater
- 1.2-kW dishwasher
- 9 kW of electric heat (in five rooms)
- 5-kW clothes dryer
- 6-A, 230-V air-conditioning unit

When using the optional method, if a house has air conditioning as well as electric heating, there is recognition in 220.60 that if “it is unlikely that two dissimilar loads will be in use simultaneously,” it is permissible to omit the smaller of the two in calculating required capacity in feeder or in service-entrance conductors. In 220.82, that concept is spelled out in the subparts of 220.82(C) to require adding only the largest of the loads described in this rule. Where the dwelling in question has air conditioning and four separately controlled electric heating units, we add capacity equal to either the total air-conditioning load or 40 percent of the connected load of *four or more* separately controlled electric space-heating units. For the residence considered here, these loads would be as follows:

$$\text{Air conditioning} = 6 \text{ A} \times 230 \text{ V} = 1.38 \text{ kVA}$$

Note: The air conditioner voltage and current ratings are from the equipment nameplate, and therefore, when converting to kilovolt-amperes, must be taken as is. The overall calculation at the end, which determines the service amperage on a 120/240 system, uses the rated system voltages from 220.5(A).

$$40\% \text{ of heating (five separate units)} = 9 \text{ kW} \times 0.4 = 3.6 \text{ kW (3600 VA)}$$

Because 3.6 kW is greater than 1.38 kVA, it is permissible to omit the air-conditioning load and provide a capacity of 3.6 kW in the service or feeder conductors to cover *both* the heating and air-conditioning loads.

The “other loads” must be totaled up in accordance with 220.82:

	Volt-amperes
1. 1500 VA for each of two small-appliance circuits (2-wire, 20-A).....	3,000
Laundry branch circuit (3-wire, 20-A).....	1,500
2. 3 VA/sq ft of floor area for general lighting and general-use receptacles (3 × 1500 sq ft)	4,500
3. Nameplate rating of fixed appliances:	
Range.....	12,000
Water heater.....	2,500
Dishwasher.....	1,200
Clothes dryer.....	5,000
Total	29,700

In reference to 220.82(C), load categories 1, 2, 3, 4, and 5 are not applicable here: “Air conditioning” has already been excluded as a load because 40 percent of the heating load is greater. The dwelling does not have a heat pump without a controller that prevents simultaneous operation of the compressor and supplemental heating. There is no thermal heating unit. There is no “central” electric space heating; and there are *not* “less than four” separately controlled electric space-heating units.

The total load of 29,700 VA, as previously summed up, includes “all other load,” as referred to in 220.82. *Then:*

1. Take 40% of the 9000-W heating load	3,600
2. Take 10 kVA of “all other load” at 100% demand	10,000
3. Take the “remainder of other load” at 40% demand factor: (29,700 – 10,000) × 40% = 19,700 × 0.4.....	7,880
Total demand	21,480

Using 240- and 120-V values, ampacities may then be calculated. At 240 V, single phase, the *ampacity of each service hot leg would then have to be*

$$\frac{21,480 \text{ W}}{240 \text{ V}} = 89.5 \text{ or } 90 \text{ A}$$

Minimum service conductor required 100 A

Then the neutral service-entrance conductor is calculated in accordance with 220.61. All 240-V loads have no relation to required neutral capacity. The water heater and electric space-heating units operate at 240 V, 2-wire and have no neutrals. By considering only those loads served by a circuit with a neutral conductor and determining their maximum unbalance, the minimum required size of neutral conductor can be determined.

When a 3-wire, 240/120-V circuit serves a total load that is balanced from each hot leg to neutral—that is, half the total load is connected from one hot leg to neutral and the other half of total load from the other hot leg to neutral—the condition of maximum unbalance occurs when all the load fed by one hot leg is operating and all the load fed by the other hot leg is off. Under that condition, the neutral current and hot-leg current are equal to half the total load watts divided by 120 V (half the volts between hot legs). But that current is exactly the same as the current that results from dividing the *total* load (connected hot leg to hot leg) by 240 V (which is twice the voltage from hot leg to neutral). Because of this relationship, it is easy to determine neutral-current load by simply calculating hot-leg current load—total load from hot leg to hot leg divided by 240 V.

In the example here, the neutral-current load is determined from the following steps that sum up the components of the neutral load:

	Volt-amperes
1. Take 1500 sq ft at 3 VA/sq ft (Table 220.12)	4,500
2. Add three small-appliance circuits (two kitchen, one laundry) at 1500 VA each (220.52).....	4,500
Total lighting and small-appliance load	9,000
3. Take 3000 VA of that value at 100% demand factor (220.42 & 220.52; Table 220.42)	3,000
4. Take the balance of the load (9000 – 3000) at 35% demand factor: 6000 VA × 0.35	2,100
Total of 3 and 4	5,100

Assuming an even balance of this load on the two hot legs, the neutral load under maximum unbalance will be the same as the total load (5100 VA) divided by 240 V (Fig. 220-25) (all results are carried to three significant figures):

Fig. 220-25. Neutral current for lighting and receptacles. The 4.4-A net load equivalence between the laundry circuit and one portion of the lighting circuit is a coincidence. (Sec. 220.82.)

$$\frac{5100 \text{ VA}}{240 \text{ V}} = 21.3 \text{ A}$$

And the neutral unbalanced current for the range load can be taken as equal to the 8000-W range demand load multiplied by the 70 percent demand factor permitted by 220.61 and then divided by 240 V (Fig. 220-26):

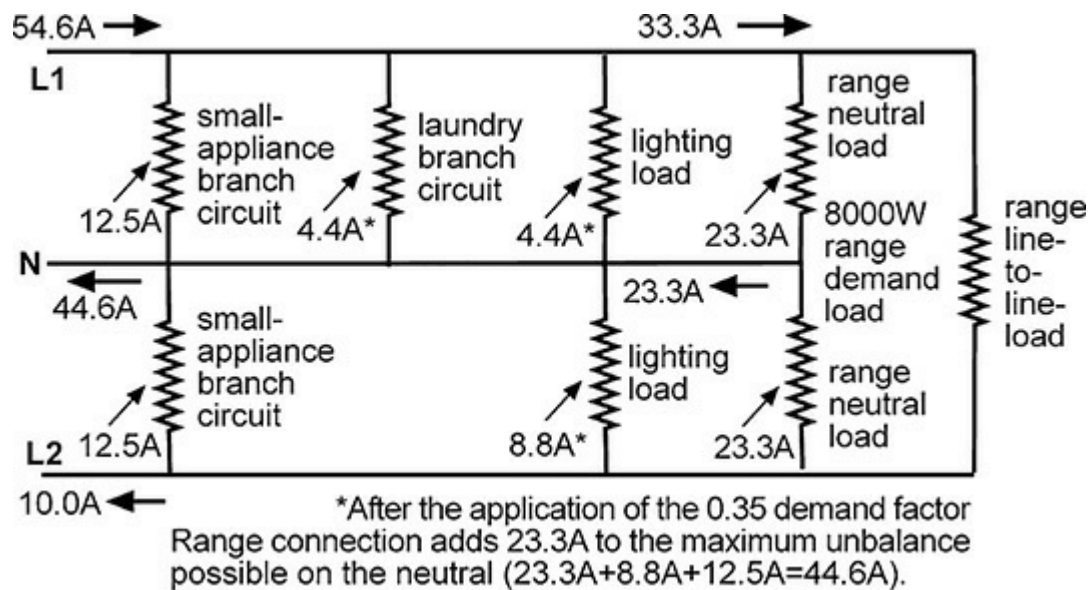

Fig. 220-26. Neutral for lighting, receptacles, and range. (Sec. 220.82.)

$$\frac{8000 \times 0.7}{240} = \frac{5600}{240} = 23.3 \text{ A}$$

The clothes dryer contributes neutral load due to the 115-V motor, its controls, and a light. As allowed in 220.61, the neutral load of the dryer may be taken at 70 percent of the load on the ungrounded hot legs. Therefore, the neutral capacity required to accommodate the dryer contribution is $(5000 \text{ W} \times 0.7) + 240 \text{ V} = 14.6 \text{ A}$.

Then, the neutral-current load that is added by the 120-V, 1200-W dishwasher must be added (Fig. 220-27): Although it could be argued that since this load is entirely on a single leg of the system, it should be added to the neutral directly, but that is not the case, as evidenced by the result in Annex D, Example D2(a) from which these numbers are taken. Making the calculation in this way only artificially inflates the size of the neutral. In the real world, the dishwasher and the small-appliance and the laundry and the general lighting circuits all originate from the same panel. There are, in this example and typically, three appliance circuits (laundry and small appliance) all taken at 1500 VA each. Obviously two will be on one line and one on the other. The number of lighting circuits is unknown but there will be some imbalance there as well. The 1200-W imbalance represented by the dishwasher will be totally lost in the distribution of loads in this panel. Simply placing it against one of the appliance circuits erases its contribution. Further, the 1200-W is not a steady load but one that cycles, depending on whether the booster element is in operation and whether the motor is running. This is why load calculations are usually done on a volt-ampere basis throughout, changing over to amperes only at the point where a conductor size must be determined.

Fig. 220-27. Neutral current for all loads in the example. The lighting load division between line

connections is to equalize the load, thereby minimizing the maximum imbalance and the need for a larger feeder neutral. (Sec. 220.82.)

The load calculations for neutral conductors assume reasonable balance for the branch circuits connected to them, as is generally required by 210.11(B). The most meticulously balanced distribution on paper will be defeated by poor panel work. For example, this calculation starts with 21.3 A of line-to-neutral load due to small-appliance and general lighting circuits. If these were arranged to connect to the same line bus, the result would be 42.6 A of current from these sources routinely. And all this could occur before the dishwasher is even connected.

The minimum required neutral capacity is, therefore,

$$\begin{array}{r} 21.3 \text{ A} \\ 23.3 \text{ A} \\ 14.6 \text{ A} \\ \underline{5.0 \text{ A}} \\ \text{Total: } 64.2 \text{ A} \end{array}$$

From Code Table 310.15(B)(16), the neutral minimum for 64 A would be:

4 AWG copper TW or 3 AWG aluminum
6 AWG THW copper* or 4 AWG aluminum*

*If the terminations are evaluated for 75°C connections; and 90°C insulation is permitted provided the conductor size remains as described. Note that if this panel were located remote from the service disconnecting means through a feeder that carried the entire load current, all of these conductors would satisfy 215.2(A)(2), requiring a reduced neutral to have enough size to carry a line-to-neutral short circuit. The minimum size in this case, per 250.122, is 8 AWG copper or 6 AWG aluminum.

This book is a handbook based on the 2017 **NEC**, and the above discussion is the best case the author can make to support the conclusion that is now in the **NEC** for this example. The method in this example has been unchanged since the 1984 **NEC** introduced the present 120/240-V nominal voltages, resulting in the recalculation of all the examples. It is also consistent with other neutral calculations throughout the examples, with one notable exception. It is glaringly inconsistent, however, with Example D(1)(b), which has been unchanged for the same amount of time. That example tracks the line contributions of specified 120-V appliances, and the end result shifts accordingly. The approach in Example D(1)(b) can also be supported based on a different reading of the rules in 210.11(B) than the one alluded to above, because the only clear command in that section is to balance loads on circuits that were determined on a load per unit area basis, and a dishwasher load was certainly not part of an area evaluation. Be advised that no clear conclusion can be reached as to how these loads should be calculated at this time.

220.83. Existing Dwelling Unit. This covers an optional calculation for additional loads in an existing dwelling unit that contains a 120/240- or 208/120-V, 3-wire service of any current rating. The method of calculation is similar to that in 220.82.

The purpose of this section is to permit the *maximum load* to be applied to an *existing* service without the necessity of increasing the size of the service. The calculations are based on numerous load surveys and tests made by local utilities throughout the country. This optional method would

seem to be particularly advantageous when smaller loads such as window air conditioners or bathroom heaters are to be installed in a dwelling with, say, an existing 60-A service, as follows:

If there is an existing electric range, say, 12 kW (and no electric water heater), it would not be possible to add any load of substantial rating. The first 8000 VA is taken at 100 percent, leaving the remainder of permissible load to be calculated at 40 percent. Use the formula $14,400 \text{ VA} (240 \text{ V} \times 60 \text{ A}) = 8000 \text{ VA} + 0.4(X \text{ VA})$, where the quantity (X) is the amount of other load to be evaluated. Rearranging terms gives $6400 \text{ VA} = 0.4X$, so $X = 16,000 \text{ VA}$, and therefore, the total “gross load” that can be connected to an existing 120/240-V, 60-A service would be $16,000 \text{ VA} + 8000 \text{ VA} = 24,000 \text{ VA}$.

example Thus, an existing 1000-sq-ft dwelling with a 12-kW electric range, two 20-A appliance circuits, a 750-W furnace circuit, and a 60-A service would have a gross load of:

	Volt-amperes
1000 sq ft \times 3 VA/sq ft.....	3,000
Two 20-A appliance circuits @ 1500 VA each.....	3,000
One electric range @.....	12,000
Furnace circuit @.....	750
	18,750
Gross volt-amperes	18,750

Since the *maximum* permitted gross load is 24,000 VA, an appliance not exceeding 5250 VA could be added to this existing 60-A service. However, the tabulation at the end of this section lists air-conditioning equipment, central space heating, and less than four separately controlled space-heating units at 100 percent demands; and if the appliance to be added is one of these, then it would be limited even more:

From the 18,750-VA gross load we already have 8000 VA @ 100 percent demand and $(10,750 \text{ VA} [18,750 - 8000] \times 0.40)$ or 4300 VA. The total for the 100 percent and the 40 percent calculation brackets is the sum of 8000 VA and 4300 VA, or 12,300 VA. Then, $14,400 \text{ VA} (60 \times 240 \text{ V}) - 12,300 \text{ VA} = 2100 \text{ VA}$ for an appliance listed at *100 percent demand*.

Although this procedure is limited with respect to saving 60-A services, it can also be applied, with considerably more headroom, to existing 100-A services.

220.84. Multifamily Dwelling. This section provides an optional method of calculating the load in a multifamily dwelling with a fairly high connected load, by reason of electric cooking equipment in all units as well as electric space heating or air conditioning or both. Any house loads are over and above the calculation results from this section, and are to be figured using the standard method in Part III. The connected load list for each dwelling unit is formatted the same as the calculation in 220.82, with two differences. There is no 40 percent bracket; instead, all connected loads are simply totaled. In addition, the heating/air-conditioning line is quite simple; just pick the larger number whether the one for heat or the one for air conditioning. Multiply the total per/unit calculation by the number of units, and then by demand factor based on the number of units in Table 220.84.

If the load for a multifamily housing project without electric cooking (and therefore does not initially qualify to use this procedure), as determined by the traditional procedures in Part III, turns out to exceed the numbers that come from Table 220.84, the smaller load is permitted to be used.

220.85. Two Dwelling Units. This section provides an optional calculation for sizing a feeder to “two dwelling units.” It notes that if calculation of such a feeder according to the basic long method of calculating given in Part III of Art. 220 exceeds the minimum load ampacity permitted by 220.84 for three identical dwelling units, then the *lesser* of the two loads may be used. This rule was added

to eliminate the obvious illogic of requiring a greater feeder ampacity for two dwelling units than for the three units of the same load makeup. Now optional calculations provide for a feeder to one dwelling unit, two dwelling units, or three or more dwelling units.

220.86. Schools. The optional calculation for feeders and service-entrance conductors for a school makes clear that feeders “within the building or structure” must be calculated in accordance with the standard long calculation procedure established by Part III of Art. 220. *But* the ampacity of any individual feeder does not have to be greater than the minimum required ampacity for the whole building, regardless of the calculation result from Part III. Note that these calculations differ from most in that they are based on actual load density. The entire connected load is added together, and then divided by the area of the school to generate a load per unit area, whether per square foot or meter. Then the unit load is reduced according to the table, in progressive steps. Finally, the applicable number of volt-amperes per unit area from each step is multiplied by the area of the building to get the final load.

The last sentence in this section excludes portable classroom buildings from the optional calculation method to prevent the possibility that the demand factors of Table 220.86 would result in a feeder or service of lower ampacity than the connected load. Such portable classrooms have air-conditioning loads that are not adequately covered by using a watts-per-square-foot calculation with the small area of such classrooms.

220.87. Determining Existing Loads. Because of the universal practice of adding more loads to feeders and services in all kinds of existing premises, this calculation procedure is given in the Code. To determine how much more load may be added to a feeder or set of service-entrance conductors, at least one year’s accumulation of measured maximum-demand data must be available. Then, the required spare capacity may be calculated as follows:

$$\text{Additional load capacity} = \text{ampacity of feeder or service conductors} - ([1.25 \times \text{existing demand kVA} \times 1000] \div \text{circuit voltage})$$

where “circuit voltage” is the line-to-line value for single-phase circuits and $\sqrt{3}$ (1.732) times the phase-to-phase value for 3-phase circuits.

A third required condition is that the feeder or service conductors be protected against overcurrent, in accordance with applicable Code rules on such protection.

If the full-year demand data is not available, an exception allows for a month of monitoring by a continuously recording ammeter, based on maximum demand for the period as defined by the highest average kilowatts reached and maintained for a 15-minute interval. This phrasing was clarified by a simple but important bit of panel work during the 2017 **NEC** cycle. The building must be occupied so the readings will be realistic. In addition, periodic or seasonal loading must be accounted for, either by direct measurements or by calculation, so that the larger of the heating and cooling loads will be included. Although utility demand meter data is commonly available for a full year for service loads, this alternative method is extremely important when the feeder in question is not subject to utility metering, such as a feeder to one part of a building or a feeder connected to a separately derived system.

220.88. New Restaurants. This calculation is available to new restaurants, and produces two

different results based on whether or not the restaurant has gas-fired cooking equipment. The numbers for the all-electric restaurants are, of course, significantly higher. The demand table looks somewhat different from comparable tables elsewhere in Art. 220, with one entry providing a 10-percent increment for additional loading over a base number, and others providing far different increments ranging from 20 to 50 percent, and in different relative orders based on the type of restaurant. The table entries are correct.

When this table first came into the **NEC**, it looked like a conventional table, but it turned out to generate paradoxical results. In one instance adding a few kVA to a load took about 80 A off the ending service calculation, and this was not in just one location. The only way to be sure that additional connected load actually resulted in additional service or feeder capacity was to go back and carefully copyfit demand curves to the utility data that provided the substantiation for the change. That data is well documented, but the resulting curves have some interesting shapes, and the current values in Table 220.88 accurately predict the electrical demand.

Part V. Farm Load Calculations This part of the article stands alone because farms usually have both a dwelling and a commercial operation connected to a single distribution point. Therefore, some of the loads are eligible for optional treatments in Part IV and others are not, requiring a direct transition from the branch circuit calculations in Part II to the calculations here. In general, the farmhouse is a dwelling unit and qualifies for the optional dwelling unit procedures in Part IV. However, if the dwelling has electric heat and the farm operation uses electric grain drying systems, the dwelling must be calculated under the conventional procedures in Part III if it and the barn have a common service.

The electrical equipment for farm operations is taken through Table 220.102, using a master compilation of farm loads in terms of those that will operate continuously and otherwise. Beginning with the continuous loads take the first 60 A at 100 percent and then add the next 60 A of load at 50 percent, and then all other load at 25 percent. Then, for the total farm load, use Table 220.103, which is organized by load. If different buildings or loads have the same function, then those loads can be combined into a single load for these purposes. After the load analysis is complete, add the farm dwelling load calculated as noted above.

ARTICLE 225. OUTSIDE BRANCH CIRCUITS AND FEEDERS

225.1 Scope. This article covers all outdoor installations of conductors “on or between buildings, structures, or poles on the premises” and utilization equipment mounted on the outside of buildings, or outdoors on other structures or poles. This rule is followed by the rule of Sec. 225.2, which indicates other Code rules that bear upon the installation of equipment and conductors outdoors on buildings, structures, or poles. Like the large majority, but not all **NEC** articles commencing with the 2014 edition, the elevated voltage cut point has been raised from 600 to 1000 V throughout.

225.4. Conductor Covering. The wiring method known as “open wiring” is recognized in Art. 225 as suitable for overhead use outdoors—“run on or between buildings, structures, or poles” (Fig. 225-1). This is derived from Secs. 225.1, 225.4, 225.14, 225.18, and 225.19. In Sec. 225.4 the Code requires open wiring to be insulated for the nominal voltage if it comes within 10 ft (3.0 m) of any building or other structure, which it must do if it attaches to the building or structure. Insulated conductors have a dielectric covering that prevents conductive contact with the conductor when it is energized. This is new as of the 2014 **NEC**; this section used to permit such wires to be “insulated

or covered.” Covered conductors, now no longer recognized—such as braided, weatherproof conductors—have a certain mechanical protection for the conductor but are not rated as having insulation, and thus there is no protection against conductive contact with the energized conductor.

Fig. 225-1. Open wiring is OK for overhead circuits. (Sec. 225.4.)

Because 225.4 says that conductors in “cables” (except Type MI) must be of the rubber or thermoplastic type, a number of questions arise.

1. What kind of “cable” does the Code recognize for overhead spans between buildings, structures, and/or poles?
2. May an overhead circuit from one building to another or from lighting fixture to lighting fixture on poles use service-entrance cable, UF cable, or Type NM or NMC nonmetallic-sheathed cable?

The Code covers specific types of cables in turn ([Chap. 3](#)), but only in Art. 396 does the Code refer to use for outdoor overhead applications. Effective with the 2008 **NEC**, 396.30(B) and (C) for the first time cover the use of messenger cable assemblies with the messenger performing an electrical function, thereby closing a long-standing gap in **NEC** coverage. In addition, the use of service-entrance cable between buildings, structures, and/or poles is supported by Art. 338 in 338.12(A)(3), which points to Part II of Art. 396, thereby including the express reference in 396.10(A).

Use of Type MI, MC, or UF cable for outdoor, overhead circuits is supported by Sec. 396.10. There are no exceptions given to the support requirements in Sec. 334.30 that would let NM or NMC be used aerially, and such cables are not recognized by Sec. 396.10(A) for use as “messenger supported wiring.”

Service-Drop Cable

The **NEC** has Art. 396, “Messenger Supported Wiring,” which covers use of “service-drop” cable, but the UL has no listing for or reference to such cable. There is a listing for a suitable medium-voltage cable, but traditionally the principal customer for service-drop cables has been the electric utilities. And, since they are not usually subject to the **NEC** because most of their applications are on

the line side of the service point, there has not been a large market for a listed product. Article 396 does not require a listing for this product. The NEC does make reference to it; and its use for aerial circuits between buildings, structures, and/or poles is particularly dictated (Fig. 225-2). Experience with this cable is very extensive and highly satisfactory. It is an engineered product specifically designed and used for outdoor, overhead circuiting.

Fig. 225-2. Aerial cable for overhead circuits. (Sec. 225.4 and 225.11.)

NEC rules in 230.21 through 230.29 cover use of service-drop cable for overhead service conductors. Because the general rules of Art. 225 on outside branch circuits and feeders do make frequent references to other sections of Art. 230, it is logical to equate cables for overhead branch circuits and feeders to cables for overhead services. Although the rules of Art. 396 refer to a variety of messenger-supported cable assemblies, for outdoor circuits, use of service-drop cable is the best choice—because such cable is covered by the application rules of 230.21 through 230.29. Other types of available aerial cable assemblies, although not listed by UL, might satisfy some inspection agencies. But, in these times of OSHA emphasis on codes and standards, use of service-drop cable has the strongest sanction.

One important consideration in the use of service-drop cable as a branch circuit or feeder is the general Code prohibition against use of bare circuit conductors. 310.106(D) generally requires conductors to be insulated, although bare or covered conductors may be used where “specifically permitted.” Bare *equipment grounding conductors* are permitted in 250.118. A bare conductor for SE cable is permitted in 338.100. Bare neutrals are permitted for service-entrance conductors in the exception to 230.41, for underground service-entrance conductors in the exception to 230.30, and for *overhead service conductors* in 230.22, exception *when used as service conductors*. When service-drop cable is used as a feeder or branch circuit, however, there is no permission for use of a bare circuit conductor—although it may be acceptable to use the bare conductor of the service-drop cable as an equipment grounding conductor. And where service-drop cable is used as a feeder from one building to another, it would seem that a bare neutral could be acceptable as a grounded neutral conductor—as permitted in the last sentence of 338.3(B), first paragraph. This is where the new language in 396.30 is useful, because it expressly recognizes this use when it complies with 225.4, and 225.4 Exception allows the bare neutral where recognized elsewhere, such as where a regrounded neutral is permitted as covered in 250.32(B)(1) Exception No. 1. Note that such regrounded neutrals are only permitted for existing premises wiring systems, so this use will gradually disappear.

When service-drop cable is used between buildings, the method for leaving one building and entering another *must* satisfy 230.52 and 230.54. This is required in Sec. 225.11.

The exception to 225.4 excludes equipment grounding conductors and grounded circuit conductors from the rules on conductor covering. This exception permits equipment-grounding conductor *and* grounded circuit conductors (neutrals) to be bare or simply covered (but not insulated) as permitted by other Code rules.

Because the matter of outdoor, overhead circuiting is complex, check with local inspection agencies on required methods. As **NEC** 90.4 says, the local inspector has the responsibility for making interpretations of the rules.

225.5. Size of Conductors 1000 V Nominal or Less. This rule calls for conductor ampacity to be determined in accordance with 310.15 and the rules of Art. 220. But remember, where the load to be supplied is continuous or a combination of continuous and noncontinuous loads, then the rules of 210.19(A) and 210.20(A) or 215.2(A) and 215.3(A), covering conductor sizing and OC protection for branch circuits and feeders supplying continuous loads, must be observed, as well.

225.6. Conductor Size and Support. Open wiring must be of the minimum sizes indicated in 225.6 for the various lengths of spans indicated.

Article 100 gives a definition of *festoon lighting* as “a string of outdoor lights suspended between two points” (Fig. 225-3). Such lighting is used at carnivals, displays, used-car lots, etc. Such

application of lighting is limited because it has a generally poor appearance and does not enhance commercial activities.

Fig. 225-3. Festoon lighting is permitted outdoors. (Sec. 225.6.) Note that 590.4(F) requires a guard on lampholder such as the one shown here if the use qualifies as temporary wiring.

As covered in 225.6(B), overhead conductors for festoon lighting must not be smaller than No. 12; and where any span is over 40 ft (12.0 m), the conductors must be supported by a messenger wire, which itself must be properly secured to strain insulators. But the rules on festoon lighting do not apply to overhead circuits between buildings, structures, and/or poles.

225.7. Lighting Equipment Installed Outdoors. Part (B) permits a common neutral for both outdoor branch circuits and feeders—something not permitted for indoor branch circuits (a neutral of a 3-phase, 4-wire circuit is *not* a common neutral), although 215.4 grants limited permission for feeders with common neutrals. For two 208Y/120-V multiwire circuits consisting of six ungrounded conductors (two from each phase) and a single neutral (serving both circuits) feeding a bank of floodlights on a pole, if the maximum calculated load on any one circuit is 12 A and the maximum calculated load on any one phase is 24 A, the ungrounded circuit conductors may be No. 14, but the neutral must be at least No. 10. This rule clearly states the need to size a common neutral for the *maximum* (most heavily loaded) phase leg made up by multiple conductors connected to any one phase and supplying loads connected phase-to-neutral.

Part (C) covers use of 480/277-V systems for supplying incandescent and electric-discharge lighting fixtures. The former requirement that outdoor fixtures installed for lighting “outdoor areas” at commercial or public buildings must be not less than 3 ft (900 mm) from “windows, platforms, fire escapes, and the like” was deleted for the 2011 edition, thereby finally eliminating the obvious inconsistency between a 277-V bollard luminaire that a three-year-old could walk up to and hug because there was no objection in 210.6(C), and yet the same luminaire covered here had to be out of reach.

225.8. Calculation of Loads 1000 Volts, Nominal, or Less. Part (A) of this section

calls for branch circuits to be sized in accordance with the rules of 220.10. And, part **(B)** of this rule calls for compliance with Part III of Art. 220 when sizing outdoor feeder conductors run “on or attached to” buildings, and so forth.

225.10. Wiring on Buildings (or Other Structures). This section identifies those wiring methods, rated up to 1000 V, that are permitted to be mounted on the exterior of buildings. Note that rigid nonmetallic conduit (PVC or RTRC) may be used for outside wiring on buildings, as well as the other raceway and cable methods covered in this section. For a long time, rigid PVC was not permitted for such application. Installation of conductors rated over 1000 V must comply with the provisions of 300.37, and electric signs and outline lighting must be installed as dictated by the rules of Art. 600.

225.14. Open-Conductor Spacings. Open wiring runs must have a minimum spacing between individual conductors (as noted in 225.14) in accordance with Table 230.51(C), which gives the spacing of the insulator supports on a building surface and the clearance between individual conductors on the building or where run in spans (Fig. 225-4).

Minimum clearance distance between conductors is given in Table 230.51 (C)

Fig. 225-4. Spacing of open-wiring conductors. (Sec. 225.14.)

It should be noted that 225.14 and Table 230.51(C) require that the *minimum spacing* between individual conductors in spans run overhead be 3 in. (75 mm) for circuits up to 300 V (such as 120, 120/240, 120/208, and 240 V). For circuits up to 1000 V, such as 480 Δ and 480/277 V, the *minimum spacing* between individual conductors must be at least 6 in. (150 mm).

225.17. Masts as Supports. Masts must have sufficient rigidity to handle the strain, or they must be guyed accordingly. If a raceway mast is used, any fittings must be identified for use with masts including the hub at the base, and only the feeder and branch-circuit conductors within the scope of Art. 225 can be attached to the mast. For example, a telephone drop is not permitted to be attached to a power circuit mast, regardless of the strength of the raceway or the amount of guy wire support provided.

As of the 2014 **NEC**, there is now a complete prohibition against attaching the drop to any mast above the highest coupling unless there is a “point of securement” above it. This is not controversial because an additional attachment to the side of a building is easily accomplished. However, the new rule goes on to prohibit, in all cases, the coupling above the roof. This is, of course, the preferred design, because the process of threading a steel conduit inevitably weakens it substantially particularly in reference to a shearing load. It is of interest that an attempt to allow for an exposed coupling in the event the strain was offset by a guy wire failed because the panel was concerned about the guy wire being released during roofing activities.

225.18. Clearance for Overhead Conductors and Cables. Overhead spans of open conductors and open multiconductor cables must be protected from contact by persons by keeping them high enough above ground or above other positions where people might be standing. And they must not present an obstruction to vehicle passage or other activities below the lines (Fig. 225-5).

Fig. 225-5. Conductor clearance from ground. (Sec. 225.18.)

The rule of 225.18 applies to “open conductors and open multiconductor cables” and gives the conditions under which clearances must be 10, 12, 15, 18, or 24.5 ft (3.0, 3.7, 4.5, 5.5, or 7.5 m)—for conductors that make up either a branch circuit or a feeder [not service-drop conductors, which are subject to 230.24(B)]. The 24.5 ft (7.5 m) span height is new as of the 2011 edition and covers overhead crossings over railroad tracks. The dimension comes from the NESC. Although the wording used here is the same as that referring to corresponding clearances in 230.24(B), 225.18 covers those “open conductors and open multiconductor cables”—such as triplex and quadruplex cables—that do not meet the definition of service conductors, which would be regulated by Art. 230. Article 225 gives minimum clearances for triplex or quadruplex cables, as well as open individual conductors, commonly used for outdoor overhead branch circuits and feeders.

As 225.18 stands, “open conductors and multiconductor cables” for an overhead *branch circuit* or *feeder* require only a 10-ft (3.05-m) clearance from ground for circuits up to 150 V to ground; just as service-drop conductors up to 150 V must have a clearance of not less than 10 ft (3.05 m) from ground.

The rules of this section agree with the clearances and conditions set forth in the *NESC (National Electrical Safety Code)* for open conductors outdoors. The distances given for clearance from ground must conform to maximum voltage at which certain heights are permitted.

225.19. Clearances from Buildings for Conductors of Not Over 1000 Volts,

Nominal. The basic minimum required clearance for outdoor conductors running above a roof is 8-ft (2.5-m) vertical clearance from the roof surface.

The basic ideas behind the rules are as follows:

1. Any branch-circuit or feeder conductors—whether insulated, simply covered, or bare—must have a clearance of at least 8 ft (2.5 m) vertically from a roof surface over which they pass. And that clearance must be maintained not less than 3 ft (900 mm) from the edge of the roof in all directions.
2. A roof that is subject to “pedestrian or vehicular traffic” must have conductor clearances “in accordance with the clearance requirements of 225.18.” That reference essentially requires a clearance of 12 ft above a roof that serves as driveway or parking area, not subject to “truck traffic,” and where the voltage to ground does not exceed 300 V to ground. Where the voltage to ground exceeds 300 V to ground, then a minimum clearance of 15 ft must be provided. And, if the area is subject to truck traffic and the conductors are operated at more than 300 V to ground, then a minimum of clearance above the roof of 18 ft must be provided.

In parts **(B)** and **(C)**, overhead conductor clearance from signs, chimneys, antennas, and other nonbuilding or nonbridge structures must be at least 3 ft (900 mm)—vertically, horizontally, or diagonally.

Part **(D)** addresses installation details regarding clearance of “final spans.” In part **(D)(1)**, the Code requires that the connection point of overhead branch circuit and feeder conductors to the building be kept at least 3 ft from any of the building openings identified by the first part of this rule. The rule exempts windows that do not open from compliance.

But in part **(D)(2)** the Code addresses those final spans that run above areas that people may occupy. Where the final span’s connection point runs above, or is within 3 ft horizontally from, “platforms, projections, or surfaces” where a person could come into contact with the conductors or cable, the clearances given in 225.18 must be observed.

Part **(D)(3)** prohibits installation of outside branch-circuit and feeder conductors beneath, or where they obstruct the entrance to, building openings through which material or equipment is intended to be moved. Barns provide a good example of the type of building opening this rule is intended to cover. Although only “farm and commercial buildings” are mentioned, they are only held up as examples. The wording used extends this requirement to any such opening, at any occupancy.

As indicated in [Fig. 225-6](#), Exception No. 2 to 225.19(A) may apply to circuits that are operated at 300 V or less.

Fig. 225-6. Conductors—whether or not they are fully insulated for the circuit voltage—must have at least 8-ft (2.44-m) vertical clearance above a roof over which they pass. (Sec. 225.19.)

Part (E) covers a preferred exclusion zone (required only if practicable) in which overhead lines should not be run adjacent to high-rise buildings in order that fire ladders can be set up.

225.22. Raceways on the Exterior Surfaces of Buildings or Other Structures.

Condensation of moisture is very likely to take place in conduit or tubing located outdoors. The conduit or tubing should be considered suitably drained when it is installed so that any moisture condensing inside the raceway or entering from the outside cannot accumulate in the raceway or fittings. This requires that the raceway shall be installed without “pockets,” that long runs shall not be truly horizontal but shall always be pitched, and that fittings at low points be provided with drainage openings.

An excellent way to accomplish this is to drill a weep hole in an appropriate location in a conduit body, such as in the heel of an LB at the bottom of a vertical run or in the bottom side of a “C” fitting in a horizontal run. This practice is now expressly allowed in 314.15.

In order to be raintight, all conduit fittings must be made up wrench-tight. Couplings and connectors used with electrical metallic tubing shall be listed as “raintight.”

225.24. Outdoor Lampholders. This section applies particularly to lampholders used in festoons. Where “pigtail” lampholders are used, the splices should be staggered (made a distance apart) in order to avoid the possibility of short circuits, in case the taping for any reason should become ineffective.

According to the UL Standard for Edison-Base Lampholders, “pin-type” terminals shall be employed only in lampholders for temporary lighting or decorations, signs, or specifically approved applications. The NEC requires that such lampholders only be used on stranded wire.

225.25. Location of Outdoor Lamps. In some types of outdoor lighting it would be difficult to keep all electrical equipment above the lamps, and hence a disconnecting means may be required. A disconnecting means should be provided for the equipment on each individual pole, tower, or other structure if the conditions are such that lamp replacements may be necessary while the lighting system is in use. It may be assumed that grounded metal conduit or tubing extending below the lamps would not constitute a condition requiring that a disconnecting means must be provided.

225.26. Vegetation As Support. Trees or any other “vegetation” must not be used “for

support of overhead conductor spans.” Note that the wording used here does not include electric equipment, but, rather, only prohibits “overhead conductor spans” from being supported by “vegetation.” The effect is to permit outdoor lighting fixtures to be mounted on trees and to be supplied by an approved wiring method—conductors in a raceway or Type UF cable—attached to the surface of the tree (Fig. 225-7).

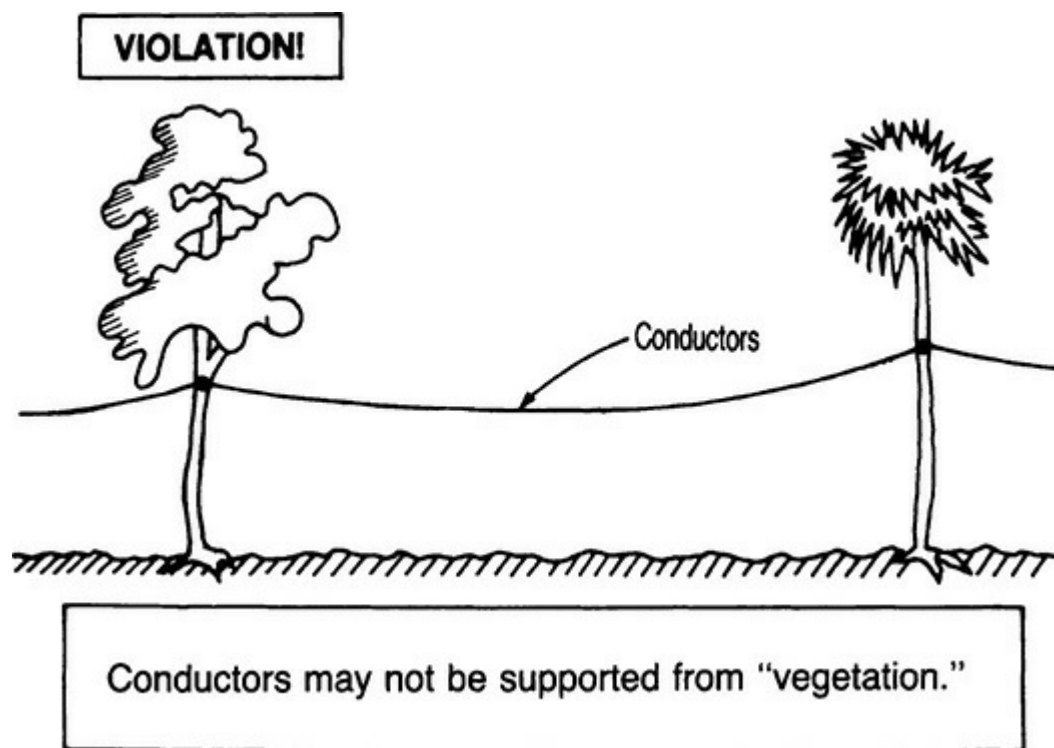

Fig. 225-7. The rule of 225.26 prohibits overhead wiring installed on trees.

225.27. Raceway Seal. This is simply the existing requirement for underground services (230.8) copied into Art. 225, so the concept will apply to additional buildings supplied by feeders under similar conditions.

Part II. Buildings or Other Structures Supplied by a Feeder(s) or Branch Circuit(s)

225.30. Number of Supplies. These rules cover those installations where several buildings are supplied from a single service. Although technically “feeder” or “branch-circuit” conductors, given that the supply conductors to the other buildings are the effective equivalent of service conductors, the rules given in Part II of Art. 225 are very nearly identical to those given for service conductors by Art. 230. In fact, many of the rules here were simply lifted from Art. 230 and modified as needed for use in Art. 225.

In 225.30, the Code stipulates the number of sources of supply to one building from another. The basic rule is similar to 230.2 for services, which calls for no more than one source of supply. Of course, as with 230.2, the rules in 225.30(A) through (E) present a number of circumstances where it would be permissible to supply one building or structure from another with more than one source. The wording used here is identical to that used in Sec. 230.2, which regulates the number of services permitted, simply because the “feeder” from the main building (i.e., the one where the service is installed) is essentially or effectively the “service” to the second building. For a group of buildings

under single management, disconnect means must be provided for each building, as in Fig. 225-8.

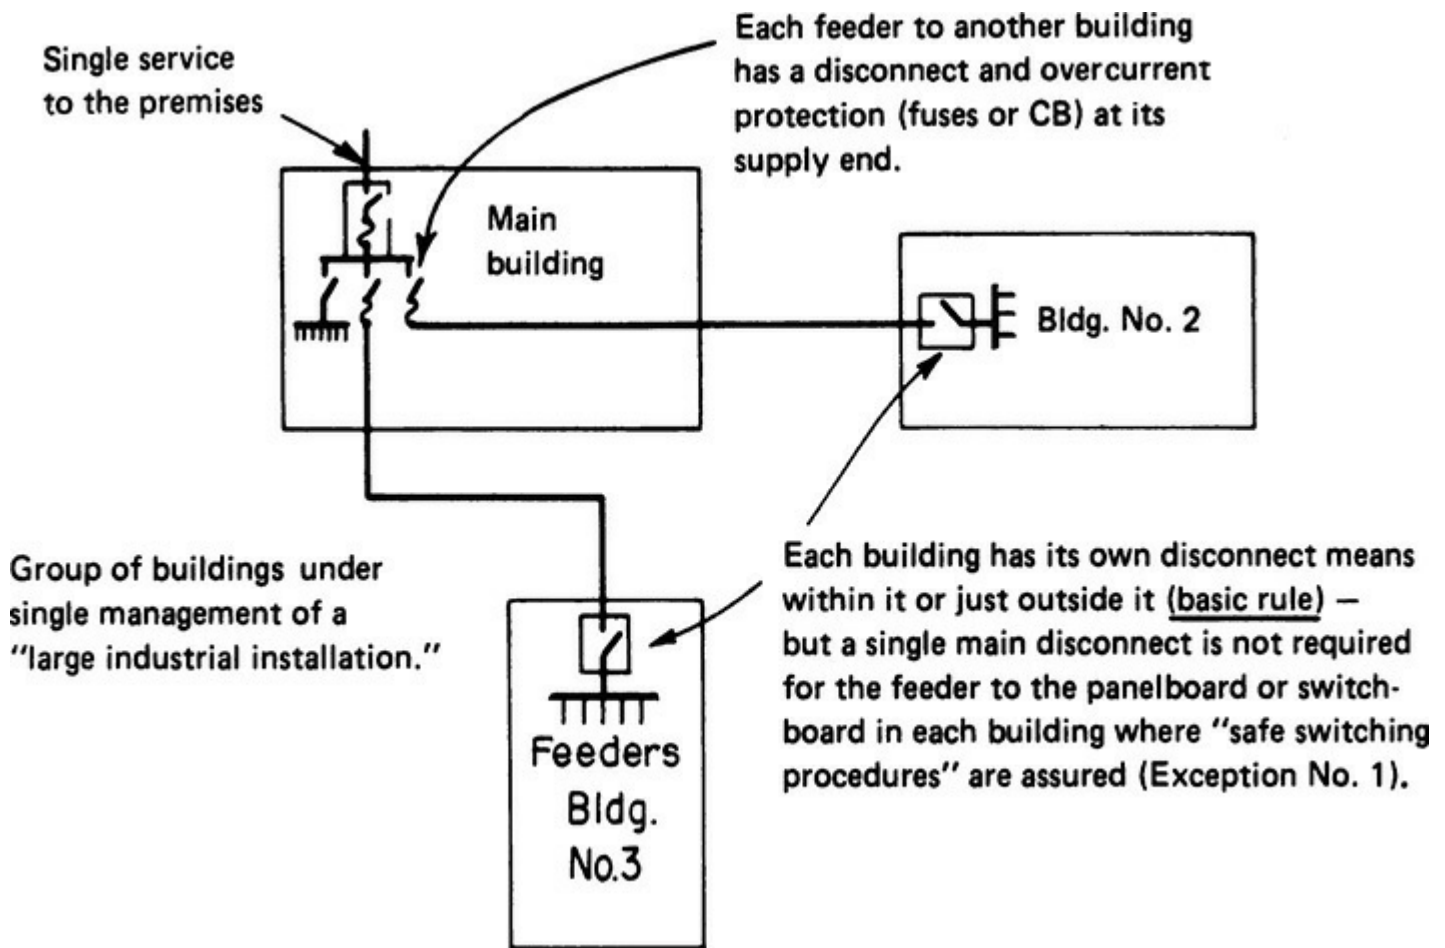

Fig. 225-8. Each building must have its own disconnect means. (Sec. 225.32.)

An important 2011 **NEC** additional paragraph to this section addresses instances where feeders leave building No. 1, arrive at building No. 2 to greet a generator in building No. 2 which has been designed to carry loads in both buildings. The literal text does not say this, but that is what was described in the documentation. When this happens, no more than one feeder or branch circuit is permitted to go back to building No. 1 unless specifically permitted under paragraphs (A) through (E) following.

The rules for services will be exhaustively covered in Art. 230, so this discussion will only focus on the differences between parts II and III of this article and the service article. The principal general difference is that wiring from one building to another, although superficially like service wiring, is not service wiring. A *service entrance* is the interface between premises wiring and the facilities of the serving utility. It is also the interface between wiring governed by the National Electrical Safety Code (NESC) and premises wiring governed by the **National Electrical Code**. These codes are very different because the NESC presumes that the maintenance of those systems will be performed by a highly regulated utility workforce operating under a unique workplace culture and environment, and that this will continue for the foreseeable future, given the organizational permanence of utility enterprises. If there is no utility interface, then there is no service. For this reason, it is incorrect to label the disconnecting means for one building fed from another as a "service" disconnect when it is actually a "building" disconnect. The real significance of the creation of this part of Art. 225 is the clarity it brings to what is encompassed by a service, and more importantly, what is not. Specific

differences are as follows:

As previously noted, only one source of supply is permitted as a general rule. This is the same general rule as for services, but there are subtle differences. The permission to run multiple service laterals from a common connection to disconnected loads does not apply. The allowance for multiple supplies where the capacity requirement exceeds that which the local utility supplies through one service does not apply for obvious reasons, and the allowance for an exemption on capacity grounds by special permission does not apply either. The final difference is the permission, granted here and not for services, for additional supplies where there are “documented switching procedures” in place for safe disconnection. This normally arises on large, campus-style industrial distributions.

The 2017 **NEC** added a seventh allowance, for multiple supplies to electrical vehicle charging stations, since they frequently are installed in multiple, and must be circuited as individual branch circuits for each unit. Some inspectors had been rejecting these arrangements based on the previous definition of “structure” in Art. 100 that could have been interpreted as describing the resulting installations as structures capable of receiving only one supply circuit. This allowance is unnecessary because the definition was changed, and it can presumably be removed in the next revision cycle. Refer to the discussion in Art. 100 for more information.

225.31. Disconnecting Means. This rule mandates the installation of a disconnecting means to permit the feeder or branch-circuit conductors that supply “or run through” a building to be deenergized.

The location and other details are presented by 225.32.

As could be anticipated, the required disconnecting means for the building supply conductors must be installed at a “readily accessible location” as defined in Art. 100 of [Chap. 1](#).

225.32 Location. This rule calls for the disconnecting means to be located at the point where the supply conductors enter the building if the disconnecting means are located inside or outside the building or structure served. This rule has been questioned by some experts. The wording here is essentially the same as it is for service conductors, although the supply conductors are fully protected against overcurrent. Where installed inside an auxiliary building or structure, supplied from a service in another building, the disconnecting means required by this rule must be at the point of conductor entry.

The reason is to back up the essential nature of the disconnect rules in this part of the article, namely, if there is a problem with the wiring system in a remote building (or structure), it should never be necessary to go to another location to disconnect the wiring, with only rare and very specific exceptions. This even applies to a powered garage at a detached single-family dwelling. Note also that 700.12(B)(6), 701.12(B)(5), and 702.12 create [Chap. 7](#) amendments to this [Chap. 2](#) requirement by allowing remote disconnects on outdoor generators provided they are “within sight” of the occupancy served. In addition, 700.12(B)(6) Exception allows out-of-sight disconnecting means under conditions that correlate with 225.32 Exception No. 1.

The last sentence of 225.32 states that the remedies provided in 230.6 apply to the feeder and branch-circuit conductors supplying an outbuilding. This allowance can be used, just as for service conductors, to artificially extend the point of entry into a building to an interior disconnecting means.

Exception No. 1 applies to commercial, industrial, and institutional occupancies where a full-time staff provides maintenance. If such a facility’s maintenance staff have established—in writing—“safe switching procedures,” then the disconnecting means required by the basic rule may be located remotely from the building supplied.

For any “integrated electrical system” as defined and regulated by Art. 685, Exception No. 2 suspends the basic rule calling for a feeder disconnect at each building.

Exception No. 3 eliminates the need for individual disconnects for individual lighting standards. The literal wording calls for a disconnect at each “structure.” The addition of this exception indicates the CMP’s intent, which is to permit one disconnect for a number of lighting poles. And Exception No. 4 extends similar recognition to “poles or similar structures” that support signs (Art. 600).

225.33. Maximum Number of Disconnects. The six-disconnect rule is almost the same as for services, but in this application, disconnects for surge-protective equipment and power monitoring equipment are not exempted from the allowable total of six. The access requirements, the grouping requirement, the requirement to segregate disconnects for certain critical systems, and the specification of minimum ratings for certain applications are the same as for services.

225.36. Type of Disconnecting Means. This section has been completely revised as of the 2014 **NEC**, and in the process two crucial changes to prior practice resulted. First, unless the supply to the second building has a regrounded neutral as covered in 250.32(B)(1) Exception No. 1 and therefore only for existing installations wired many years ago when such connections were routinely permitted, a disconnecting means that is suitable for use as service equipment is no longer required. Such disconnects have increased spacings and provisions to reground the neutral, and have no relevance to most of today’s applications.

Any disconnecting means that complies with 225.38, including a snap switch, is permitted if it has the required number of poles and the applicable voltage and current ratings. Note that the former exception in 225.38 allowing three-way and four-way switches for residential outbuildings, even though they were not indicating as normally required in 225.38(D), has been deleted. Therefore, although snap switches are permitted, three-way and four-way switches cannot be used as the required disconnecting means.

Each disconnecting means must be grouped and marked to indicate its function and the load served as covered in 225.34(A). A residential compromise in 225.37 Exception No. 2 involves a waiver of the reciprocal labeling rule when multiple circuits supply a dwelling outbuilding. The Code-making panel decided that reciprocal signage in such a building to the effect of “This is disconnect 1 of 2, controlling the overhead light; disconnect 2 of 2 located on the west side of the garage door controls the GFCI receptacle” would be excessive. The reciprocal labeling waiver does not, however, waive the identification rule on each switch; nor does it waive any other disconnecting requirements covered here. Specifically:

1. Ungrounded conductors supplying a load intended to stay energized, such as a receptacle, must pass through a disconnecting means located at a readily accessible point nearest the point of entrance.
2. A snap switch is a permissible disconnecting means as long as it is indicating.
3. The switches associated with a single source of supply, such as a single branch circuit, must be grouped, although they needn’t be as close as adjacent snap switches in a two-gang box.
4. Each switch must be marked with its function. If that function is obvious, such as the overhead light, **NEC** 110.22 allows some basis for omitting this marking. However, by providing the marking you will avoid challenges.

Suppose you install a receptacle that will supply a freezer, and the owner wants to be assured that it won’t be turned off inadvertently. Assume there will also be a light controlled from the house and

the garage using three-way switches. Run the three-way switch travelers through a two-pole snap switch in another box near the point of entry, perhaps at an odd height, say 3 ft above the floor, and mark it **LIGHT**. Run the receptacle feed through a single-pole snap switch near the disconnect for the three-way switch and mark it **RECEP DISC**. or similar. It would be permitted, but not required, to install some sort of weatherproof cover over these disconnect switches to preclude inadvertent operation, as long as the disconnect functions could be read with the cover closed.

Part III, Over 1000 Volts

This part covers medium-voltage supply wiring (over 1000 V).

225.50. Sizing of Conductors. This incorporates the usual medium-voltage circuit sizing provisions from 215.2(B) (for feeders) and 210.19(B) for branch circuits.

225.51. Isolating Switches. This carries over the provisions of 230.204 so they will apply to applications within the scope of Art. 225.

225.52. Disconnecting Means. Part (A) and (B) (principal text) are unchanged from the 2008 **NEC** and essentially follow 230.205(A) and (C) with one major difference. The grade-operable pole-top disconnect now found in 230.205(A) has now, as of the 2014 **NEC**, been included in these rules.

The exception to the simultaneous disconnecting means requirement for the ungrounded conductors is new as of the 2011 **NEC** and covers fused cutouts, which can be safely opened as single-pole devices provided the load has been removed by some other means. There must be a sign installed adjacent to the cutouts stating this requirement. Therefore, the exception now mandates the wording on the sign to read: “DISCONNECT LOAD BEFORE OPENING CUTOUPS.”

Parts (C), (D), and (E), although new as of 2011, cover some of the usual features of disconnects, including a lock-open function, a clear indication of their state, (off) or (on), and that when oriented vertically up is to be the on position unless a double-throw switch makes that irrelevant. Part (F) is also new and restates 225.37 [and thereby 230.2(E)], but without either the dwelling unit exception (obvious) or the safe switching procedures exception for multibuilding industrial installations (not a single word of substantiation having been offered for effectively removing the more usual application of that exception).

225.56. Inspections and Tests. This section sets forth the parameters for acceptance testing generally prior to placing the installation into service, although the tests in 225.56(A)(7) necessarily occur after operation is underway. See also 110.41, which provides a more universal platform for these procedures.

225.60. Clearances over Roadways, Walkways, Rail, Water, and Open Land. Medium-voltage feeders run overhead need to meet enhanced clearances reflecting the increased hazard involved for circuits operating over 1000 V.

225.61. Clearances over Buildings and Other Structures. These conductors must be installed so that they are at least 2.3 m (7.5 ft) away (horizontally separated) from building walls, projections, and windows. They must observe the same horizontal spacing from balconies, catwalks, and similar areas that people would have access to, and the same distance applies to other structures. The same conductors must be at least 3.8 m (12.5 ft) either above or below a roof (or other projection) where run at that level. For roofs accessible to vehicles (but not truck traffic) such as

parking garages, the vertical clearance rises to 4.1 m (13.5 ft), 5.6 m (18.5 ft) if truck traffic uses the roof. Clearances over open ground vary by the type of traffic as well, beginning at 4.1 m (12.5 ft) for walkways and then rising a foot to 4.4 m (14.5 ft) for pedestrian ways and restricted traffic. Water areas not suitable for boating come in at 5.2 m (17 ft) and then open land suitable for grazing, cultivation, or vehicles, along with ways subject to vehicular access generally, including roads, driveways, alleys, and parking lots, all at 5.6 m (18.5 ft). The highest prescribed clearance, 8.1 m (26.5 ft), applies to runs over railways. These clearances all apply to medium voltages up to and including 22 kV *measured to ground*. Higher voltages add 10 mm (0.4 in) per kilovolt above 22 kV, and special cases, including clearances over navigable waters, and areas with large vehicles such as mining operations may require special engineering and review by the authority having jurisdiction.

ARTICLE 230. SERVICES

230.2. Number of Services. For any building, the service consists of the conductors and equipment used to deliver electric energy from the utility supply lines to the interior distribution system. Service may be made to a building either overhead or underground, from a utility pole line or from an underground transformer vault.

The first sentence of this rule requires that a building or structure be supplied by “only one service.” Because “service” is defined in Art. 100 as “The *conductors* and equipment for delivering energy from the serving utility to the wiring system of the premises served,” use of one “service” corresponds to use of one “service drop” or one “service lateral,” or one set of “overhead service conductors” or set of “underground service conductors,” depending on the location of the service point. For more information, refer to the discussion in [Chap. 1](#) of this book regarding crucial changes in definitions of service terms in Art. 100.

These changes have forced interesting terminology changes throughout Art. 230. Now that service drops and service laterals are exclusively under utility control on the line side of the service point, many rules in the **NEC** no longer mention these terms. Other rules in the article (and explanations in this book) mention both drops and laterals along with overhead and underground service conductors. It depends on whether or not a construction rule applies to how a drop or lateral interfaces with the rule. For example, the rules in 230.40 on the permitted number of service-entrance conductor sets apply whether they connect to a service drop or overhead service conductors, or to a service lateral or underground service conductors, and the rule is written accordingly. On the other hand, the majority of the rules in the article only refer to components on the load side of the service point, and the old “service drop” and “service lateral” terminology has been discarded. As an example of this, the ampacity requirement in 230.31(A) only applies to underground service conductors. A utility is free to use the NESC to size a service lateral because conductors qualifying as such are now necessarily on the utility side of the service point and under their exclusive control.

The basic rule of this section requires that a building or other structure be fed by only one service drop (overhead service) or by only one set of service lateral conductors (underground service). As shown in [Fig. 230-1](#), a building with only one service drop to it satisfies the basic rule even when more than one set of service-entrance conductors are tapped from the single drop (or from a single lateral circuit). Also note that only a utility may supply a service. A power source consisting of a generator, or even an on-site electric plant, is a separately derived system and the applicable rules for disconnects, etc., will be found in Part II of Art. 225 and not this article. And when such energized conductors reach the premises in question, they will pass through a “building disconnect” and not a

“service disconnect.” Review the coverage at the beginning of Part II of Art. 225 for more information on this crucial topic.

Fig. 230-1. One set of service-drop conductors supplies this building from utility line (coming from upper left) and two sets of SE conductors are tapped through separate metering CTs. In this case, the incoming wires are probably service drops because of the location of the metering CTs, but not necessarily. If the service point is at the utility pole, then they are overhead service conductors instead. (Sec. 230.2.)

230.2 adds an important qualification of that rule as it applies only to 230.40, Exception No. 2, covering service-entrance layouts where two to six service disconnects are to be fed from one drop, lateral, or set of service conductors and are installed in separate individual enclosures at one location, with each disconnect supplying a separate load. As described in 230.40, Exception No. 2, such a service equipment layout may have a separate set of service-entrance conductors run to “*each or several*” of the two to six enclosures. The second sentence in 230.2 notes that where a separate set of underground conductors of size 1/0 or larger is run to each or several of the two to six service disconnects, the several sets of underground conductors are considered to be one service even though they are run as separate circuits, that is, connected together at their supply end (at the transformer on the pole or in the pad-mount enclosure or vault) *but not* connected together at their load ends. The several sets of conductors are taken to be “one service” in the meaning of 230.2, although they actually function as separate circuits (Fig. 230-2).

In the past, *NE Code* had this limitation on service laterals (and this is still acceptable)—

"Service lateral" conductors are not "service entrance" conductors and were, therefore, not applicable to the subdivision permission of 230.40, Exception No. 2. The requirement of 230.2 for one set of service lateral conductors demanded one circuit of single-conductor or parallel-conductor makeup.

Now, the second sentence in 230.2 considers this type of hookup to be one set of service lateral conductors —

Fig. 230-2. "One" service lateral may be made up of several circuits. Depending on the service point location, these may be sets of underground service conductors instead of service laterals. See Art. 100. (Sec. 230.2.)

Although 230.40, Exception No. 2, applies to "service-entrance conductors" and service

equipment layouts fed by *either* an overhead or underground service, the second sentence in 230.2 is addressed specifically and only to underground service conductors because of the need for clarification based on the Code definitions of “service conductors” (both overhead and underground), “service drop,” “service lateral,” “service-entrance conductors, overhead system,” and “service-entrance conductors, underground system.” (Refer to these definitions in the Code book to clearly understand the intent of this part of 230.2 and its relation to 230.40, Exception No. 2.)

The matter involves these separate but related considerations:

1. Because a “service lateral” or set of underground service conductors may (and usually does) run directly from a transformer on a pole or in a pad-mount enclosure to gutter taps where short tap conductors feed the terminals of the service disconnects, most layouts of that type literally do not have any “service-entrance conductors” that would be subject to the application permitted by 230.40, Exception No. 2—other than the short lengths of tap conductors in the gutter or box where splices are made to the underground conductors.
2. Because 230.40, Exception No. 2, refers only to sets of “service-entrance conductors” as being acceptable for individual supply circuits tapped from *one* drop or lateral to feed the separate service disconnects, that rule clearly does not apply to “service lateral” or “underground service conductors” conductors which by definition are not “service-entrance conductors.” So there is no permission in 230.40, Exception No. 2, to split up the capacity of either laterals or sets of underground service conductors. And the first sentence of 230.2 has the clear, direct requirement that a building or structure be supplied through only *one* run for any underground service. That is, either the underground service wiring must be a single circuit of one set of conductors, or if circuit capacity requires multiple conductors per phase leg, the wiring must be made up of sets of conductors in parallel—connected together at *both* the supply and load ends—in order to constitute a single circuit.
3. 230.2 permits “underground sets of conductors” to be subdivided into separate, nonparallel sets of conductors in the way that 230.40, Exception No. 2, permits such use for “service-entrance conductors”—*but only* for conductors of 1/0 and larger and *only* where each separate set of conductors (each separate underground circuit) supplies *one* or *several* of the two to six service disconnects.

230.2 recognizes the importance of subdividing the total service capacity among a number of sets of smaller conductors rather than a single parallel circuit (i.e., a number of sets of conductors connected together at *both* their *supply and load* ends). The single parallel circuit would have much lower impedance and would, therefore, require a higher short-circuit interrupting rating in the service equipment. The higher impedance of each separate set of lateral conductors (not connected together at their load ends) would limit short-circuit current and reduce short-circuit duty at the service equipment, permitting lower AIR (ampere interrupting rating)-rated equipment and reducing the destructive capability of any faults at the service equipment.

Subparts (A) through (E) cover cases where two or more service drops or laterals, or sets of overhead or underground service conductors may supply a single building or structure.

230.2(A) permits a separate supply to a fire pump and/or to emergency electrical systems, such as emergency lighting or exit lights and/or standby systems.

Part (A), which is essentially an exception to the basic rule that a building “shall be supplied by only one service,” also recognizes use of an additional power supply to a building from any “parallel power production systems.” This would permit a building to be fed by a solar photovoltaic, wind, or

other electric power source—in addition to a utility service—just as an emergency or standby power source is also permitted (Fig. 230-3). Fire pumps may be supplied from separate service conductors, and service from optional standby systems, legally required standby systems, and emergency systems is permitted in addition to the “one” service required by the basic rule in 230.2, “Number of Services.” The final condition covered in this part is the “system designed for connection to multiple sources of supply for the purpose of enhanced reliability.” This is the widely used double-ended switchboard with services provided to each end, and some form of throw-over in the middle so if one end goes down, the other end can supply the entire occupancy.

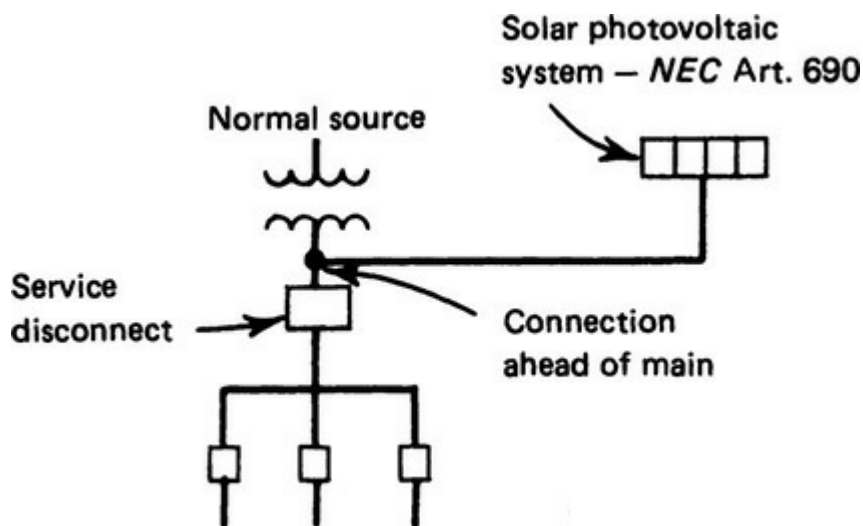

Fig. 230-3. Electric power generated by a solar voltaic assembly or by a wind-driven generator may be used as a source of power in “parallel” with the normal service. (Sec. 230.2.)

In 230.2(B) the Code recognizes other situations in which more than one service (i.e., more than one service drop or lateral, or set of overhead or underground service conductors depending on the service point location) may be used. By “special permission” of the inspection authority, more than one service may be used for a multitenant building when there is no single space that would make service equipment available to all tenants. Do not confuse this allowance with the similar one in 230.40 Exception No. 1 where a single service supplies an unlimited number of occupancies using multiple sets of service conductors originating from the service location. Refer to the discussion at that point for extensive coverage on this topic.

Part (B)(2) requires special permission to install more than one service to buildings of large area. Examples of large-area buildings are high-rise buildings, shopping centers, and major industrial plants. In granting special permission the authority having jurisdiction must examine the availability of utility supplies for a given building, load concentrations within the building, and the ability of the utility to supply more than one service. Any of the special-permission clauses in 230.2 require close cooperation and consultation between the authority having jurisdiction and the serving utility. And, as always, such “special permission” must be provided in writing to satisfy the wording of the definition for “special permission” given in Art. 100.

Two or more services to one building are also permitted by part (C) when the total demand load of all the feeders is more than 2000 A, up to 1000 V, where a single-phase service needs more than one supply as determined by the policies of the serving utility, or by special permission (Fig. 230-4). 230.2(C) relates capacity to permitted services. Where requirements exceed 2000 A, two or more sets of service conductors may be installed. Below this value, special permission is required to

install more than one set. The term “capacity requirements” appears to apply to the total calculated load for sizing service-entrance conductors and service equipment for a given installation, which would mean that the load calculated in accordance with Art. 220 must exceed 2000 A before one can assume permission for more than one set of service conductors.

230.2(C)

1. . . .when the total demand load of all feeders is greater than 2000 amps (up to 600 volts), or

2. . . .when the load demand of a single-phase installation is higher than the utility’s normal maximum for a single service, or

3. . . .when special permission is obtained from the inspection authority.

NOTE: “Two or more services” means two or more service drops or service laterals—not sets of service-entrance conductors tapped from one drop or lateral.

230.2(D)

Fig. 230-4. Exceptions to 230.2 permit two or more services under certain conditions. Depending on the location of the service point, the reference in the note to the upper drawing may refer to sets of either overhead or underground service conductors, as the case may be. (Sec. 230.2.)

Cases of separate light and power services to a single building and separate services to water heaters for purposes of different rate schedules are also permitted. And if a single building is so large that one service cannot handle the load, special permission can be given for additional services.

230.2(D) is illustrated at the bottom of [Fig. 230-4](#).

The last part of the rules in 230.2, part (E), introduces a requirement that applies to any installation where more than one service is permitted by the Code to supply one building. It requires a “permanent plaque or directory” to be mounted or placed “at each service drop or lateral or at each service-equipment location” to advise personnel that there are other services to the premises and to tell where such other services are and what building parts they supply.

This directory must be placed at *each* service. So, if there are two services, there should be two plaques at *each* service location. The directory (or directories) must identify all feeders and branch circuits supplied from that service. Further, such directories must be *fully reciprocal* both as to load descriptions and locations. That is, if plaque number one says: “This is Service #1 of 2, for the north half of the building. Service #2, located in the middle of the south wall, is for the south end of the building” then there must be another such plaque in the middle of the south end of the building, reading something like this: “This is Service #2 of 2, for the south half of the building. Service #1, located in the middle of the north end of the building, is for the north end of the building.” Labeling that provides this type of fully reciprocal information is required at every service equipment location if more than one service arrives at the building, for whatever reason. In addition, in some cases a building will be fed directly by a service and also by a feeder from another building or perhaps from a separately derived system. The reciprocal labeling rules apply to those supply systems just as if they were services.

230.3. One Building or Other Structure Not to Be Supplied Through

Another. For the most part, the service conductors supplying each building or structure shall not *pass through the inside* of another building. The concern here is related to the fact that service-entrance conductors have no overcurrent protection at their line end. They are simply connected to the utility’s supply without any type of OC device. Although the utility may have fuses in its lines, the fuses probably won’t open the circuit unless there is a bolted-fault, which represents the smallest percentage of all faults. Effectively speaking, this means that any other fault in the service conductor is expected to “burn” itself clear. That being the case, the Code here prohibits running unprotected service conductors through one building to another, unless they are in a raceway encased by 2 in. (50 mm) of concrete or masonry ([Fig. 230-5](#)). 230.6 points out that conductors in a raceway enclosed within 2 in. (50 mm) of concrete or masonry are considered to be “outside” the building even when they are run within the building.

Fig. 230-5. This is not a violation of the basic rule of 230.3. (Sec. 230.3.)

A building as defined in Art. 100 is a “structure which stands alone or which is cut off from adjoining structures by fire walls with all openings therein protected by approved fire doors.” A building divided into four units by such fire walls may be supplied by four separate sets of service conductors, but a similar building without the fire walls may be supplied by only one set of service conductors, except as permitted in 230.2.

A commercial building may be a single building but may be occupied by two or more tenants whose quarters are separate, in which case it might be undesirable to supply the building through one set of service conductors. Under these conditions special permission may be given to install more than one service.

230.6. Conductors Considered Outside the Building. A complement to the requirement in 230.3, this section presents certain criteria that, when satisfied, render the service equipment and/or conductors “outside” the building. For example, in part (1), the Code states that service conductors are considered “outside” the building when run in conduit under a building, and the conduit is covered with either brick or concrete at least 2 in. thick.

In part (2) the Code recognizes that conductors in conduit or duct *encased* by concrete or brick not less than 2 in. (50 mm) thick are considered to be outside the building, even though they are actually run within the building. The word “encased” replaced the word “enclosed” in the 1990 **NEC** to indicate actual embedment of the wiring in mortar and masonry (or concrete) and not just a masonry or concrete chase. [Figure 230-6](#) shows how a service conduit was encased within a building so that the conductors are considered as entering the building right at the service protection and disconnect where the conductors emerge from the concrete, to satisfy the rule of 230.70(A), which requires the service disconnect to be as close as reasonably possible to the point where the SE conductors enter the building. [Figure 230-7](#) shows an actual case of this application, where forms were hung around the service conduit and then filled with concrete to form the required concrete encasement.

Fig. 230-6. “Service raceways” in concrete are considered “outside” a building. (Sec. 230.6.)

Fig. 230-7. Top photo shows service conduit carried above suspended ceiling, without the SE disconnect located at the point of entry. When conduit was concrete-encased, the service conductors then “enter” the building at the SE disconnect—where they emerge from the concrete. Service conduit enters building at lower left and turns up into SE disconnect (right) in roof electrical room.

Part (3) considers service equipment and conductors, installed within a fire-rated vault that

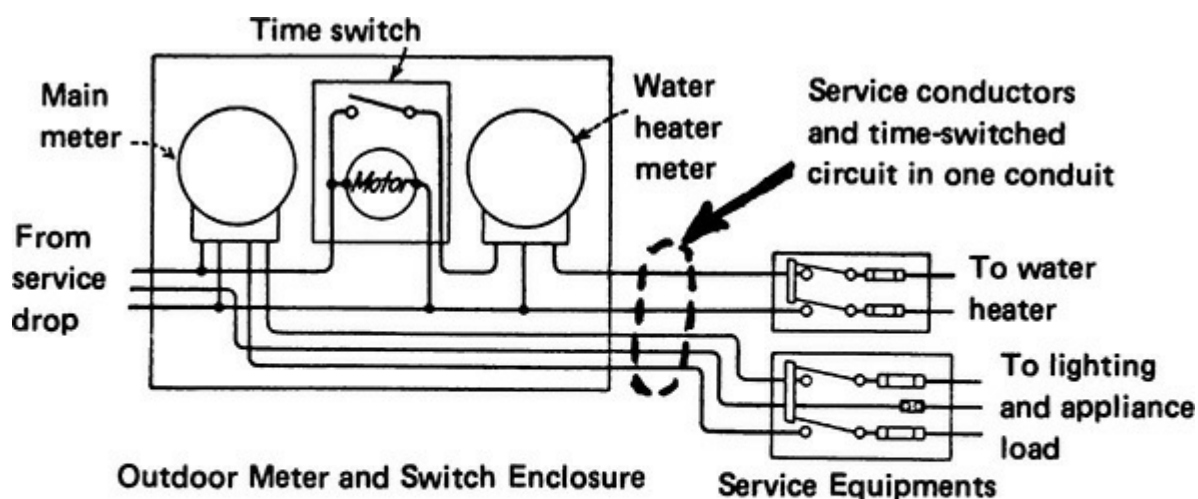

conforms with the Code rules for transformer vaults given in part III of Art. 450, to be outside the building. Part (4) presents recognition similar to that given in part (1), but this covers conductors buried in raceways under at least 18 in. of earth and running below a building or other structure.

Part (5) was new in the 2011 NEC and covers overhead service masts that typically penetrate at least the outer membrane of a building envelope in order to rise above the roof to establish a required clearance in 230.24. It would be unheard of to require concrete encasement for a typical heavy-wall steel or aluminum conduit mast that passes directly through an eave cavity, but that is what the previous literal text theoretically required.

Some eave cavities, particularly in old-fashioned Victorian balloon frame construction, are completely open to the adjoining attic and such a mast is well within the interior of the building. More modern construction typically has the eaves as part of a soffit that is separated from the interior of the building. In either case, however, once the outer membrane of the building is penetrated the disconnect location rule in 230.70(A) applies, making this allowance necessary.

As of the 2014 NEC, this provision has been severely limited to prevent abuse. It is now limited to heavy wall metal conduits passing directly through the eave cavity. The now prohibited procedure had actually been attempted using PVC conduit running through a roof, passing horizontally through 15 ft of the eave cavity, and then descending to a meter on the side of a building below the soffit.

230.7. Other Conductors in Raceway or Cable. Although the basic rule permits only service-entrance conductors to be used in a service raceway or service cable, exceptions do recognize the use of grounding conductors in a service raceway or cable and also permit conductors for a time switch if overcurrent protection is provided for the conductors, as shown in Fig. 230-8. Refer to the discussion of the definition of “raceway” in Art. 100 (Chap. 1 in this book) for more information regarding the status of auxiliary gutters with respect to this rule and why, for this reason, they are not classified as raceways.

NOTE: Time-switch conductors may be hooked up so they are in same conduit as service conductors but the time-switch conductors must be supplied with overcurrent protection.

Fig. 230-8. A time switch with its control circuit connected on the supply side of the service equipment. (Sec. 230.7.)

230.8. Raceway Seal. Figure 230-9 indicates that Sec. 300.5(G) applies to underground service conduits. Where service raceways are required to be sealed—as where they enter a building from underground—the sealing compound used must be marked on its container or elsewhere as suitable for safe and effective use with the particular cable insulation, with the type of shielding used, and with any other components it contacts. Some sealants attack certain insulations, semiconducting shielding layers, and so forth.

Fig. 230-9. Service raceways may have to be sealed. (Sec. 230.8.)

230.9. Clearances on Buildings. Parts (A), (B), and (C) cover the clearance requirements for service conductors, including the final portion of overhead spans and their point of connection to the building or structure.

In part (A), the Code makes clear that any overhead service conductors—open wiring or multiplex drop cable—must have the 3-ft (900-mm) clearance from windows, doors, porches, and so forth, to prevent mechanical damage to and accidental contact with service conductors (Figs. 230-10 and 230-11). The clearances required in 230.24, 230.26, and 230.29 are based on safety-to-life considerations in that wires are required to be kept a reasonable distance from people who stand, reach, walk, or drive under overhead service conductors. As the exception notes, conductors that run above the top level of a window do not have to be 3 ft (900 mm) away from the window.

Fig. 230-10. Drop conductors must have clearance from building openings. If the service point is remote from the building, these are overhead service conductors, but the same clearance rules apply. (Sec. 230.9.)

Fig. 230-11. Drop conductors above top level of a window or door do not require 3-ft horizontal clearance. (Sec. 230.9, Exception.)

Note that if the window in the upper drawing of [Fig. 230-10](#) is not “designed to be opened” the clearance rules do not apply and there would be no violation. This topic was a frequent source of discussion. Was the intent of the rule to prevent a reaching exposure, or was it to address window washing hazards? CMP 4 decided that it should only address the reaching exposure and added the clarifying language in the 1993 **NEC**, thereby also correlating with the NESC coverage on this topic.

The rule of 230.9(B) recognizes clearances of less than 3 ft horizontally from porches, balconies, and so on, provided the minimum vertical clearance, measured from the floor of the porch or balcony, is in accordance with 230.24(B). The service-drop conductors shown in the drawing at the bottom of [Fig. 230-10](#) would have to be either 10 or 12 ft above the balcony’s floor surface.

In part (C) of this section the Code says that service-drop or service-entrance conductors must not be mounted on or secured to a building wall directly beneath an elevated opening through which supplies or materials are moved into and out of the building. Such installations of conductors—say, beneath a high door to a barn loft—would obstruct access to the opening and present a hazard to personnel ([Fig. 230-12](#)).

Fig. 230-12. This violates the rule of the last paragraph of 230.9.

230.22. Insulation or Covering. In the past, the use of “covered”—not “insulated”—wire, such as triple-braid weatherproof wire, resulted in quite a few tragic accidents, including a number of electrocutions. As a result, for many years now, only the use of insulated wire for ungrounded conductors was permitted with service conductors. For the 2002 **NEC**, however, Code-making panel (CMP) 4 has, with very little substantiation, gone ahead and again recognized the use of “covered” instead of insulated conductors for overhead service conductors. The panel did specifically mention the legitimacy of this application for medium-voltage applications. There were no comments received during the comment period, either positive or negative, on this change.

The exception recognizes the use of a bare grounded (neutral) conductor of a multiconductor cable. The exception only covers multiconductor cables, and therefore grounded neutral of open wiring must be insulated or covered just as the ungrounded conductors.

230.24. Clearances. There are five exceptions to the basic rule of part (A) that service-drop conductors must have at least an 8-ft (2.5-m) vertical clearance from the highest point of roofs over which they pass.

Exception No. 1 to the basic rule calling for 8-ft (2.5-m) clearance of overhead service conductors above a roof requires that clearance above a flat roof subject to pedestrian traffic or used for auto and/or truck traffic must observe the heights for clearance of these conductors from the ground as given in part (B) of 230.24.

The intent of Exception No. 2 is that where the roof has a slope greater than 4 in. (100 mm) in 12 in. (300 mm), it is considered difficult to walk upon, and the height of conductors could then be less than 8 ft (2.5 m) from the highest point over which they pass but in no case less than 3 ft (900 mm) except as permitted in Exception No. 3. Figure 230-13 shows the rule. Exception No. 4 eliminates the need for maintaining the 8-ft minimum for 3 ft vertically in all directions where the final span attaches to the side of the building. This exception is particularly useful for a service drop hitting a building on a front corner above a porch roof below it. Without this provision, the drop would have to attach at a great height or else a second pole would be required to redirect the drop so it missed the projected footprint of the porch roof. Figures 230-14 and 230-15 show the conditions permitted by Exception Nos. 3 and 4.

Fig. 230-13. Service-drop conductors may have less than 8-ft (2.5-m) roof clearance. (Sec. 230.24.)

Fig. 230-14. Reduced clearance for overhead service conductors. (Sec. 230.24.)

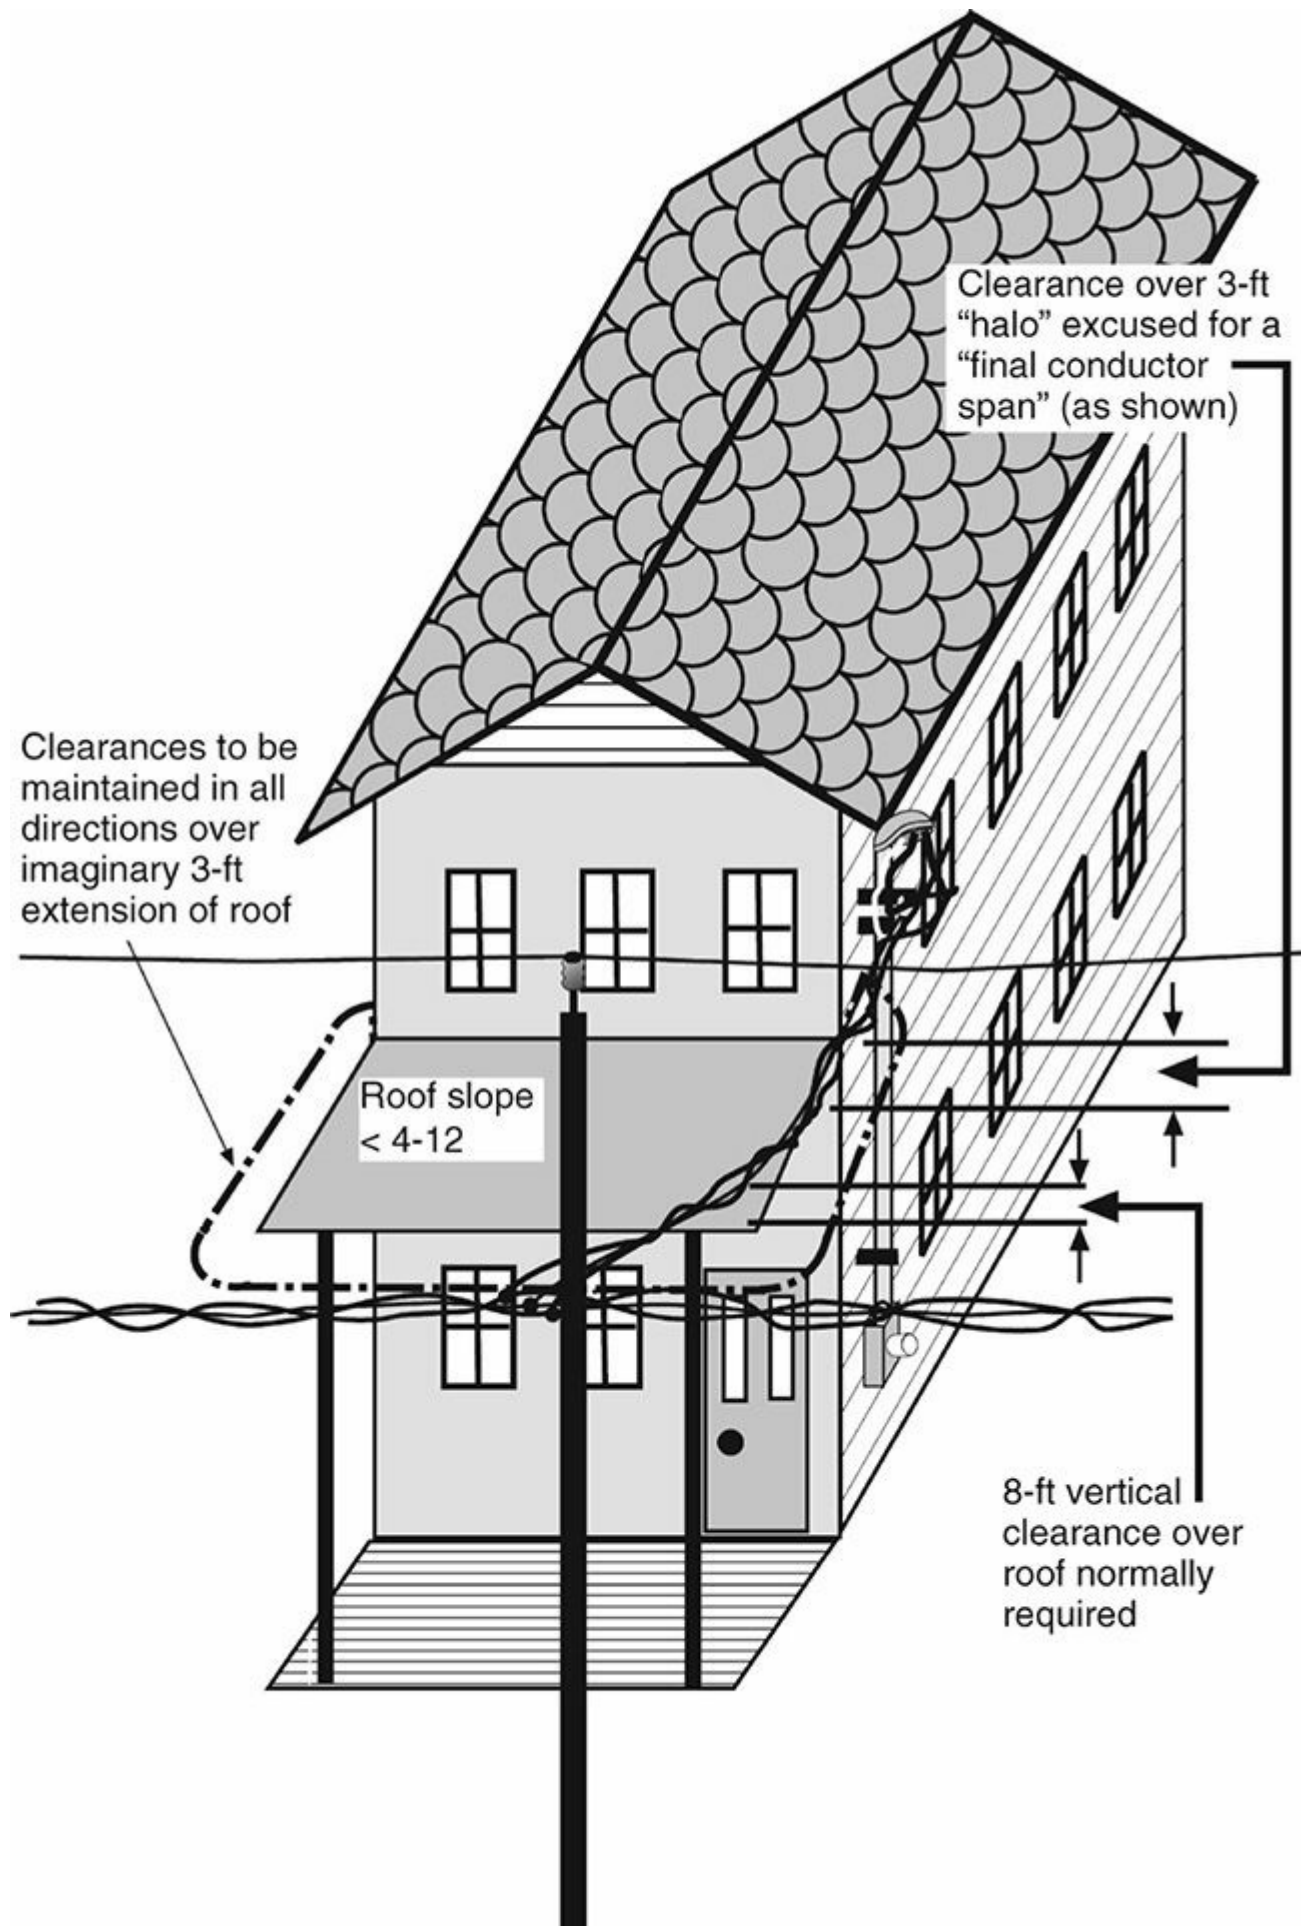

Fig. 230-15. Reduced clearances permitted for final spans, such as adjacent to this porch roof with a gradual pitch. (Sec. 230.24 Exception No. 4.) (From *Practical Electrical Wiring*, 22nd edition, © Park Publishing, 2014, all rights reserved.)

Exception No. 5 was new for the 2011 **NEC** and covers roof areas that are guarded or isolated. If the voltage between conductors does not exceed 300, the clearance can be reduced to 900 mm (3 ft). This provision brings the **NEC** in closer agreement with the NESC, although the voltage limitation in the latter standard is 750 V.

Part **(B)** covers the clearance to grade of overhead service conductor spans, as shown in **Fig. 230-16**. The five dimensions of clearance from ground—10, 12, 15, 18, and 24½ ft (3.0, 3.7, 4.5, 5.5, and 7.5 m)—are qualified by voltage levels and, for the 10-ft (3.0-m) mounting height, by the phrase “only for service-drop cables.” Note that in this case the terminology “service drop cables” is correct, even if the span meets the definition for overhead service conductors. The terminology is referring to a type of wiring construction defined in product standards as service drop cable, and consisting of insulated conductors spiraled around a bare messenger wire. These **NEC** rules are generally in agreement with the *National Electrical Safety Code*. Where mast-type service risers are provided, the clearances in 230.24(B) will have to be considered by the installer.

Fig. 230-16. Service-drop clearance to “final grade.” (Sec. 230.24.)

230.28. Service Masts as Supports. Figure 230-17 illustrates this rule. The last sentence of the rule is both important and controversial. It disallows all drops except the service drop from collocating on a service mast. No telephone drops, coaxial cable drops, or any other drop. This is an

absolute prohibition and it applies no matter how stout the mast, no matter how well the mast is guyed, no matter how long the mast, and no matter what spacing would be provided between the service drop and other prospective drops from other utilities.

Fig. 230-17. Service mast must provide adequate support for connecting drop conductors. The hub at the base of the mast must be identified for use with service equipment. (Sec. 230.28.)

As of the 2014 **NEC**, there is now a complete prohibition against attaching the drop to any mast above the highest coupling unless there is a “point of securement” above it. This is not controversial because an additional attachment to the side of a building is easily accomplished. However, the new rule goes on to prohibit, in all cases, the coupling above the roof. This is, of course, the preferred design, because the process of threading a steel conduit inevitably weakens it substantially particularly in reference to a shearing load. As in the case of 225.17, it is of interest that an attempt to allow for an exposed coupling in the event the strain was offset by a guy wire failed because the panel was concerned about the guy wire being released during roofing activities.

230.29. Supports over Buildings. The 2017 **NEC** added an important requirement with respect to the use of metal support structures for overhead services using a grounded circuit conductor. This section now expressly requires that the metal support structure be bonded to the grounded conductor.

230.30. Installation. This rule presents the requirement that underground service conductors must be insulated. Although service-drop conductors were previously required to be insulated, CMP

4 has seen fit to reinstate permission to use “covered” overhead service conductors, as given in 230.22. No such permission is granted here.

The exceptions to 230.30 and 230.41 clarify the use of aluminum, copper-clad aluminum, and bare copper conductors used as grounded conductors in underground service and service-entrance conductors (Fig. 230-18).

INSULATED PHASE CONDUCTORS and a bare copper neutral for an underground service lateral in buried raceway. Note: A bare aluminum or copper-clad aluminum neutral could be used here when part of a moisture- and fungus-resistant cable.

BARE COPPER NEUTRAL in a direct-buried cable assembly with moisture- and fungus-resistant outer covering. Note: A bare aluminum or copper-clad aluminum could be used like this, but it must be within the same type of cable assembly.

TYPE USE PHASE CONDUCTORS and a bare copper neutral directly buried where soil conditions are suitable for the bare copper.

Fig. 230-18. 230.30 and 230.41 permit bare neutrals for service conductors. (Secs. 230.30 and 230.41.)

For underground service conductors, an individual grounded conductor (such as a grounded neutral) of *aluminum* or *copper-clad aluminum* without insulation or covering may *not* be used in a

raceway underground. A bare *copper* neutral may be used—in a raceway, in a cable assembly, or even directly buried in soil where local experience establishes that soil conditions do not attack copper.

The wording of part (4) of the exception permits an aluminum grounded conductor of an underground service lateral to be without individual insulation or covering “when part of a cable assembly identified for underground use” where the cable is directly buried or run in a raceway. Of course, a lateral made up of individual insulated phase legs and an *insulated* neutral is acceptable in underground conduit or raceway (Fig. 230-19).

Fig. 230-19. Underground bare aluminum grounded leg must always be in a cable assembly. (Sec. 230.30.)

Part (B), which is new as of the 2014 **NEC**, presents in list form the acceptable wiring methods for underground service conductors. Item (9) groups MC and MV cables together with a requirement for suitability for direct burial. This will raise a question as to whether this rating is still required in the event the wiring is pulled into a buried raceway also appearing in the list. For example, it is very common to pull MV cable into PVC raceways either directly buried or run with concrete encasement and it is difficult to understand why the direct burial rating requirement should apply. It would seem

that in such cases the method should simply be interpreted as that of the enclosing raceway.

230.32. Protection Against Damage. Underground service conductors—whether directly buried cables, conductors in metal conduit, or conductors in nonmetallic conduit—must comply with 300.5 for protection against physical damage. But WATCH OUT! Where conductors are buried at depths of 450 mm (18 in.) or more below grade, compliance with a special rule in Sec. 300.5 for service conductors is mandatory. As called for by Sec. 300.5(D)(3), the local inspector will always require that a warning ribbon be buried in the trench not less than a certain distance (i.e., 300 mm [12 in.]) *above* the buried service lateral or buried service entrance conductors (Fig. 230-20).

Fig. 230-20. Protecting underground service conductors. (Sec. 230.32.)

230.33. Spliced Conductors. Service conductors in the form of underground service laterals and all service entrance conductors are permitted to be spliced as long as the splicing method complies with the usual rules in the **NEC** for general wiring of comparable size and location. The **NEC** does not expressly cover splices in overhead service runs, but given the other rules as long as the splice meets industry standards for strain tolerance and workmanship, it would normally be permitted subject to the judgment of the authority having jurisdiction.

230.40. Number of Service-Entrance Conductor Sets. As a logical follow-up to the basic rule of 230.2, which requires that a single building or structure must be supplied “by only one service,” this rule calls for only one set of service-entrance (SE) conductors to be supplied by each service drop or lateral, or by each set of overhead or underground service conductors as the case may be, that is permitted for a building. Exception No. 1 covers a multiple-occupancy building (a two-family or multifamily building, a multitenant office building, or a store building, etc.). In such cases, a set of SE conductors for each occupancy or for groups of occupancies is permitted to be tapped from a single drop or lateral (Fig. 230-21).

One service
per 230.2

230.40: ONE
set of SE conductors
(single or parallel makeup)

230.2:
Two or more
drops (or laterals)

230.40: Only one
set of SE conductors
from each drop (or lateral)

FOR SINGLE-OCCUPANCY
BUILDINGS WITH ONE
SERVICE (CAN ALSO BE
USED FOR MULTIPLE-OCCUPANCY
BUILDING)

FOR SINGLE-OCCUPANCY
BUILDINGS WITH ONE OR
MORE ADDITIONAL SERVICES
PERMITTED BY 230.2

Fig. 230-21. Service layouts must simultaneously satisfy 230.2, 230.40, 230.71, and all other NEC rules that are applicable. (Sec. 230.40.)

When a multiple-occupancy building has a separate set of SE conductors run to each occupancy, in order to comply with 230.70(A), the conductors should either be run on the outside of the building to each occupancy or, if run inside the building, be encased in 2 in. (50.8 mm) of concrete or masonry in accordance with 230.6. In either case, the service equipment should be located “nearest to the entrance of the conductors inside the building,” and each occupant would have to have “access to his disconnecting means.”

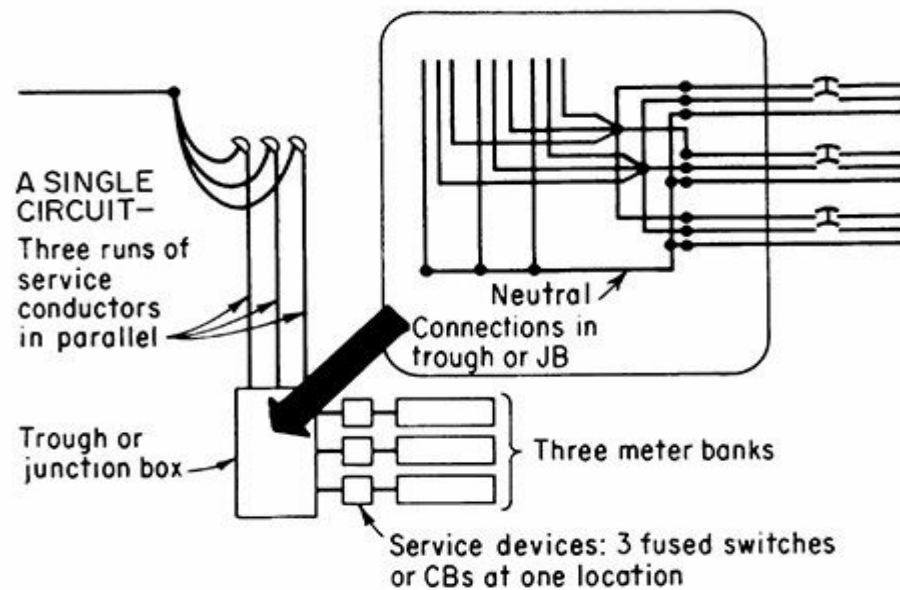

Any desired number of sets of service-entrance conductors may be tapped from the service drop or lateral, or two or more subsets of service-entrance conductors may be tapped from a single set of main service conductors, as shown for the multiple-occupancy building in Fig. 230-21.

As written, there are no limitations on this permission comparable to the parallel allowance in 230.2(B)(1) that allows multiple services to supply individual occupancies where there is no common location available for a conventional service. That allowance only operates by special permission. Part of the special permission process can and usually does allow a review of reciprocal labeling. In the case of 230.40 Exception No. 1, since there is only one service, 230.2(E) does not apply. For example, suppose a multitenant building has seven occupancies. This allowance can result in a group of six disconnects (that being the limit in any one location) in the vicinity of the service drop or lateral, and then a seventh set of service entrance conductors extended around the building (or

through concrete) to the seventh occupancy. Since 230.2(E) does not apply, there was absolutely no requirement to post a sign or directory at the principal service location advising emergency personnel that opening the six disconnects at that location does not, in fact, disconnect the entire building. Given the cost of providing a master disconnect for a group of services, this was far from a purely academic concern. Some jurisdictions placed limits on this allowance for that reason.

The 2011 **NEC** made a major step forward in addressing this problem through extensive additional text included at the end of this exception. First, if the number of disconnects for any classification of service does not exceed six, then the reciprocal labeling rules of 230.2(E) are incorporated by reference. Second, if the number of disconnects for any classification of supply exceeds six, then full reciprocal labeling is deemed too cumbersome and confusing, and a complete description of disconnect locations, using graphics, text, or both must be created on one or more plaques. This information must be mounted in an approved, readily accessible location on the building and as near as practicable to the point of arrival of the supply conductors. This will put emergency service personnel on notice as to how to disconnect the entire location when needed.

Exception No. 2 permits two to six disconnecting means to be supplied from a single set of service conductors where each disconnect supplies a separate load ([Fig. 230-22](#)). Exception No. 2 recognizes the use of, say, six 400-A sets of service-entrance conductors to a single-occupancy or multiple-occupancy building in lieu of a single main 2500-A service. It recognizes the use of up to six subdivided loads extending from a single set of conductors in a *single-occupancy* as well as multiple-occupancy building. Where single metering is required, doughnut-type CTs could be installed at the service drop.

THIS WAS COMMONLY REQUIRED TO SATISFY PREVIOUS *NE CODE* BUT IS NOT NOW NECESSARY

From two to six separate sets of service-entrance conductors may be supplied by a single service drop for either single- or multiple-occupancy buildings. Disconnects can be of same or different ratings, and each set of service-entrance conductors can be installed using any approved wiring method.

Fig. 230-22. Tapping sets of service-entrance conductors from one drop (or lateral). (Sec. 230.40.)

The real importance of this rule is to eliminate the need for “paralleling” conductors of large-capacity services, as widely required by inspection authorities to satisfy previous editions of the NEC (Fig. 230-22). This same approach could be used in subdividing services into smaller load blocks to avoid the use of the equipment ground-fault circuit protection required by 230.95.

This rule can also facilitate expansion of an existing service. Where less than six sets of service-entrance conductors were used initially, one or more additional sets can be installed subsequently without completely replacing the original service. Of course, metering considerations will affect the layout.

But, the two to six disconnects (CBs or fused switches) must be installed close together at one location and not spread out in a building. Since under this exception the disconnects are still grouped, the objection formerly raised under Exception No. 1 does not apply.

Exception No. 3 recognizes tapping two sets of service conductors from a single drop or lateral at a dwelling unit to supply the dwelling *and* one other building. Exception No. 4 recognizes an additional set of service entrance conductors to supply the “common area” panel required by Sec. 210.25. And Exception No. 5 specifically recognizes supplying “other” equipment as indicated in 230.82(5) and 230.82(6).

230.41. Insulation of Service-Entrance Conductors. Except for use of a bare neutral, as permitted, all service-entrance conductors must be insulated and may not simply be “covered”—as discussed under 230.22. The wording used in part (3) of the exception in 230.41 is slightly different from that described previously for 230.30. In this section, the reference is to “service-entrance conductors” instead of “service lateral conductors.” But here, a *bare individual* aluminum or copper-clad aluminum grounded conductor (grounded neutral or grounded phase leg) may be used in a raceway or a cable assembly or for direct burial where “identified” for direct burial.

Aluminum SE cable with a bare neutral may be used aboveground as an SE conductor. *But*, an aluminum SE cable with a bare neutral may be used underground *only* if it is “identified” for underground use in a raceway or directly buried. Conventional-style SE-U aluminum SE cable with a bare neutral is not “identified” for use underground but may be used, as the first sentence of 230.40 describes, for “service-entrance conductors entering or on the exterior of buildings or other structures.” In “SE-U,” the “U” stands for “unarmored” not “underground.”

230.42. Minimum Size and Rating. Sizing of service-entrance conductors involves the same type of step-by-step procedure as set forth for sizing feeders covered in Art. 220. A set of service-entrance conductors is sized just as if it were a feeder. In general, the service-entrance conductors must have a minimum ampacity—current-carrying capacity—selected in accordance with the ampacity tables and rules of 310.15, as well as the rules for “continuous loading” following part (A), here, that is sufficient to handle the total lighting and power load as calculated in accordance with Art. 220. Where the Code gives demand factors to use or allows the use of acceptable demand factors based on sound engineering determination of less than 100-percent-demand requirement, the lighting and power loads may be modified.

According to the last sentence of 230.42(A), the “maximum allowable current” of busways used as service-entrance conductors must be taken to be the ampere value for which the busway has been listed or labeled. This is an “exception” to the basic rule that requires the ampacity of service-

entrance conductors to be “determined from 310.15”—which does not give ampacities of busways. Parts **(A)(1)** and **(A)(2)** repeat the rule of 215.2(A). This now includes the exception for sizing continuously loaded feeder neutrals at 100 percent and not 125 percent if they arrive at a busbar and not an overcurrent device. (See 215.2.)

From the analysis and calculations given in the feeder-circuit section, a total power and lighting load can be developed to use in sizing service-entrance conductors. Of course, where separate power and lighting services are used, the sizing procedure should be divided into two separate procedures.

When a total load has been established for the service-entrance conductors, the required current-carrying capacity is easily determined by dividing the total load in kilovolt-amperes (or kilowatts with proper correction for power factor or the load) by the voltage of the service.

From the required current rating of conductors, the required size of conductors is determined. Sizing of the service neutral is the same as for feeders, and the 2014 **NEC** added 230.42(A)(2) to correlate with 215.2(A)(1) Exception No. 2 and thereby avoid upsizing for continuous loads. Although suitably insulated conductors must be used for the phase conductors of service-entrance feeders—except as permitted for overhead conductors as described in 230.22—the **NEC** does permit use of bare grounded conductors (such as neutrals) under the conditions covered in 230.30 and 230.41.

An extremely important element of service design is that of fault consideration. Service busway and other service conductor arrangements must be sized and designed to ensure safe application with the service disconnect and protection. That is, service conductors must be capable of withstanding the let-through thermal and magnetic stresses on a fault.

After calculating the required circuits for all the loads in the electrical system, the next step is to determine the minimum required size of service-entrance conductors to supply the entire connected load. The **NEC** procedure for sizing SE conductors is the same as for sizing feeder conductors for the entire load—as set forth in 215.2(A).

Basically, the service “feeder” capacity must be not less than the sum of the loads on the branch circuits for the different applications.

The *general lighting load* is subject to demand factors from Table 220.12, which takes into account the fact that simultaneous operation of all branch-circuit loads, or even a large part of them, is highly unlikely. Thus, service or feeder capacity does not have to equal the connected load. The other provisions of Art. 220 are then factored in.

Reference to 230.79 in part **(B)** of 230.42 makes a 100-A service conductor ampacity a mandatory minimum if the system supplied is a one-family dwelling. And for all other occupancies where more than two 2-wire circuits are supplied, the minimum rating of the service conductors may not be less than 60 A. This reference is not intended to require the service conductors to *always* have an ampacity equal to the rating of the service disconnect(s). That is, for those installations described in 230.79, the service conductors must have the minimum ampacity required by 230.79. But for all other installations, the ampacity as established in accordance with 310.15 must be not less than the calculated load as determined in accordance with Art. 220, and the service conductors must be sized as required by 230.42(A), for continuous loading.

Another point of confusion is the wording here, “less than the rating of the service disconnecting means specified....” This does not mean that if you install a 400-A fused service switch for a 250-A load and with 250-A fuses, the service needs to be cabled for 400 A. It simply means that in the specified applications, the conductors must meet the minimums set in 230.79. The following table

correlates the requirements for service lateral, service drop, and service entrance conductors in a single location.

<i>Conductors</i>	<i>Minimum Allowable Copper Size</i>
Service entrance for all installations, except ones specified below	6 AWG (to supply a 60 A minimum disconnect size using 75°C terminations)
Service entrance supplying a single branch circuit	14 AWG (to supply a 15 A minimum disconnect size)
Service entrance supplying a two-circuit installation	10 AWG (to supply a 30 A minimum disconnect size)
Service entrance supplying a single-family house	4 AWG [to supply a 100 A minimum disconnect size, using 310.15(B)(7)]
Overhead or underground service	12 AWG (overhead: hard-drawn) for a single circuit installation
Overhead or underground service	8 AWG, for other installations
Service of over 1000 V	6 AWG, except that in multiconductor cables 8 AWG may be used

230.43. Wiring Methods for 1000 Volts, Nominal, or Less. The list of acceptable wiring methods for running service-entrance conductors does include flexible metal conduit (Greenfield) and liquidtight flexible metal conduit, but limits use of such raceways to a maximum length of 6 ft (1.8 m), and an equipment bonding conductor must be run with it. Although such raceways were prohibited at one time, effectively bonded flexible metal conduit and liquidtight flexible metal conduit in a length not over 6 ft (1.8 m) may be used as a raceway for service-entrance conductors (Fig. 230-23). A length of flex or liquidtight flex not longer than 6 ft (1.8 m)—in total—may be used as a service raceway, provided an equipment bonding conductor sized from Table 250.66 (and with a cross-sectional area at least 12½ percent of the csa of the largest service phase conductor for conductors larger than 1100 MCM copper or 1750 MCM aluminum) is used. This rule recognizes that the flexibility of such raceway is often needed or desirable in routing service-entrance conductors around obstructions in the path of connections between metering equipment and service-entrance switchboards, panelboards, or similar enclosures. The required equipment grounding conductor may be installed either inside or outside the flex, using acceptable fittings and termination techniques for the grounding conductor.

Fig. 230-23. These two flexible conduits may be used for service raceway. (Sec. 230.43.)

It should be noted that *liquidtight* flexible metal conduit is recognized as an acceptable service raceway, provided the bonding requirements given in 250.102 are satisfied. And, liquidtight flexible *nonmetallic* conduit—of any length—may be used as a service raceway containing service-entrance conductors.

230.44. Cable Trays. This section recognizes the use of a cable tray for the support of service-entrance conductors, provided the cable tray contains only service-entrance conductors. Cable trays are now limited as to the service wiring they are allowed to contain, namely Types SE, MC, MI, and IGS cables, along with single conductors not smaller than 1/0 AWG provided they are marked for cable tray use (a “CT” rating). They must also be field labeled with the designation “Service-Entrance Conductors” in a manner that is visible after the tray is installed and at intervals and in such positions that the service conductors can be easily tracked over the full length of the tray installation, but no interval between labels can exceed 10 ft. Note that the relief granted for medium-voltage warning labeling for cable trays in 392.18(H) Exception for qualified industrial occupancies does not govern the labels required here. Formerly, this marking rule only applied when the tray was divided into two sections, one with service conductors and one for other purposes. As in prior Codes, if the tray is to be shared in this way, the requirement is for a solid barrier compatible with the tray to be installed. Note that 392.10(B) will additionally limit the use of single conductors in cable tray to industrial occupancies with qualified maintenance and supervision, using certain types of tray and certain rung intervals if ladder tray is used for conductors smaller than 250 kcmil.

230.46. Spliced Conductors. The wording in this section used to prohibit splicing of SE conductors, and that prohibition was followed by a number of exceptions. However, that long-standing rule was eliminated in the 1999 **NEC**. The Code now makes specific references to recognized methods, that is, “clamped or bolted connections.” Now splicing of SE conductors may be accomplished using the methods described by the applicable rules in 110.14, 300.13, and 300.15, which recognize use of the splicing methods previously described. (See [Fig. 230-24](#).)

Fig. 230-24. Permitted splices in service-entrance conductors. The comment on the “service lateral” now applies to underground service entrance conductors only. Service laterals are now utility wiring only on the line side of the service point, and the **NEC** has no jurisdiction over how a utility may choose to repair one of its underground conductors. (Sec. 230.46.)

230.50. Protection Against Physical Damage. The wording in part (A) of this section no longer contains the “laundry list” of instances where physical protection would be required. Instead, it is now strictly up to the local inspector to determine where such protection must be provided. It seems reasonable to assume that those cases previously identified would be covered.

In parts (A)(1) through (6), the Code indicates specific methods that may be utilized to achieve the desired and required physical protection. In keeping with the broad discretion given by the wording used in this rule, part (A)(6) recognizes “other approved means.” Given the definition of the term “approved” in Art. 100, that wording essentially means “whatever the inspector will accept.” Since it is up to the inspector to decide when such protection is needed, it seems reasonable to grant the inspector the latitude to establish another method to ensure the required physical protection needed for service cables ([Fig. 230-25](#)).

Fig. 230-25. Outdoor service raceway must be raintight *and* drained and SE cable must be protected if subject to physical damage. (Secs. 230.50 and 230.53.)

Part **(B)** exception allows use of type MI and MC cables for service-entrance or service lateral applications, without need for mounting at least 10 ft (3.0 m) above grade—provided they are not exposed to damage or are protected.

230.51. Mounting Supports. Service-entrance cable must be clamped to building surface by straps at intervals not over 30 in. (750 mm). And the cable must still be clamped within 12 in. (300 mm) of the service weatherhead and within 12 in. (300 mm) of cable connection to a raceway or enclosure.

Where the cable assembly is not listed for attachment to building surfaces, in part **(B)** the Code calls for such cables to be mounted on insulators that provide at least 2 in. of clearance from the building surface, and the insulators must be mounted no more than 15 ft apart. Similar requirements are given in part **(C)** for service conductors run as open individual conductors. Table 230.51(C) spells out the maximum spacing for the insulators and the minimum clearance from the building surface.

230.53. Raceways to Drain. Service-entrance conductors in conduit must be made raintight, using raintight raceway fittings, and must be equipped with a drain hole in the service ell at the bottom of the run or must be otherwise provided with a means of draining off condensation (Fig. 230-25). Use of a “pitch” equivalent to 1/8 in. per foot, or 1 in. per 8 ft (10.4 mm per meter) will serve to satisfy the rule given by the last sentence for arranging conduit to drain where embedded in masonry. The same rule applies in 225.22. Refer to that discussion for more information about potential conflicts with 110.12(A).

230.54. Overhead Service Locations. When conduit or tubing is used for a service, the raceway must be provided with a service head (or weatherhead). Figure 230-26 shows details of a service-head installation. As covered in the exception to part **(B)**, service cable may be installed without a service head, provided it is bent to form a “gooseneck”; then tape the end with a “self-

sealing water-resistant thermoplastic”: that is, where no service head is used at the upper end of a service cable, the cable should be bent over so that the individual conductors leaving the cable will extend in a downward direction, and the end of the cable should be carefully taped and painted or sealed with water-resistant tape to exclude moisture.

From 230.54:

From 230.54 (G):

Fig. 230-26. Location of service head minimizes entrance of rain. (Sec. 230.54.) The violation at the lower right can often be cured by twisting the service head so it points straight down, thereby avoiding the arrangement to the left that many consider unsightly, particularly if run in a large raceway for which the required bends will occupy considerable area on the side of the building.

Part (C) of this section requires that service heads be located above the service-drop attachment. Although this arrangement alone will not always prevent water from entering service raceways and equipment, such an arrangement will solve most of the water-entrance problems. An exception to this rule permits a service head to be located not more than 24 in. (600 mm) from the service-drop termination where it is found that it is impractical for the service head to be located above the service-drop termination. In such cases, a *mechanical connector* is advisable at the lowest point in the drip loop to prevent siphoning. This exception will permit the Code-enforcing authority to handle hardship cases that may occur.

As covered by the wording in part (D), service cables shall be “held securely in place.” And each phase and neutral must be routed through an individual bushed opening in the service head to satisfy the basic rule in 230.54(E). But, the exception following this rule permits deviation from the one-phase one-bushed opening where the service conductors are in a jacketed multiconductor cable, as would be required in the case of a gooseneck.

The intent of parts **(F)** and **(G)** is to require use of connections or conductor arrangements, both at the pole and at the service, so that water will not enter connections and siphon under head pressure into service raceways or equipment.

230.56. Service Conductor with the Higher Voltage to Ground. This Code rule presents the requirement that the “high” leg (the 208-V-to-ground leg) of a 240/120-V 3-phase, 4-wire delta system must be identified by marking to distinguish it from the other hot legs, which are only 120 V to ground. One method permitted is color-coding the so-called high leg orange. The rule recognizes “other means,” but any such “identification” must be provided “at each termination or junction point.” Clearly, the use of an overall orange-colored insulation will most easily satisfy this rule.

230.66. Marking. Service equipment must be marked as being suitable for the use. Since individual meter socket enclosures do not function as the main cutoff and control of the supply, they are not service equipment as defined in Art. 100 and therefore not subject to this rule. All service equipment must, as of the 2011 **NEC**, be listed. Although as noted meter sockets are not service equipment, the 2017 **NEC** instituted a listing requirement for service meter sockets, unless they were supplied by and remained under the exclusive control of the serving utility.

230.70. General. Parts **(A)(1)**, **(2)**, and **(3)** cover the place of installation of a service disconnect. The disconnecting means required for every set of service-entrance conductors must be located at a readily accessible point outside the building; or, where installed inside, nearest to the point at which the service conductors enter the building ([Fig. 230-27](#)). The service disconnect switch (or CB) is generally placed on the inside of the building as near as possible to the point at which the conductors come in.

GENERAL CONCEPT

TYPICAL COMPLIANCE

Fig. 230-27. Service disconnect must open current for any conductors within building. (Sec. 230.70.)

And part **(B)** requires lettering or a sign on the disconnect(s) to identify it (them) as “Service Disconnect.” There are no exceptions to this marking requirement. Most panels with an integral main breaker come with an embossed or stamped marking “MAIN” next to that breaker, along with “SERVICE DISCONNECT” labels to be applied in the event the panel will be used as service equipment. These labels must be applied as appropriate, and nowhere else. A main breaker and a service disconnect are two different things. A building disconnect and a service disconnect are two different things. In many cases, the function is obvious, but not all. This author recalls having been called by fire officials to a convenience store with a line up of six identically sized panels, all with “Main” breakers and no other designation. Two of those breakers were service disconnects and four were not, as definitively determined only after spending 20 min actually removing the dead fronts and tracing conductors. Fortunately there was no emergency at the time; the department was engaged in a valuable exercise in advance preparation. While part **(C)** calls for the equipment to be “suitable” for use as service equipment, in all practicality this means that such disconnects must be listed and

marked as being suitable for use as service equipment.

Although the Code does not set any maximum distance from the point of conductor entry to the service disconnect, various inspection agencies set maximum limits on this distance. For instance, service cable may not run within the building more than 18 in. (450 mm) from its point of entry to the point at which it enters the disconnect. Or, service conductors in conduit must enter the disconnect within 10 ft (3.0 m) of the point of entry. Or, as one agency requires, the disconnect must be within 10 ft (3.0 m) of the point of entry, but overcurrent protection must be provided for the conductors right at the point at which they emerge from the wall into the building. The concern is to minimize the very real and proven potential hazard of having unprotected service conductors within the building. Faults in such unprotected service conductors must burn themselves clear and such application has caused fires and fatalities. Check with your local inspection agency to find out what it intends to enforce. Such action should serve to prevent any surprises on the job.

Often shifting the point of entry, with somewhat longer conductors run outdoors, will solve a problem. In extreme cases a combination meter and overcurrent protection/disconnect can be installed, which then allows the conductors to run anywhere in the building. Many jobs have issues with obstructions such as oil tanks that need to be discussed with the inspector. Every cycle the Code-making panel receives, and rejects, proposals to set a specific allowable distance on the indoor length of service conductors. The panel intends that this remain a topic of negotiation and discussion between installers and inspectors with respect to the specific problems that arise in the field.

230.71. Maximum Number of Disconnects. Service-entrance conductors must be equipped with a readily accessible means of disconnecting the conductors from their source of supply. As stated in part (A), the disconnect means for each service and each set of SE conductors permitted by Sec. 230.2 and Sec. 230.40 Exception Nos. 1 and 3, respectively, may consist of not more than six switches or six CBs, in a common enclosure or grouped individual enclosures, located either “within sight of” and outside the building wall, or inside, as close as possible to the point at which the conductors enter the building. [Figure 230-28](#) shows the basic application of that rule to a single set of SE conductors.

SINGLE SERVICE DISCONNECT

TWO TO SIX DISCONNECTS IN SINGLE ENCLOSURE

TWO TO SIX DISCONNECTS IN SEPARATE ENCLOSURES GROUPED CLOSE TOGETHER AT ONE LOCATION

Fig. 230-28. The three basic ways to provide service disconnect means. (Sec. 230.71.)

The last sentence in part (A) identifies a number of specific applications where the disconnecting means is not to be counted as “service disconnecting means” and applied against the maximum number of six disconnects permitted in the first two sentences. That is, when control power for a ground-fault protection system is tapped from the line side of the service disconnect means, the disconnect for the control power circuit is not counted as one of the six permitted disconnects for a service. A ground-fault-protected switch or CB supplying power to the building electrical system *counts* as one of the six permitted disconnects. But a disconnect supplying only the control-circuit power for a ground-fault protection system, installed as part of the listed equipment, does not count as one of the six service disconnects. The same idea applies to all other specifically identified equipment disconnects that are generally located at services, including surge protective devices and power monitoring equipment.

The rule of this section correlates “number of disconnects” with 230.2 and 230.40, which permit a separate set of SE conductors to be run to each occupancy (or group of occupancies) in a multiple-occupancy building, as follows:

230.2 permits more than one “service” to a building—that is, more than one service drop or lateral—under the conditions set forth. As set forth in the first sentence of 230.40 each such “service” must supply *only* one set of SE conductors in a building that is a single-occupancy (one-tenant) building, and each set of SE conductors may supply up to six SE disconnects grouped together at one location—in the same panel or switchboard or in grouped individual enclosures. If the grouped disconnects for one set of SE conductors are not at the same location as the grouped disconnects for one or more other sets of SE conductors, for those situations described and permitted in 230.2, then a “plaque or directory” must be placed at each service-disconnect grouping to tell where the other group (or groups) of disconnects are located and what loads each group of disconnects serves.

Exception No. 1 to 230.40 says that a single service drop or lateral may supply *more than one set* of SE conductors for a multiple-occupancy building. Then at the load end of each of the sets of SE conductors, in an individual occupancy or adjacent to a group of occupancy units (apartments, office, stores), up to six SE disconnects may be supplied by each set of SE conductors. And Exception No. 3 recognizes two sets of SE conductors at a dwelling unit to supply the dwelling and one other separate “structure.”

The first sentence of part (A) to 230.71 ties directly into 230.40, Exception No. 1. It is the intent of this basic rule that, where a multiple-occupancy building is provided with more than one set of SE conductors tapped from a drop or lateral, each set of those SE conductors may have up to six switches or CBs to serve as the service disconnect means for that set of SE conductors. The rule does recognize that six disconnects for each set of SE conductors at a multiple-occupancy building with, say, 10 sets of SE conductors tapped from a drop or lateral does result in a total of 6×10 , or 60, disconnect devices for completely isolating the building’s electrical system from the utility supply. 230.72(B) also recognizes use of up to six disconnects for each of the “separate” services for fire pumps, emergency lighting, and so on, which are recognized in 230.2 as being separate services for specific purposes. And if service is provided for different classes of service, six disconnects could be provided for *each* class of service to *each* occupancy, resulting in 120 disconnects! This is why 230.40 Exception No. 1 was modified in the 2011 **NEC** to address the required labeling and signage in a coherent way.

Although the basic rule of 230.40 specifies that only one set of SE conductors may be tapped from a single drop for a building with single occupancy, Exception No. 2 to 230.40 recognizes that a separate set of SE conductors may be run from a single service drop or lateral to each of up to six service disconnects mounted in separate enclosures at one location, constituting the disconnect means for a single service to a single-occupancy building.

For any type of occupancy, a panel containing up to six switches or CBs may be used as service equipment with the enclosed six or fewer breakers comprising the service disconnecting means under a special exception (408.36 Exception No. 1). A panel used as service equipment for renovation of an existing service in an individual residential occupancy (but not for new installations) may have up to six main breakers or fused switches under 408.36 Exception No. 3. A panel meeting the old 42-circuit limitation for the former lighting and appliance branch-circuit panelboards may have up to two main breakers (or sets of fuses), per 408.36 Exception No. 2. However, a panel used without these limitations and used as service equipment for new buildings of any type must have not more than a single main device—with its rating not greater than the panel bus rating. See 408.36.

The first sentence of 230.71(A) and that of 230.72(A) note that from one to six switches (or CBs) may serve as the service disconnecting means for each class of service for a building. For example, if a *single-occupancy* building has a 3-phase service and a separate single-phase service, each such service may have up to six disconnects (Fig. 230-29). Where the two sets of service equipment are not located adjacent to each other, a plaque or directory must be installed at each service-equipment location indicating where the other service equipment is—as required by 230.2(E).

AS PERMITTED BY 230.2 (D)

Fig. 230-29. Each separate service may have up to six disconnect devices. (Sec. 230.71.)

230.71(B) notes that single-pole switches or circuit breakers equipped with handle ties may be used in groups as single disconnects for multiwire circuits, simultaneously providing overcurrent protection for the service (Fig. 230-30). Multipole switches and circuit breakers may also be used as single disconnects. The requirements of the Code are satisfied if all the service-entrance conductors can be disconnected with no more than six operations of the hand—regardless of whether each hand motion operates a single-pole unit, a multipole unit, or a group of single-pole units with “handle ties” or a “master handle” controlled by a single hand motion. Of course, a single main device for service disconnect and overcurrent protection—such as a main CB or fused switch—gives better protection to the service conductors.

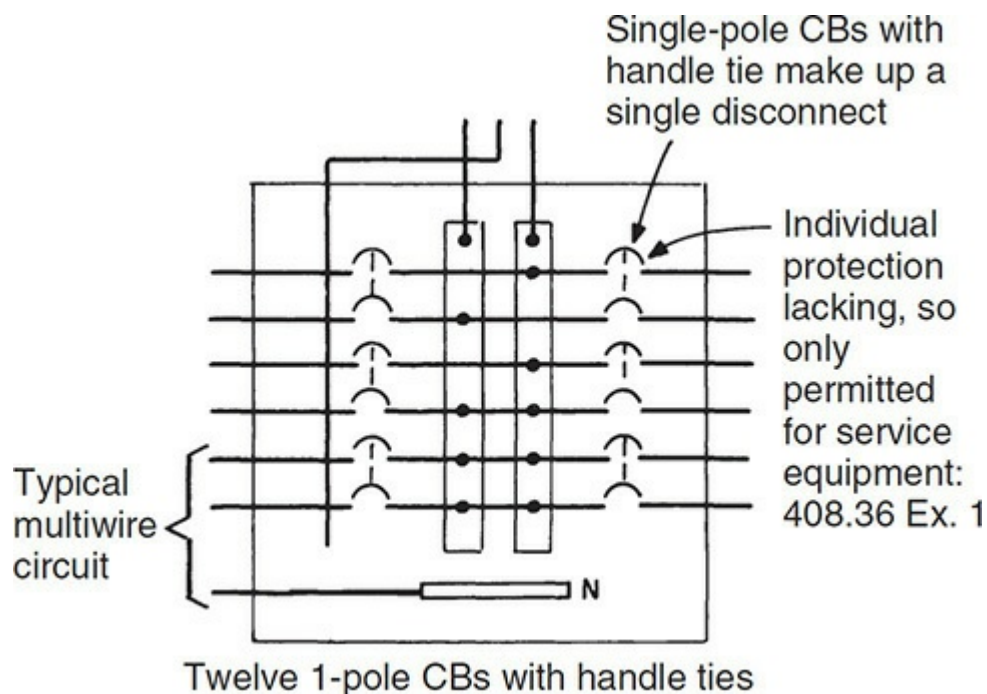

Fig. 230-30. This arrangement constitutes six disconnects. (Sec. 230.71.)

The informational note to this section refers to 408.36 Exceptions 1 and 3, which vary from the individual protection requirements that now apply to panelboards generally, and as discussed

previously. The reference to 430.95 is intended to point out the limitations associated with installations where the service equipment is within a motor control center. For such installations, the rule of 430.95 mandates the use of a single main disconnect.

230.72. Grouping of Disconnects. The basic rule of part (A) requires that for a service disconnect arrangement of more than one disconnect—such as where two to six disconnect switches or CBs are used, as permitted by 230.71(A)—all the disconnects making up the service equipment “for each service” must be grouped and not spread out at different locations. The basic idea is that anyone operating the two to six disconnects must be able to do it while standing at one location. Service conductors must be able to be readily disconnected from all loads at one place. And each of the individual disconnects must have lettering or a sign to tell what load it supplies (Fig. 230-31).

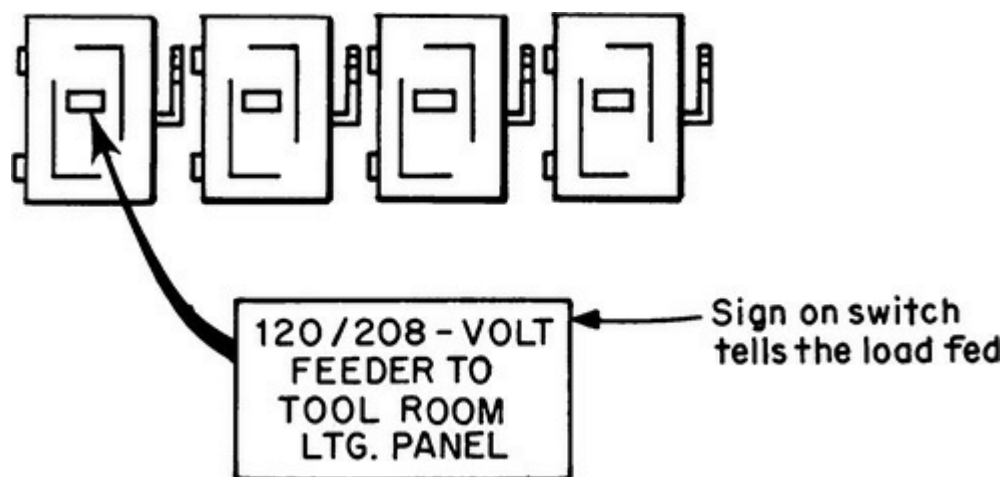

Fig. 230-31. Two to six disconnect switches or CBs must be grouped and *identified*. (Sec. 230.72.)

This rule makes clear that the two to six service disconnects that are permitted by 230.71(A) for *each* “service” or for “*each* set of SE conductors” at a multiple-occupancy building must be grouped. But, where permitted by 230.2, the individual groups of two to six breakers or switches do not have to be together, and if they are not together, a sign at each location must tell where the other service disconnects are. (See 230.2.) Each grouping of two to six disconnects may be within a unit occupancy—such as an apartment—of the building.

The exception to part (A) *permits* (Note: It permits, it does not *require*, but read the next paragraphs) one of the two to six service disconnects to be located remote from the other disconnecting means that are grouped in accordance with the basic rule—PROVIDED THAT *the remote disconnect is used only to supply a water pump that is intended to provide fire protection*. In a residence or other building that gets its water supply from a well, a spring, or a lake, the use of a remote disconnect for the water pump will afford improved reliability of the water supply for fire suppression in the event that fire or other faults disable the normal service equipment. And it will distinguish the water-pump disconnect from the other normal service disconnects, minimizing the chance that firefighters will unknowingly open the pump circuit when they routinely open service disconnects during a fire. This exception ties into the rule of 230.72(B), which *requires* (not simply permits) remote installation of a true, Art. 695-compliant fire-pump disconnect switch that is required to be tapped ahead of the one to six switches or CBs that constitute the normal service disconnecting means [see 230.82(5)]. The exception provides remote installation of a *normal service disconnect* when it is used for the comparable purpose (water pump used for fire fighting) as an authentic fire-

pump disconnecting means, which joins various standby disconnecting means that are specifically recognized as meriting remote placement from the rest of the service disconnecting means for the purposes of increasing reliability covered in 230.72(B). In both cases, remote installation of the pump disconnect isolates the critically important pump circuit from interruption or shutdown due to fire, arcing-fault burndown, or any other fault that might knock out the main (normal) service disconnects.

The 2011 **NEC** added a very important qualification to the remote location exception; when it applies, there must be a plaque at the principal service disconnect location advising as to the location of this remote disconnecting means.

A wide variety of layouts can be made to satisfy the Code *permission* for remote installation of a disconnect switch or CB service as a *normal* service disconnect (one of a maximum of six) supplying a water pump. [Figure 230-32](#) shows three typical arrangements that would basically provide the isolated fire-pump disconnect.

Fig. 230-32. Rule *permits* remote installation of one of the two to six service disconnects to protect fire-pump circuits (typical layouts). (Sec. 230.72.)

Part (B), as noted above, makes it mandatory to install emergency disconnect devices where they would not be disabled or affected by any fault or violent electrical failure in the normal service equipment (Fig. 230-33). Figure 230-34 shows a service disconnect for emergency and exit lighting installed very close to the normal service switchboard. An equipment burndown or fire near the main switchboard might knock out the emergency circuit. And the tap for the switch, which is made in the switchboard ahead of the service main, is particularly susceptible to being opened by *an arcing*

failure in the board. The switch should be 10 or 15 ft (3.0 or 4.5 m) away from the board. And because the switchboard is fed from an outdoor transformer-mat layout directly outside the building, the tap to the safety switch would have greater reliability if it was made from the transformer secondary terminals rather than from the switchboard service terminals. Although the rule sets no specific distance of separation, remote locating of emergency disconnects is a mandatory Code rule.

THIS DISTANCE SHOULD ISOLATE STANDBY POWER SOURCE DISCONNECT(S) FROM FAULTS IN NORMAL SERVICE EQUIPMENT.

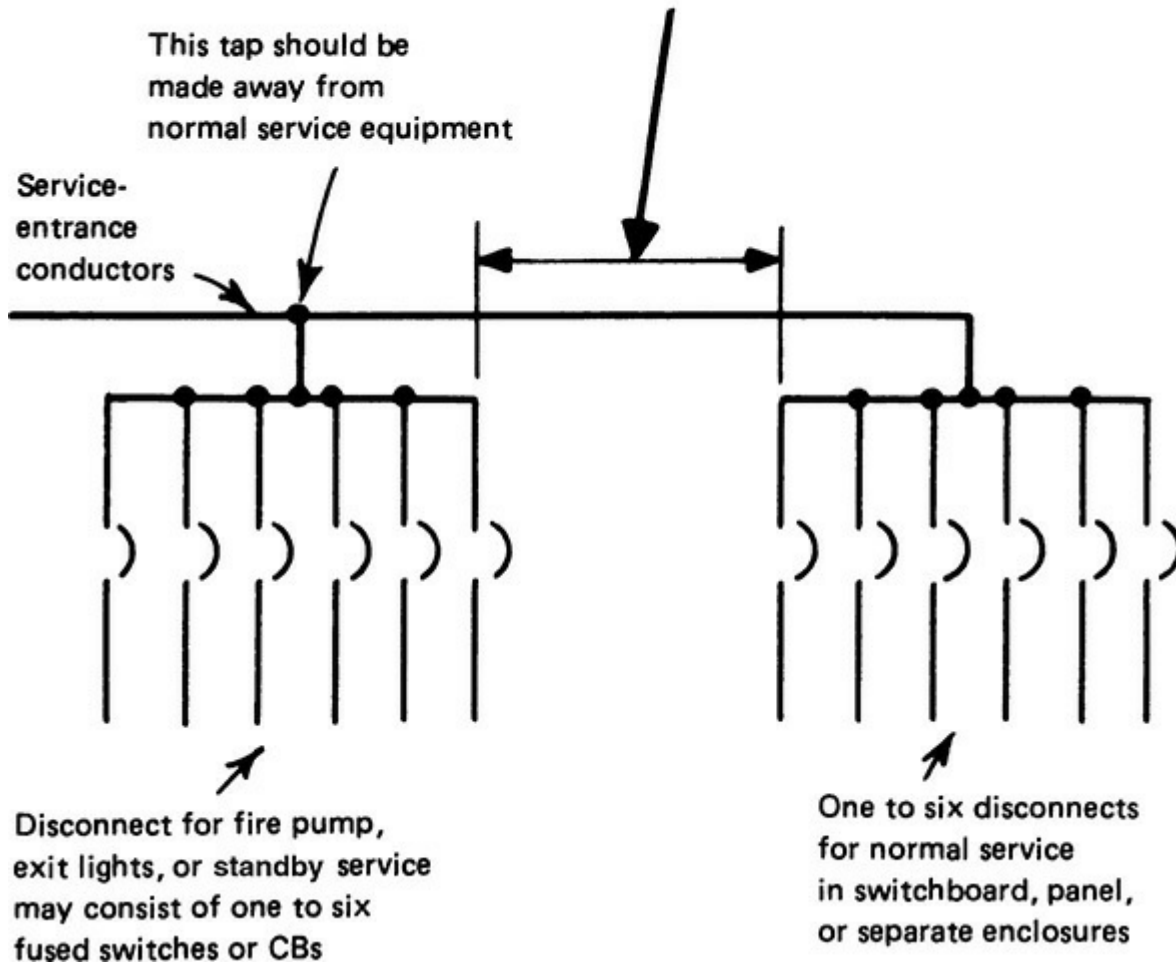

Fig. 230-33. Emergency service disconnects must be isolated from faults in normal SE equipment. Note that taps ahead of the service main are no longer recognized in 700.12 as an acceptable source of emergency circuits, but that a separate service is permitted if allowed for this purpose by the AHJ. Therefore, this drawing must be understood as applicable to installations made under the 1993 or prior editions of the **NEC** that recognized such connections, or as covering installations supplied by two entirely separate services that comply with the separation requirements in 700.12(D). (Sec. 230.72.)

Fig. 230-34. Emergency disconnect close to service switchboard and fed by tap from it could readily be disabled by fault in board. (Sec. 230.72.)

Class R fuses These fuses are made in two designations: RK1 and RK5. UL data are as follows:

In part (B), the phrase “permitted by 230.2” makes clear that each separate service permitted for fire pumps or for either legally required or optional standby service may be equipped with up to six disconnects in the same way as the normal service—or any service—may have up to six SE disconnects. And the disconnect or disconnects for a fire-pump or standby services must be remote from the normal service disconnects, as shown in [Fig. 230-33](#).

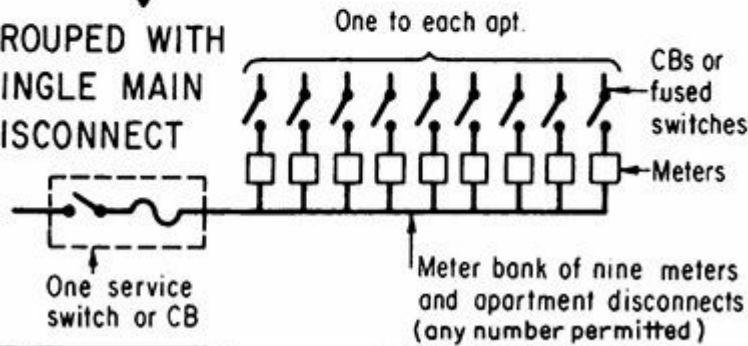

Part (C) applies to applications of service disconnect for multiple-occupancy buildings—such as apartment houses, condominiums, town houses, office buildings, and shopping centers. Part (C) requires that the disconnect means for each occupant in a multiple-occupancy building be accessible to each occupant. For instance, for the occupant of an apartment in an apartment house, the disconnect means for deenergizing the circuits in the apartment must be in the apartment (such as a panel), in an accessible place in the hall, or in a place in the basement or outdoors where it can be reached.

As covered by the exception to part (C), the access for each occupant as required by paragraph (C) would be modified where the building was under the management of a building superintendent or the equivalent and where electrical service and maintenance were furnished. In such a case, the disconnect means for more than one occupancy may be accessible only to authorized personnel. [Figure 230-35](#) summarizes the way the grouping requirements are typically applied to multiple occupancy applications.

Such a building may have no more than six service disconnect switches-but may have any number of disconnect switches for individual occupancies depending upon the number of occupancies.

A. GROUPED WITH SINGLE MAIN DISCONNECT

B. GROUPED WITH NOT MORE THAN SIX DISCONNECT DEVICES

Multiple-occupancy building with individual occupancy above the second floor

FOR EACH SERVICE DROP OR LATERAL NOT MORE THAN SIX SERVICE DISCONNECTS ARE GROUPED AT A COMMON ACCESSIBLE LOCATION.

Three utility services, overhead or underground, as permitted by 230.2 (B)(2) for Buildings of Large Area.

Fig. 230-35. These groupings of service disconnects represent good and acceptable practice that has been followed widely. (Sec. 230.72.)

230.75. Disconnection of Grounded Conductor. In this section, the other means for disconnecting the grounded conductor from the interior wiring may be a screw or bolted lug on the neutral terminal block. The grounded conductor must not be run straight through the service equipment enclosure with no means of disconnection.

230.76. Manually or Power Operable. Any switch or CB used for service disconnect must be manually operable. In addition to manual operation, the switch may have provision for electrical operation—such as for remote control of the switch, provided it can be manually operated to the open or OFF position.

Code wording clearly indicates that an electrically operated breaker with a mechanical trip button that will open the breaker even if the supply power is dead is suitable for use as a service disconnect. The manually operated trip button ensures that the breaker “can be opened by hand.” To provide manual closing of electrically operated circuit breakers, manufacturers provide emergency manual handles as standard accessories. Thus, such breaker mechanisms can be both closed and opened manually if operating power is not available, which fully satisfies this rule (Fig. 230-36).

Note: Some local codes require both manual and electrical means of operation.

Fig. 230-36. Manual operation of any service switch is required. (Sec. 230.76.)

Local requirements on the use of electrically operated service disconnects should be considered in selecting such devices.

230.79. Rating of Service Disconnecting Means. Aside from the limited conditions covered in parts (A) and (B), this section requires that service equipment (in general) shall have a

rating not less than 60 A, applicable to both fusible and CB equipment. Part (C) requires 100-A minimum rating of a single switch or CB used in the service disconnect for *any* “one-family dwelling.” It should be noted that the rule applies to one-family houses only, because of the definition of “one-family dwelling” as given in Art. 100. It does not apply to apartments or similar dwelling units that are in two-family or multifamily dwellings. These rules and the requirements in 230.42(B) must be carefully correlated. Review the discussion at 230.42(B) in this chapter for more information on this topic.

Even if the demand on a total connected load, as calculated from 220.40 through 220.61 or any of the applicable optional calculations permitted by part (C) of Art. 220, is less than 10 kVA, a 100-A service disconnect, as well as 100-A rated service-entrance conductors [230.42(B)], must be used.

If a 100-A service is used, the demand load may be as high as 24 kVA. By using the optional service calculations of Table 220.82, a 24-kVA demand load is obtained from a connected load of as much as 45 kVA, depending on how the load is configured. This shows the effect of diversity on large-capacity installations.

230.80. Combined Rating of Disconnects. Figure 230-37 shows an application of this rule, based on determining what rating of a single disconnect would be required *if* a single disconnect were used instead of multiple ones. It should be noted that the sum of ratings above 400 A does comply with the rule of this section and with Exception No. 3 of 230.90(A), even though the 400-A service-entrance conductors could be heavily overloaded. Exception No. 3 exempts this type of layout from the need to protect the conductors at their rated ampacity, as required in the basic rule of 230.90. The Code assumes that the 400-A rating of the service-entrance conductors was carefully calculated from Art. 220 to be adequate for the maximum sum of the demand loads fed by the five disconnects shown in the layout.

From Art. 220, calculation of demand load indicated that a single disconnect for this service must be rated at least 400 amps. The rating of multiple disconnects must total at least that value.

Fig. 230-37. Multiple disconnects must have their sum of ratings at least equal to the minimum rating of a single disconnect. (Sec. 230.80.)

230.82. Equipment Connected to the Supply Side of Service Disconnect. Cable limiters, fuses or CBs away from the building, high-impedance shunt circuits (such as potential coils of meters), supply conductors for time switches, surge-protective capacitors, instrument transformers, lightning arresters and circuits for emergency systems, fire-pump equipment, and fire and sprinkler alarms may be connected on the supply side of the disconnecting means. Emergency-lighting circuits, surge-protective capacitors, and fire-alarm and other protective signaling circuits, when placed ahead of the regular service disconnecting means, must have separate disconnects and overcurrent protection.

Part (1) of the rule prohibiting equipment connections on the line side of the service disconnect permits “cable limiters or other current-limiting devices” to be so connected.

Cable limiters are used to provide protection for individual conductors that are used in parallel (in multiple) to make up one phase leg of a high-capacity circuit, such as service conductors. A cable limiter is a cable connection device that contains a fusible element rated to protect the conductor to which it is connected.

As indicated in Part (2), meters, and meter sockets can be connected on the supply side of the service disconnecting means and OCPDs if the meters are connected to service not in excess of 1000 V where the grounded conductor bonds the meter equipment cases and enclosures to the grounding electrode. (See Fig. 230-38.)

Fig. 230-38. A “meter” may be connected on the supply side of the service disconnect. [Sec. 230.82(2).]

Part (3) allows meter disconnect switches ahead of a service disconnect, provided they have a suitable load rating and fault-current interrupting capability. **WARNING:** Many bypass meter sockets contain a switch that is used to maintain continuity across the meter jaws when the meter is removed. Utility personnel will close this switch, remove the meter for service, replace the meter, and then open the switch. It is of paramount importance that *this switch never be opened or closed under load*. The switches are unsuitable for load switching, only to maintain continuity.

Electrical utilities are requiring meter disconnect switches with ever-increasing frequency for the safety of their metering departments, so they can work the metering equipment cold. For this reason they are an important safety enhancement. From a code enforcement perspective, they present some challenges and opportunities for conflict in the field, especially since they are now fully load-break rated. If such a fuse were fused to contribute to the fault duty of the switch, the switch would arguably contain all the elements of service equipment as defined in the **NEC**.

This immediately raises the question, did the location of the service disconnect just move? The orderly application of a plethora of **NEC** rules depends on common agreement on exactly what device constitutes the service disconnecting means for any premises wiring application. If the service

disconnect, in effect, relocates, then the number of conductors to the building changes because the neutral cannot be used for equipment grounding, the permitted point of connecting the grounding electrode conductor changes, and on and on. In fact, there has never been any intent to change the intended service disconnect locations, and this switch is only for the use of utility employees, who may well lock the switch in the ON position except while it is under active use. However, since it may also meet the Art. 100 definition, it would be wise to review the plans and the utility site policies with the inspector so there will not be surprises at the time of the final service inspection. The 2014 **NEC** took a giant step toward making sure that the function would not be misinterpreted. A meter disconnect must now be field labeled as such, and with the additional words “NOT SERVICE EQUIPMENT.”

It must also be noted that this rule does not mandate the electrical location of this disconnect. Different utilities have different policies as to whether the switch is ahead (cold sequence) or after (hot sequence) the meter, policies that can change based on the voltage and currents involved. Most self-contained meters operating on 480 V distributions use cold sequence switching, because a fault created in the process of removing a meter will tend to be self-sustaining, particularly in the likely event of a transfer to the grounded meter socket. If that happens the damage will be extensive. On the other hand, some utilities prefer hot sequence metering on 208Y/120 V systems because they reduce the likelihood of power theft. These provisions simply allow for certain equipment ahead of service disconnects; the exact location is left to the serving utility that would be the specifier for the equipment.

Part (4) recognizes the connection of current and voltage transformers, high-impedance shunts, and surge protection on the line side of the service disconnecting means, *but* only where such devices are listed for such application. Where supply conductors are installed as service conductors, load management devices, fire alarm and suppression equipment, and standby power systems are permitted to be connected on the line side of the service disconnecting means by part (5). This part allows transfer switches ahead of the service disconnecting means in accordance with the limitations spelled out in 700.5, 701.5, and 702.5. Transfer switches are also available with ratings for service disconnecting means, in which case they will be marked accordingly.

As permitted by part (6), an electric power production source that is auxiliary or supplemental to the normal utility service to a premises may be connected to the supply (incoming) side of the normal service disconnecting means. This part of the rule permits connection of a solar photovoltaic system, fuel cells, or interconnected power sources into the electrical supply for a building or other premises, to operate as a parallel power supply. The 2017 **NEC** added wind electric systems and energy storage systems to this list.

Where properly protected and provided with suitable disconnects, control circuits for power-operated service disconnects may be connected ahead of the service disconnect as recognized by subpart (7). And part (8) recognizes that control power for a ground-fault protection system may be tapped from the supply side of the service disconnecting means. Where a control circuit for a ground-fault system is tapped ahead of the service main and “installed as part of listed equipment,” suitable overcurrent protection and a disconnect must be provided for the control-power circuit.

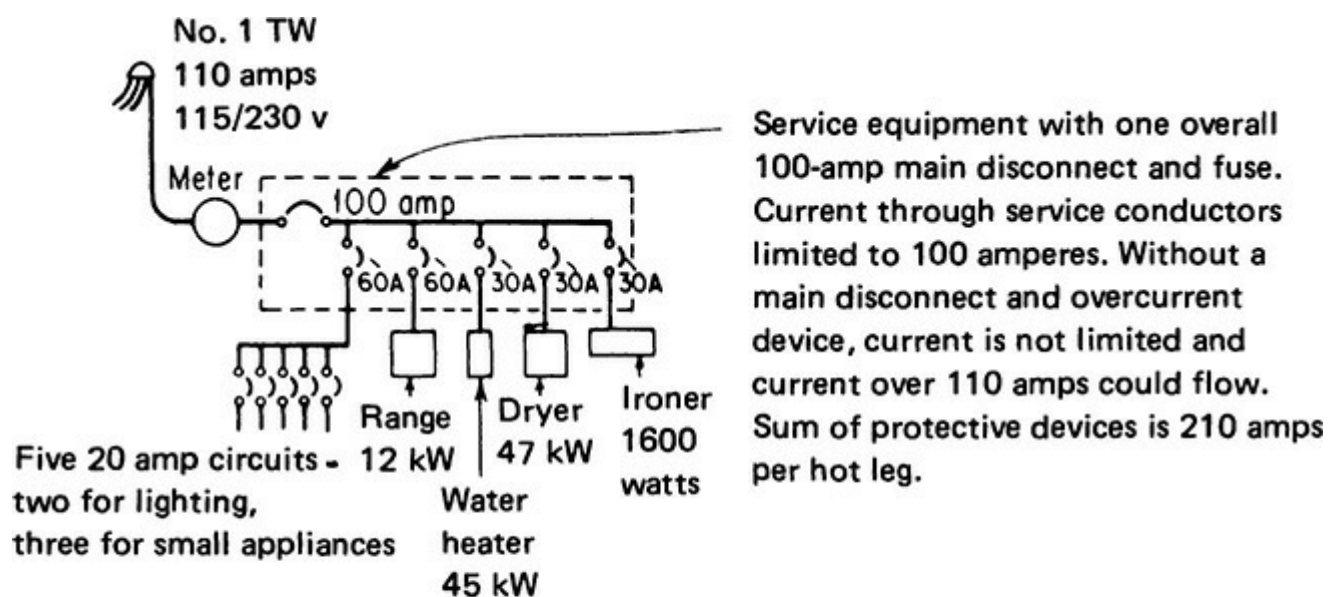

Part (9) was new in the 2011 edition and covers communications equipment provided by the utility and under its exclusive control. This equipment must be listed and equipped with both a disconnecting means and overcurrent protection. The disconnect need not be installed if the equipment is enclosed within a metering compartment so access is impossible unless the meter is

removed. This sort of allowance will be critical to enable increasingly sophisticated methods of sophisticated metering and other smart grid technologies to be put in place.

230.90. Where Required. The intent in paragraph (A) is to ensure that the overcurrent protection required in the service-entrance equipment protects the service-entrance conductors from “overload.” It is obvious that these overcurrent devices cannot provide “fault” protection for the service-entrance conductors if the fault occurs in the service-entrance conductors (which are on the line side of the service overcurrent devices), but they can protect the conductors from overload where so selected as to have proper rating. Conductors on the load side of the service equipment are considered as feeders or branch circuits and are required by the Code to be protected as described in Arts. 210, 215, and 240.

Part (A) states that the term “set” of fuses means all the fuses required to protect all the ungrounded service-entrance conductors in a given circuit.

Each ungrounded service-entrance conductor must be protected by an overcurrent device in series with the conductor (Fig. 230-39). The overcurrent device must have a rating or setting not higher than the allowable current capacity of the conductor, with the exceptions noted.

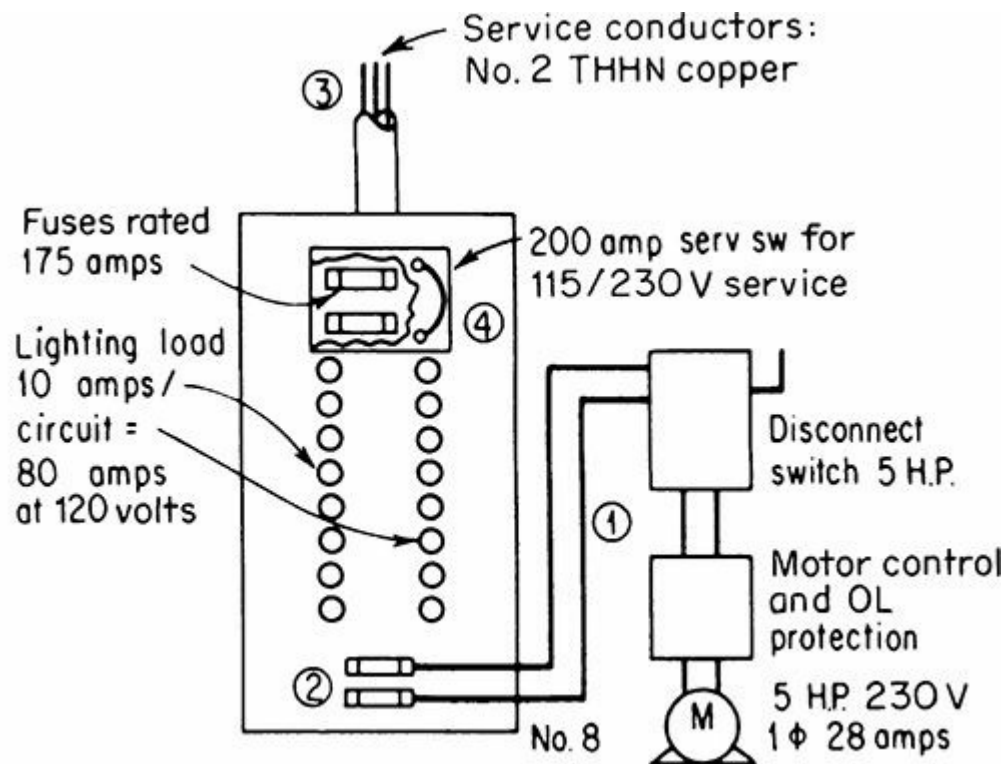

Note: Service-entrance conductors must be selected with adequate ampacity for the calculated service demand load, from 220.40 through 220.61, or any applicable optional calculation covered in Part IV of Art. 220.

Fig. 230-39. Single main service protection must not exceed conductor ampacity (or may be next higher rated device above conductor ampacity). (Sec. 230.90.)

The rule of Exception No. 1 says that if the service supplies one motor in addition to other load (such as lighting and heating), the overcurrent device may be rated or set in accordance with the required protection for a branch circuit supplying the one motor (430.52) plus the other load, as shown in Fig. 230-40. Use of 175-A fuses where the calculation calls for 170-A conforms to Exception No. 2 of 230.90—next higher standard rating of fuse (240.6). For motor branch circuits and feeders, Arts. 220 and 430 permit the use of overcurrent devices having ratings or settings higher than the capacities of the conductors. Article 230 makes similar provisions for services where the service

supplies a motor load or a combination load of both motors and other loads.

1. Size of motor branch circuit conductors: $125\% \times 28$ amps equals 35 amps. This requires No. 8's.

2. Size of motor branch circuit fuses: $300\% \times 28$ amps equals 84 amps. This requires maximum fuse size of 90 amps. Smaller fuses, such as time-delay type, may be used.

3. Size of service entrance conductors must be adequate for a load of $125\% \times 28$ amps plus 100 amps (continuous lighting load of 80 amps $\times 1.25$) or 135 amps.

4. Size of main fuses: 90 amps (from 2 above) plus 100 amps (80 amps $\times 1.25$) equals 190 amps. This requires maximum fuse size of 200 amps. Again, smaller fuses may and should be used where possible to improve the overload protection on the circuit conductors.

Fig. 230-40. Service protection for lighting plus motor load. (Sec. 230.90.)

If the service supplies two or more motors as well as other load, then the overcurrent protection must be rated in accordance with the required protection for a feeder supplying several motors plus the other load (430.63). Or if the service supplies only a multimotor load (with no other load fed), then 430.62 sets the maximum permitted rating of overcurrent protection.

Exception No. 3. Not more than six CBs or six sets of fuses may serve as overcurrent protection for the service-entrance conductors even though the sum of the ratings of the overcurrent devices is in

excess of the ampacity of the service conductors supplying the devices—as illustrated in Fig. 230-41. The grouping of single-pole CBs as multipole devices, as permitted for disconnect means, may also apply to overcurrent protection.

For a demand load of 125 amps, SE conductors could be No. 1 THW copper (130 amps).

In this case, service conductors could be overloaded (up to 240 amps, if CBs here are 2-pole). If main overcurrent protection, rated at 125 amps, were installed at point "A", service conductors would be protected against any load in excess of the calculated demand.

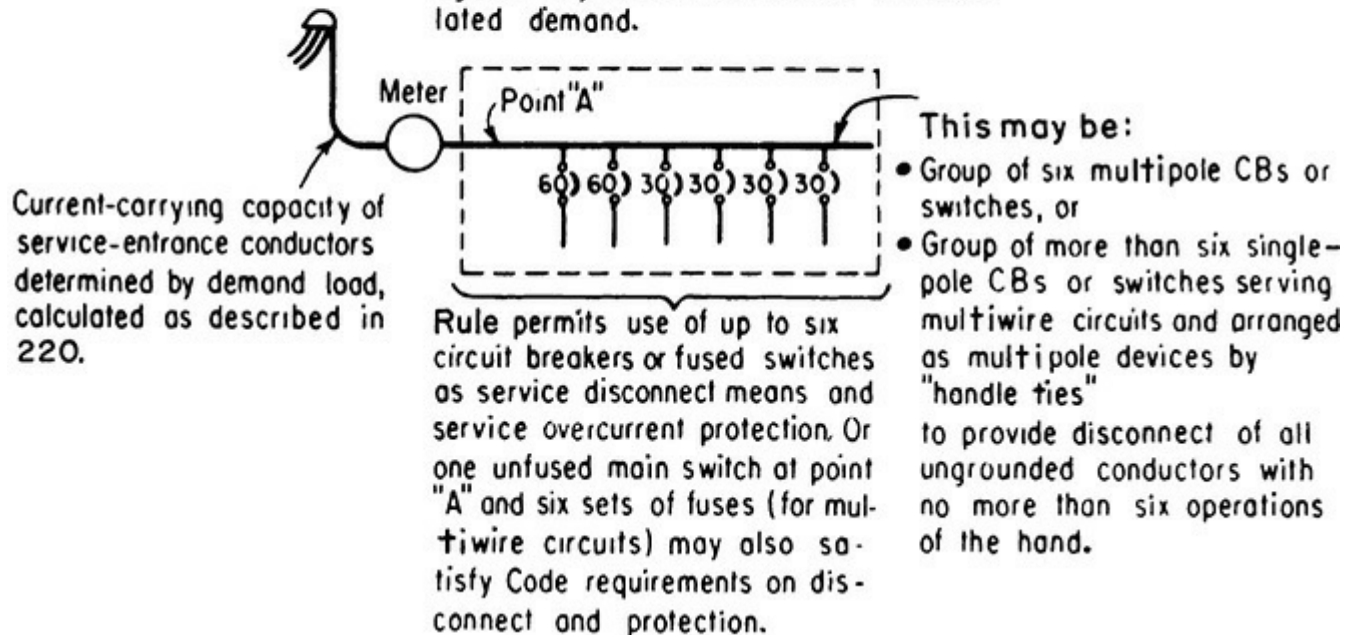

Fig. 230-41. With six subdivisions of protection, conductors could be theoretically overloaded. In effect, the service conductors are being protected from overload by the accuracy of the Art. 220 load calculation that sized them. (Sec. 230.90.)

Exception No. 3 ties into 230.80. Service conductors are sized for the *total* maximum demand load—applying permitted demand factors from Art. 220. Then each of the two to six feeders fed by the SE conductors is also sized from Art. 220 based on the load fed by each feeder. When those feeders are given overcurrent protection in accordance with their ampacities, it is frequently found that the sum of those overcurrent devices is greater than the ampacity of the SE conductors, which were sized by applying the applicable demand factors to the total connected load of all the feeders. Exception No. 3 recognizes that possibility as acceptable even though it departs from the rule in the first sentence of 230.90(A). The assumption is that if calculation of demand load for the SE conductors is correctly made, there will be no overloading of those conductors because the diversity of feeder loads (some loads “on,” some “off”) will be adequate to limit load on the SE conductors.

Assume that the load of a building computed in accordance with Art. 220 is 255 A. Under 240.4(B), 300-A fuses or a 300-A CB may be considered as the proper-size overcurrent protection for service conductors rated between 255 and 300 A if a single service disconnect is used.

If the load is separated in such a manner that six 70-A CBs could be used instead of a single service disconnecting means, total rating of the CBs would be greater than the ampacity of the service-entrance conductors. And that would be acceptable.

Exception No. 4 to 230.90(A) is shown in Fig. 230-42 and is intended to prevent opening of the

fire-pump circuit on any overload up to and including stalling or even seizing of the pump motor. Because the conductors are “outside the building,” operating overload is no hazard; and, under fire conditions, the pump must have no prohibition on its operation. It is better to lose the motor than attempt to protect it against overload when it is needed.

Fig. 230-42. (Sec. 230.90.)

Exception No. 5 specifically recognizes the use of conductors in accordance with 310.15(B)(7). There the Code considers the conductor sizes in Table 310.15(B)(7) to be adequately protected by the value of OC protection indicated.

230.91. Location. The 2017 NEC added a requirement that if fuses are used as the overcurrent protection, they must be on the load side of the disconnect. This, in general, is common sense, but it was ill-advised here because the information is incomplete. For one thing a fusible limiter, which is expressly allowed elsewhere by 230.82(1), may get caught up in this. The entire, surprisingly complicated topic is fully covered in 240.40, and the extra sentence here should be disregarded.

230.95. Ground-Fault Protection of Equipment. Fuses and CBs, applied as described in the previous section on “Overcurrent Protection,” are sized to protect conductors in accordance with their current-carrying capacities. The function of a fuse or CB is to open the circuit if current exceeds the rating of the protective device. This excessive current might be caused by operating overload, by a ground fault, or by a short circuit. Thus, a 1000-A fuse will blow if current in excess of that value flows over the circuit. It will blow early on heavy overcurrent and later on low overcurrents. But it will blow, and the circuit and equipment will be protected against the damage of the overcurrent. But, there is another type of fault condition which is very common in grounded systems and will not be cleared by conventional overcurrent devices. That is the phase-to-ground fault (usually arcing) which has a current value less than the rating of the overcurrent device.

On any high-capacity feeder, a line-to-ground fault (i.e., a fault from a phase conductor to a conduit, to a junction box, or to some other metallic equipment enclosure) can, and frequently does, draw current of a value less than the rating or setting of the circuit protective device. For instance, a 500-A ground fault on a 2000-A protective device which has only a 1200-A load will not be cleared by the device. If such a fault is a “bolted” line-to-ground fault, a highly unlikely fault, there will be a certain amount of heat generated by the I^2R effect of the current; but this will usually not be dangerous, and such fault current will merely register as additional operating load, with wasted energy (wattage) in the system. Further, such bolted faults usually draw large values of current, particularly if the equipment grounding system has been installed correctly, and the result will be a trip in very short order. But, bolted phase-to-ground faults are very rare. The usual phase-to-ground fault exists as an intermittent or arcing fault, and an arcing fault of the same current rating as the essentially harmless bolted fault can be fantastically destructive because of the intense heat of the arc.

Of course, any ground-fault current (bolted or arcing) above the rating or setting of the circuit protective device will normally be cleared by the device. But, even where the protective device eventually operates, in the case of a heavy ground-fault current which adds to the normal circuit load current to produce a total current in excess of the rating of the normal circuit protective device (fuse or CB), the time delay of the device may be minutes or even hours—more than enough time for the arcing-fault current to burn out conduit and enclosures, acting just like a torch, and even propagating flame to create a fire hazard.

In the interests of safety, definitive engineering design must account for protection against high-impedance ground faults, as is required by this Code rule. Phase OCPDs are normally limited in their effectiveness because (1) they must have a time delay and a setting somewhat higher than full load to ride through normal inrushes and (2) they are unable to distinguish between normal currents and low-magnitude fault currents, which, when combined, may be less than the trip rating of the OCPD.

Dangerous temperatures and magnetic forces are proportional to current for overloads and short circuits; therefore, OCPDs usually are adequate to protect against such faults. However, the temperatures of arcing faults are, generally, independent of current magnitude; and arcs of great and extensive destructive capability can be sustained by currents not exceeding the overcurrent device settings. Other means of protection are therefore necessary. A ground-detection device, which “sees” only ground-fault current, is coupled to an automatic switching device to open all three phases when a line-to-ground fault exists on the circuit. Such protective systems are readily available in listed configurations from electrical equipment manufacturers, which eases compliance with this rule. Careful attention to manufacturer’s installation instructions is mandatory to ensure proper operation and the desired level of protection.

230.95 requires ground-fault protection of equipment (GFPE) to be provided for each service *disconnecting means* rated 1000 A or more in a solidly grounded-wye electrical service that operates with its ungrounded legs at more than 150 V to ground. Note that this applies to the rating of the disconnect, not to the rating of the overcurrent devices or to the capacity of the service-entrance conductors.

The wording of the first sentence of this section makes clear that service GFPE (ground-fault protection of equipment) is required under specific conditions: only for grounded-wye systems that have voltage over 150 V to ground and less than 1000 V phase-to-phase. In effect, that means the rule applies only to 480/277-V grounded-wye and *not* to 120/208-V systems or any other commonly used systems (Fig. 230-43). Recent recognition of the 600Y/347-V distribution systems—used in Canada

—would subject any system so rated to the rule of Sec. 230.95. And, each disconnect rated 1000 A, or more, must be provided with equipment GFPE. GFPE is *not* required on any systems operating over 1000 V phase-to-phase. The reason for this voltage parameter is that on ac systems an arc naturally self-extinguishes at every current zero, 120 times per second. The likelihood of damage is directly related to the likelihood of the arc restriking, and that is related to the peak voltage in the system. Testing has shown this is a major problem above about 375 V. Since the peak voltage of a 120-V-to-ground system is 170 V ($120 \times \sqrt{2}$), these systems aren't so much of a problem. However, on 480Y/277-V systems, the peak voltage is about 390 V, easily high enough to keep the arc in business.

. . . applies to solidly grounded wye services over 150 volts to ground but not over 600 volts phase-to-phase — i.e., 480Y/277 V or 600/347 V.

For each service disconnect rated 1000 amps or more, ground-fault protection with maximum trip setting of 1200 amps must be provided.

Fig. 230-43. Service ground-fault protection is mandatory. (Sec. 230.95.)

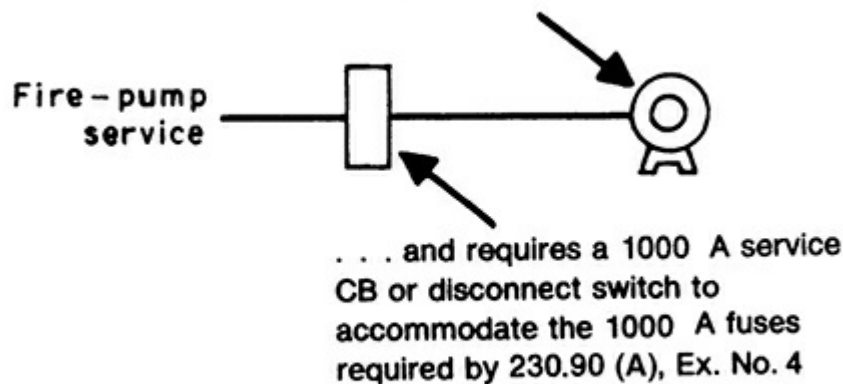

The second paragraph clearly indicates that the “rating” to be considered is the rating of the largest

fuse a switch can accommodate, or the longtime trip rating of a nonadjustable CB, or the maximum “setting” for adjustable-trip CBs. If the fusible switch, nonadjustable CB, or adjustable-trip CB used as the service disconnect is rated at, or can be set at, 1000 A or more, then ground-fault protection is required.

In a typical GFPE hookup, as shown in Fig. 230-44, part (A) of the section specifies that a ground-fault current of 1200 A or more must cause the disconnect to open all ungrounded conductors. Thus, the maximum GF pick-up setting permitted is 1200 A, although it may be set lower.

100 hp, 460 V fire-pump motor has full-load current of 124 A and locked-rotor current of 906 A . . .

**GROUND-FAULT PROTECTION
MUST NOT BE USED!**

Fig. 230-44. GFPE is required for each disconnect rated 1000 A or more, but not for a fire-pump disconnect. (Sec. 230.95.)

With a GFPE system, at the service entrance a ground fault anywhere in the system is immediately sensed in the ground-relay system, but its action to open the circuit usually is delayed to allow some normal overcurrent device near the point of fault to open if it can. As a practical procedure, such time delay is designed to be only a few cycles or seconds, depending on the voltage of the circuit, the time-current characteristics of the overcurrent devices in the system, and the location of the ground-fault relay in the distribution system. Should any of the conventional short-circuit OCPDs fail to operate in the time predetermined to clear the circuit, and if the fault continues, the ground-fault

protective relays will open the circuit. This provides added overcurrent protection not available by any other means.

The rule requiring GFPE for any service disconnect rated 1000 A or more (on 480/277-V or 600/347-V services) specifies a maximum *time delay of 1 s for ground-fault currents of 3000 A or more* (Fig. 230-45).

Fig. 230-45. The rule specifies maximum energy let-through for GFPE operation. [Sec. 230.95(A).]

The maximum permitted setting of a service GFPE hookup is 1200 A, but the time-current trip characteristic of the relay must ensure opening of the disconnect in not more than 1 s for any ground-fault current of 3000 A or more. This change in the Code was made to establish a specific level of protection under GFPE by setting a maximum limit on I^2t of fault energy.

The reasoning behind this change was explained as follows:

The amount of damage done by an arcing fault is directly proportional to the time it is allowed to

burn. Commercially available GFPE systems can easily meet the 1-s limit. Some users are requesting time delays up to 60 s so all downstream overcurrent devices can have plenty of time to trip thermally before the GFP on the main disconnect trips. However, an arcing fault lasting 60 s can virtually destroy a service equipment installation. Coordination with downstream overcurrent devices can and should be achieved by adding GFPE on feeder circuits where needed. The Code should require a reasonable time limit for GFP. Now, 3000 A is 250 percent of 1200 A, and 250 percent of setting is a calibrating point specified in ANSI 37.17. Specifying a maximum time delay starting at this current value will allow either flat or inverse time-delay characteristics for ground-fault relays with approximately the same level of protection.

Selective coordination between GFPE and conventional protective devices (fuses and CBs) on service and feeder circuits is now a very clear and specific task as a result of rewording of 230.95(A) that calls for a maximum time delay of 1 s at any ground-fault current value of 3000 A or more.

For applying the rule of 230.95, the rating of any service disconnect means shall be determined, as shown in [Fig. 230-46](#).

FUSED SWITCH (bolted pressure switch, service protector, etc.)

Rating of switch is taken as...

... the amp rating of the largest fuse that can be installed in the switch fuseholders.

EXAMPLE

If 900-amp fuses are used in this service switch, ground-fault protection would be required, because the switch can take fuses rated 1200 amps—which is above the 1000-amp level at which GFPE becomes mandatory.

CIRCUIT BREAKER

Rating of breaker is taken as...

... the maximum continuous current rating (pickup of long time-delay) for which the trip device in the breaker is set or can be adjusted.

Example: GFPE would be required for a service CB with, say, an 800-amp trip setting if the CB had a trip device that can be adjusted to 1000 amps or more.

Fig. 230-46. Determining rating of service disconnect for GFPE rule. (Sec. 230.95.)

Because the rule on required service GFPE applies to the rating of each service disconnect, there are many instances where GFPE would be required if a single service main disconnect is used but *not* if the service subdivision option of 230.71(A) is taken, as shown in [Fig. 230-47](#).

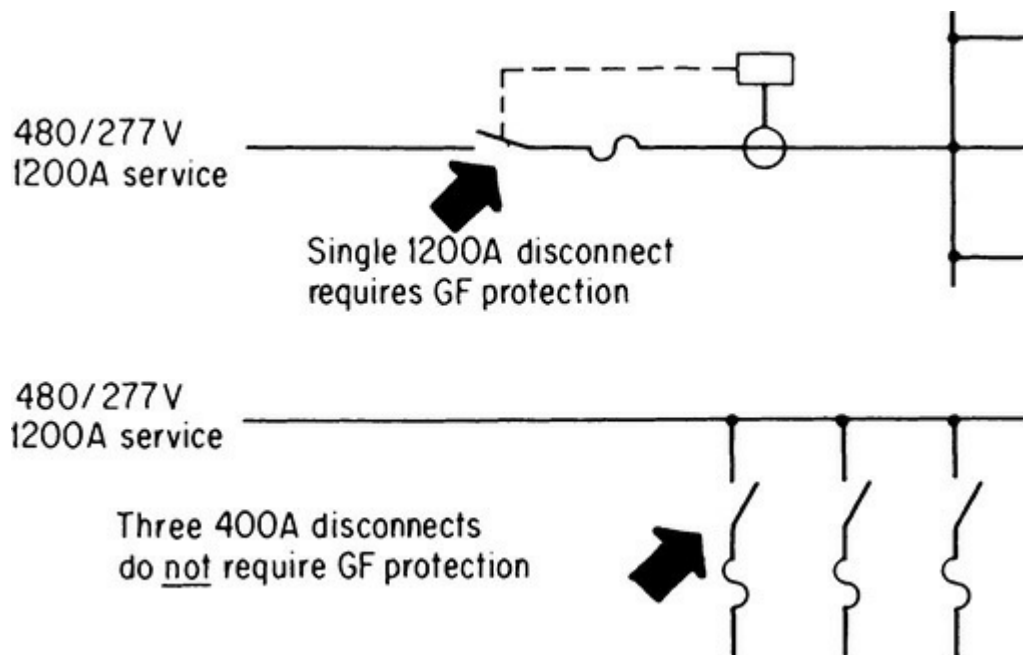

Fig. 230-47. Subdivision option on disconnects affects GFPE rule. (Sec. 230.95.)

By the exception to 230.95, continuous industrial process operations are exempted from the GFPE rules of parts (A), (B), and (C) where the electrical system is under the supervision of qualified persons who will effect orderly shutdown of the system and thereby avoid hazards, greater than ground fault itself, that would result from the nonorderly, automatic interruption that GFPE would produce in the supply to such critical continuous operations. The exception excludes GFPE requirements where a nonorderly shutdown will introduce additional or increased hazards. The idea behind that is to provide maximum protection against service outage of such industrial processes. With highly trained personnel at such locations, design and maintenance of the electrical system can often accomplish safety objectives more readily without GFPE on the service. Electrical design can account for any danger to personnel resulting from loss of process power versus damage to electrical equipment.

The former Exception No. 2 at this location excluded fire-pump service disconnects from the basic rule that requires ground-fault protection on any service disconnect rated 1000 A or more on a grounded-wye 600/347-V or 480/277-V system. This exception has been deleted, not because it is a bad idea, but because the fire pump article now has a clear statement [at 695.6(G)] that forbids the use of GFPE on a fire pump circuit. Since per 90.3 a provision in [Chap. 6](#) (or 5 or 7) automatically supersedes a contrary provision in [Chaps. 1](#) through 4, an exception to the same effect here is a waste of space. There are good reasons for the prohibition.

Because fire pumps are required by 230.90, Exception No. 4, to have overcurrent protection devices large enough to permit locked-rotor current of the pump motor to flow without interruption, larger fire pumps (100 hp and more) would have disconnects rated 1000 A or more. Without Exception No. 2, those fire-pump disconnects would be subject to the basic rule and would have to be equipped with ground-fault protection. But GFP on any fire pump is objectionable on the same basis that 230.90, Exception No. 4, wants nothing less than protection rated for locked rotor. The intent is to give the pump motor every chance to operate when it functions during a fire, to prevent opening of the motor circuit or any overload up to and including stalling or seizing of the shaft or bearings. For the same reason, 430.31 exempts fire pumps from the need for overload protection, and 430.72(C) exception requires overcurrent protection to be omitted from the control circuit of a starter

for a fire pump.

Important considerations are given in the informational notes in this section. Obviously, the selection of ground-fault equipment for a given installation merits a detailed study. The option of subdividing services discussed under *six service entrances from one lateral* [230.2(A)(1)] should be evaluated. A 4000-A service, for example, could be divided using five 800-A disconnecting means, and in such cases GFPE would not be required.

One very important note in 230.95 warns about potential desensitizing of ground-fault sensing hookups when an emergency generator and transfer switch are provided in conjunction with the normal service to a building. The note applies to those cases where a solid neutral connection from the normal service is made to the neutral of the generator through a 3-pole transfer switch. With the neutral grounded at the normal service and the neutral bonded to the generator frame, ground-fault current on the load side of the transfer switch can return over two paths, one of which will escape detection by the GFPE sensor, as shown in [Fig. 230-48](#). Such a hookup can also cause nuisance tripping of the GFPE due to normal neutral current. Under normal (nonfaulted) conditions, neutral current due to normal load unbalance on the phase legs can divide at common neutral connection in transfer switch, with some current flowing toward the generator and returning to the service main on the conduit—indicating falsely that a ground fault exists and causing nuisance tripping of GFPE. The note points out that “means or devices” (such as a 4-pole, neutral-switched transfer switch) “may be needed” to ensure proper, effective operation of the GFPE hookup ([Fig. 230-49](#)).

3. This GF current coming back on neutral goes through GFPE sensor and is not sensed as fault current.

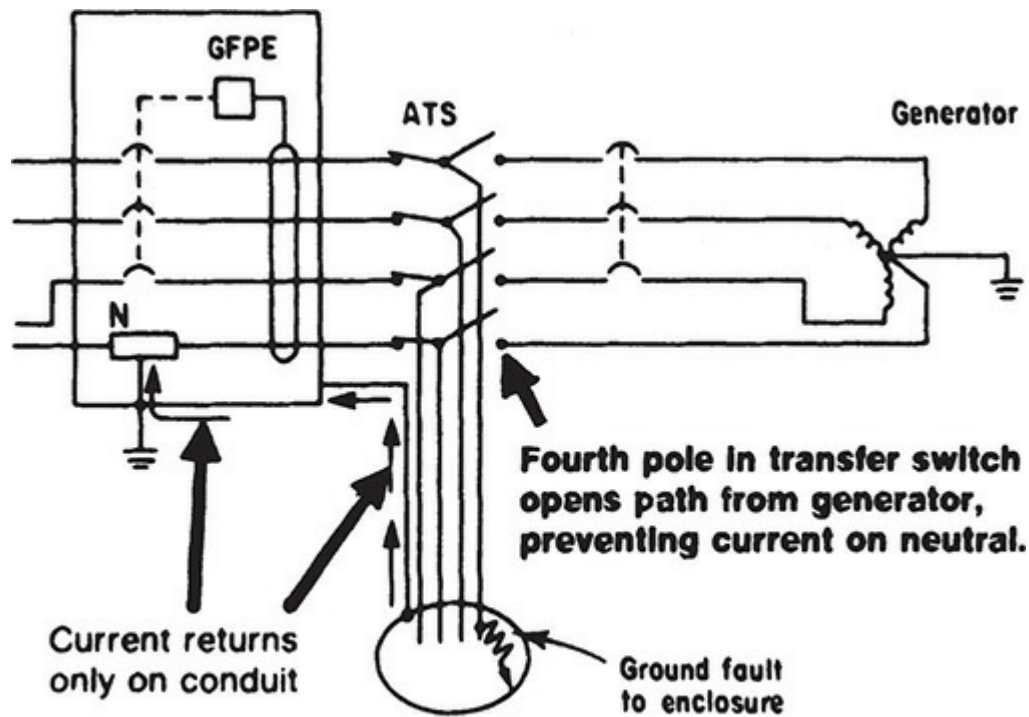

Fig. 230-48. Improper operation of GFPE can result from emergency system transfer switch. (Sec. 230.95.)

Refer to Fig. 230-48

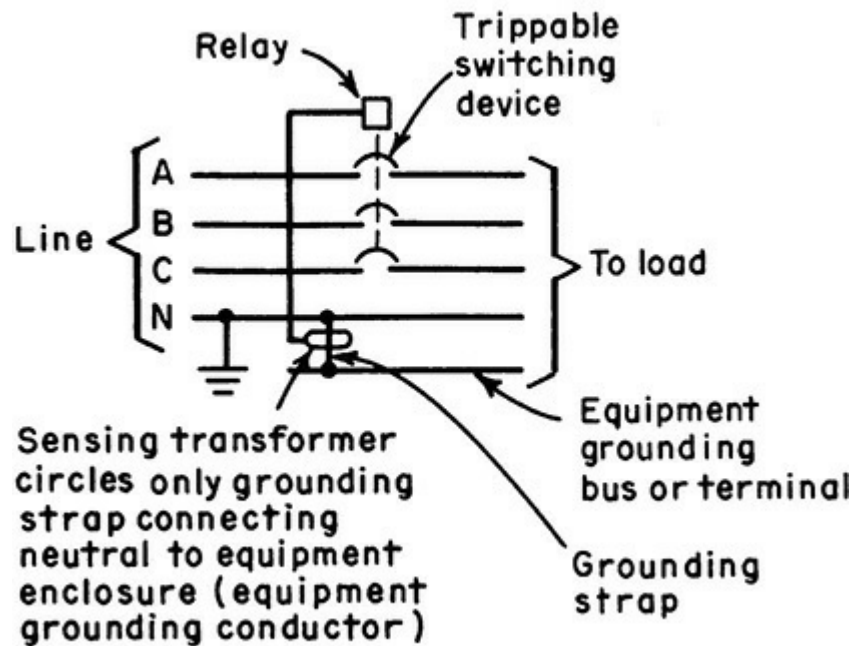

Fig. 230-49. Four-pole transfer switch is one way to avoid desensitizing GFPE. (Sec. 230.95.)

Very Important!

Because of so many reports of improper and/or unsafe operation (or failure to operate) of ground-fault protective hookups, part (C) of 230.95 *requires* (a mandatory rule) that *every* GFPE hookup be "performance tested when first installed." And the testing **MUST** be done *on the job site!* Factory testing of a GFPE system does not satisfy this Code rule. This rule requires that such testing be done according to "instructions ... provided with the equipment." The 2017 **NEC** took all this a step further by mandating that the on-site testing be done by a qualified person and include a "process of primary current injection." A written record must be made of the test and must be available to the inspection authority.

Figure 230-50 shows two basic types of GFPE hookup used at service entrances.

GROUND-STRAP SENSING

ZERO-SEQUENCE SENSING

Fig. 230-50. Types of ground-fault detection that may be selected for use at services. (Sec. 230.95.)

230.200. General (Services Exceeding 1000 V, Nominal). The rules on medium-voltage services given in the provisions of Art. 230 apply only to equipment on the load side of the “service-point.” Because there has been so much controversy over identifying what is and what is not “service” equipment in the many complicated layouts of outdoor high-voltage circuits and transformers, the definition in Art. 100 provides clarification. In any particular installation, identification of that point can be made by the utility company and design personnel. The definition clarifies that the property line is not the determinant as to where **NEC** rules must begin to be applied. This is particularly important in cases of multibuilding industrial complexes where the utility has distribution circuits on the property. See “Service Point” in Art. 100.

230.200 says that “service conductors and equipment used on circuits exceeding 1000 V” must comply with *all* the rules in Art. 230 (including any “applicable provisions” that cover services up to 1000 V). And Art. 100 says that for services up to 1000 V, the “service conductors” are those conductors—whether on the primary or secondary of a step-down transformer or transformers—that carry current from the “service point” (where the utility connects to the customer’s wiring) to the service disconnecting means for a building or structure. See “Service Point” in Art. 100. All conductors between the defined points—“service point” and “service disconnecting means”—must comply with all requirements for service conductors, whether above or below 1000 V.

Design and layout of any “service” are critically related to safety, adequacy, economics, and effective use of the whole system. It is absolutely essential that we know clearly and surely what circuits and equipment of any electrical system constitute the “service” and what parts of the system are not involved in the “service.” For instance, in a system with utility feed at 13.2 kV and step down to 480/277 V, the mandatory application of 230.95 requiring GFPE hinges on establishing whether the “service” is on the primary or secondary side of the transformers. If the secondary is the service, where the step-down transformer belongs to the utility and the “service point” is on its secondary, we have a mandatory need for GFPE and none of the Code rules on service would apply to any of the 13.2-kV circuits—regardless of their length or location. If the transformer belongs to the customer and the “service point” is on the primary side, the primary is the service, 230.95 does not require GFPE on services over 1000 V phase-to-phase, all the primary circuit and equipment must comply with all of Art. 230, and the secondary circuits are feeders and do not have to comply with any of the service regulations. This potential loophole has been closed by the addition of comparable GFPE rules to feeder circuits in 215.10.

The whole problem involved here is complex and requires careful, individual study to see clearly the many interrelated considerations. Let us look at a few important things to note about Code definitions as given in Art. 100:

1. “Service conductors” run to the *service disconnect* of the premises supplied. Note that they run to “premises” and are not required to run to a “building.” The Code does not define the word *premises*, but a typical dictionary definition is “a tract of land, including its buildings” ([Fig. 230-51](#)).

TRANSFORMER NOT IN BLDG. SERVED

TRANSFORMER IN BLDG. SERVED

Conditions where SECONDARY conductors may be considered service conductor to a building when transformers are located within the building

Fig. 230-51. Where the transformer belongs to the utility, the “service point” is on its secondary and the secondary conductors are the service conductors to the building or structure. (Sec. 230.202 and Art. 100.)

2. “Service equipment” *usually* consists of “a circuit breaker or switch and fuses, and their accessories, located near the point of entrance of *supply* conductors to a building or other structure, or an otherwise defined area.” Note that the service equipment is the means of cutoff of the supply, and the service conductors may enter “a building” or “other structure” or a “defined area.” But, again, a service does not necessarily have to be to “a building.” It could be to such a “structure” as an outdoor switchgear or unit substation enclosure.

The wording in Art. 100 bases identification of “service conductors” as extending from the “service point.” Because of the definition of “service point,” it is essential to determine whether the transformers belong to the power company or the property owner.

If a utility-owned transformer that handles the electrical load for a building is in a locked room or locked enclosure (accessible only to qualified persons) in the building and is fed, say, by an underground medium-voltage (over 1000 V) utility line from outdoors, the secondary conductors from the transformer would be the “service conductors” to the building. *And* the switching and control devices (up to six CBs on fused switches) on the secondary would constitute the “service equipment” for the building. Under such a condition, if any of the secondary section “service disconnects” were

rated 1000 A or more, at 480/277-V grounded wye, they would have to comply with 230.95, requiring GFP for the service disconnects.

However, if the utility made primary feed to a transformer or unit substation belonging to the owner, then the primary conductors would be the service conductors and the primary switch or CB would be the “service disconnect.” In that case, no GFPE would be needed on the “service disconnect” because 230.95 applies only up to 1000 V, and there is no requirement for GFPE on medium-voltage services (Fig. 230-52). But in that case, there would be a need for GFPE on the secondary section disconnects, even though they would not be “service disconnects”—and those are the same disconnects that might be subject to 230.95 if the transformer belonged to the utility. However, 215.10 or 240.13 may require such protection for these secondary section disconnects. (See also Fig. 230-53.)

Fig. 230-52. The primary is the “service” for any indoor transformer belonging to the owner and fed by utility line. (Sec. 230.200.)

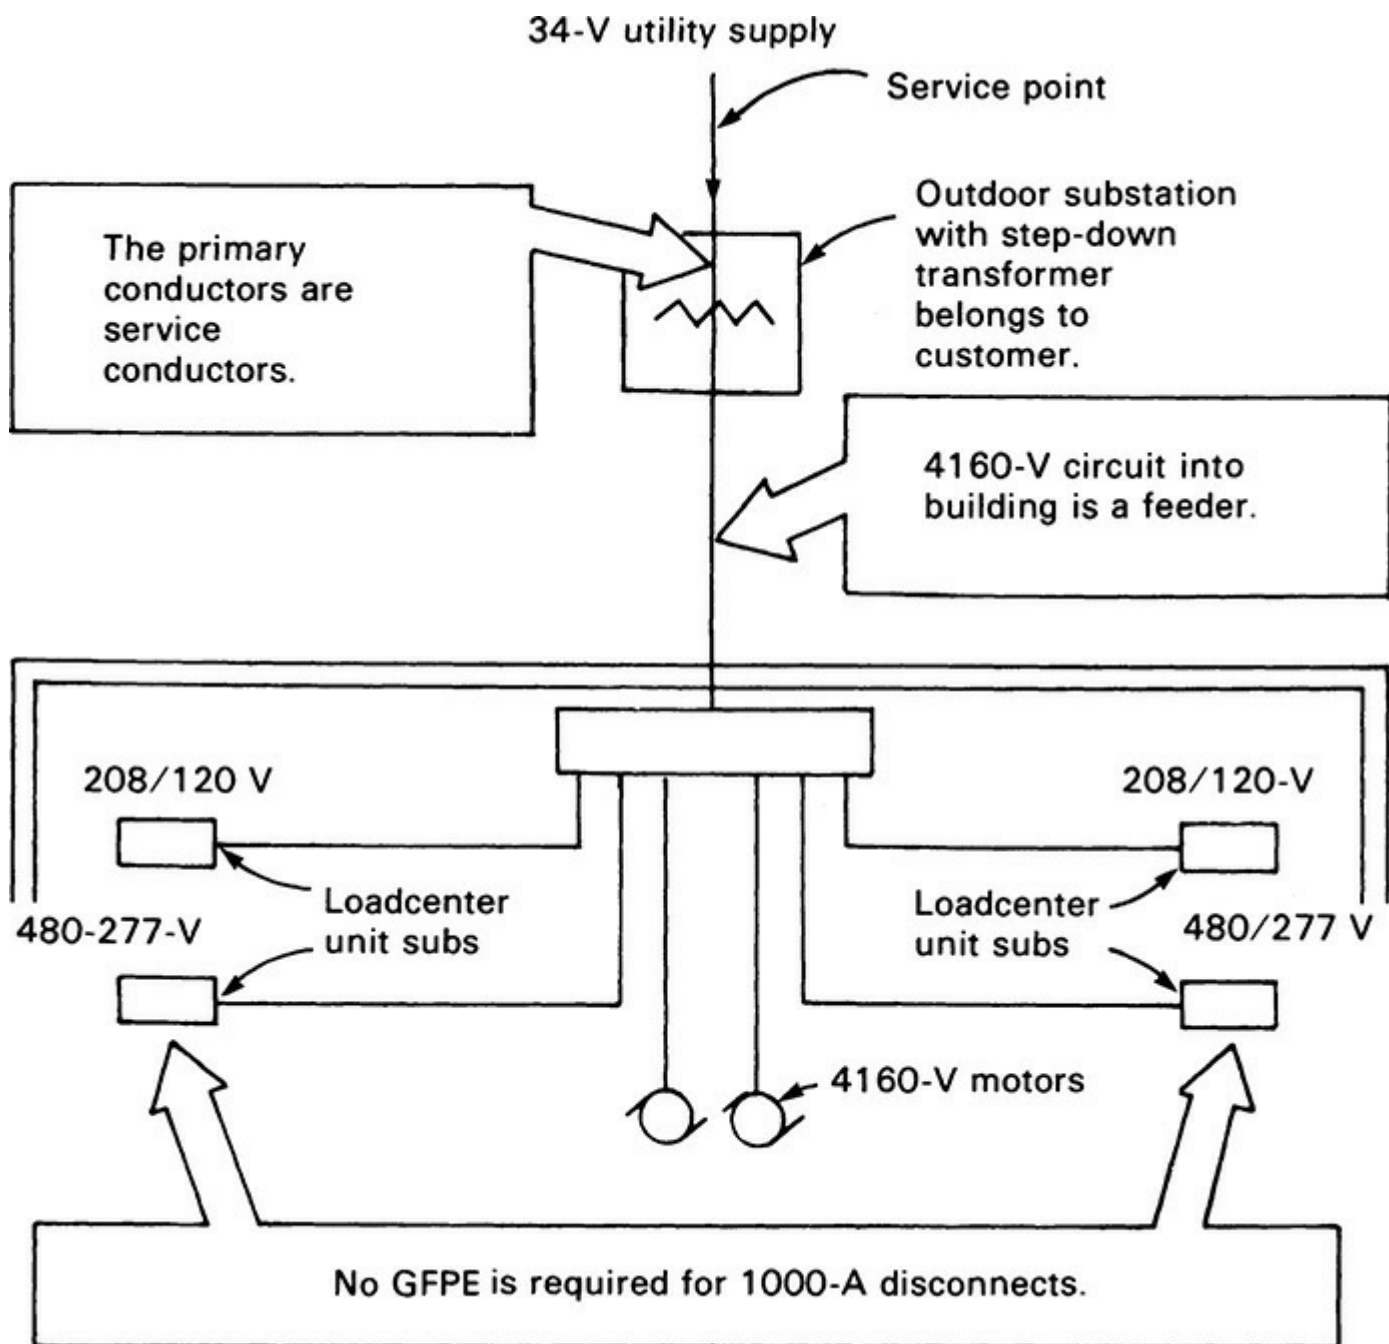

Fig. 230-53. The primary circuit must be taken as the “service conductors” where the “service point” is on the primary side of an outdoor transformer. Although GFPE is not required by 230.95 for the 480Y/277-V disconnects shown, it still is required because 215.10 applies instead.

230.202. Service-Entrance Conductors. This section specifies the minimum conductor size, that is, No. 6 in a raceway and No. 8 in a multiconductor cable. In addition, it indicates that only those wiring methods given in Secs. 300.37 (aboveground) and 300.50 (underground) may be used. That section gives the wiring methods that are acceptable for use as service-entrance conductors where it has been established that primary conductors (over 1000 V) are the service conductors or where the secondary conductors are the service conductors and operate at more than 1000 V. The basic conduits that may be used are rigid metal conduit, intermediate metal conduit, RTRC and PVC nonmetallic conduits, and electrical metallic tubing. In addition, cable tray, cable bus, or “other identified” raceways or even type MC may be used. Note, too, that bare conductors, bare bus-work, or open runs of type MV are permitted as indicated. And the **NEC** no longer requires concrete encasement of the nonmetallic conduit.

Section 300.37 points out that *cable tray* systems are also acceptable for high-voltage services. However, any such application for service work would still require application of the cable tray rules in 230.44 regarding segregation and marking if used for dual voltages. Medium-voltage (over 1000 V) service-entrance cables may be used if they meet the requirements for the cables in Art. 426 and the rules for cable trays with medium-voltage wiring in Art. 392. Details of this section are shown in [Fig. 230-54](#).

300.37 HIGH-VOLTAGE SERVICE CONDUCTORS FOR LOCATIONS ACCESSIBLE TO OTHER THAN QUALIFIED PERSONS

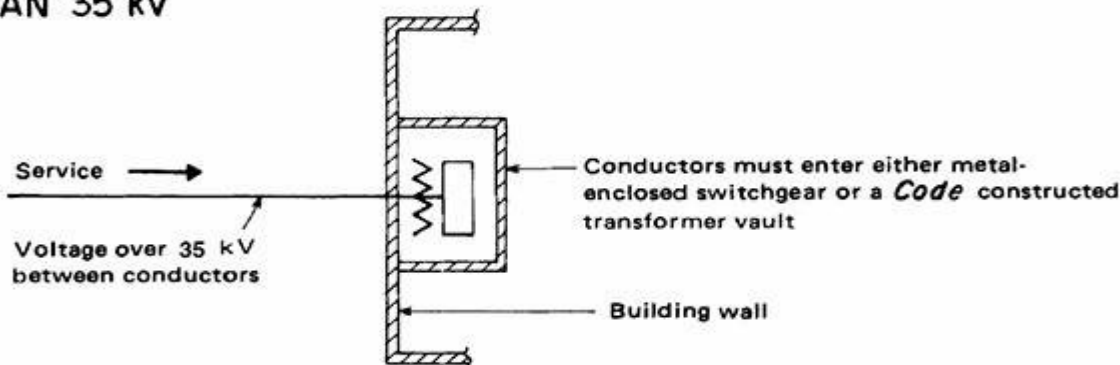

Note: Underground runs may be in conduit or duct or approved cable assemblies and must conform to 300.50

230.212 SERVICE CONDUCTORS OPERATING AT MORE THAN 35 kV

300.42 POTHEAD ON SERVICE CONDUCTORS

REMEMBER, 230.6 ALSO APPLIES TO HIGH-VOLTAGE CONDUCTORS (OVER 600 V NOMINAL) AS GIVEN IN 230.200, THEREFORE CONDUCTORS ENCLOSED IN MASONRY ARE CONSIDERED AS INSTALLED OUTSIDE THE BUILDING

Concrete or brick at least 2 in. thick all around conduit or duct

Fig. 230-54. Provisions for service conductors rated over 1000 V (refer to subpart letter identification of rules). (Sec. 230.202.)

230.204. Isolating Switches. An air-break isolating switch capable of visible verification of the blade position must be used ahead of an oil switch or an air, oil, vacuum, or sulfur hexafluoride CB used as a service disconnecting means, unless removable truck panels or metal-enclosed units are used providing disconnection of all live parts in the removed position. In addition, such removable equipment must not be openable unless the circuit is disconnected. This line-side disconnect ensures safety to personnel in maintenance (Fig. 230-55). Part (D) requires a grounding connection for an isolating switch, as in Fig. 230-56.

Fig. 230-55. Isolating switch may be needed to kill line terminals of service disconnect. (Sec. 230.204.)

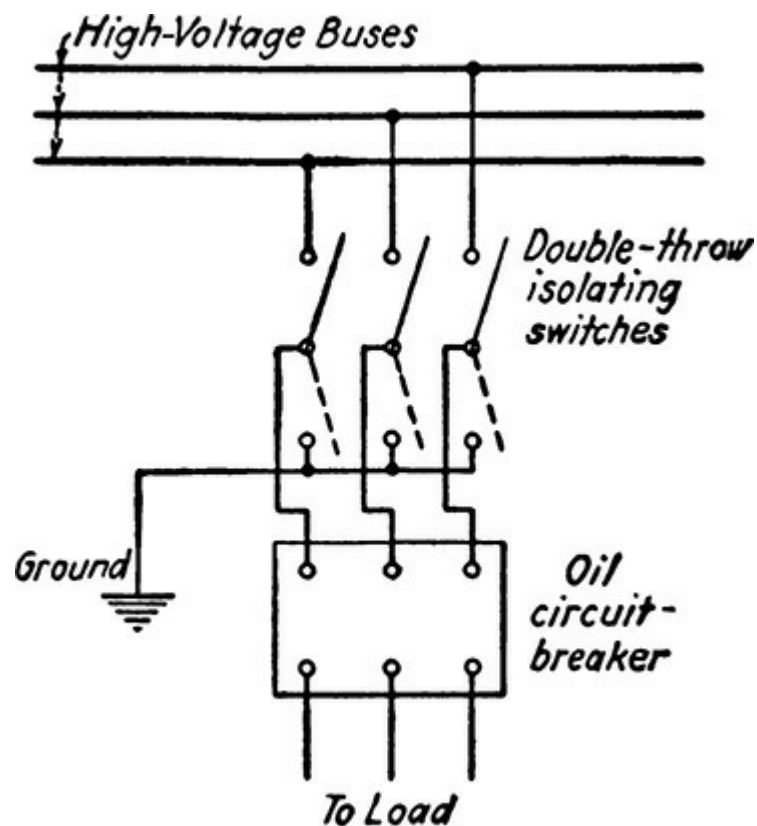

Fig. 230-56. One method for grounding the load side of an open isolating switch. (Sec. 230.204.)

230.205. Disconnecting Means. In part (A), the basic rule requires a high-voltage service disconnecting means to be located “outside and within sight of, or inside nearest the point of entrance of, the service conductors” into the building or structure being supplied—as for 1000-V equipment in 230.70. A new provision in 2008 allows this disconnecting means to be located where it is not readily accessible if part of an “overhead or underground primary distribution system.” The intent was to recognize the customary load break switches at the top of utility poles. Now it is true that the switch mechanism itself is not readily accessible. However, it is operable through a mechanical linkage at the pole base, and although mechanical, this meets all the provisions of 230.205(C) in that the switch is at a separate structure and operated remotely.

The real problem with this wording under the 2008 **NEC**, however, was that it avoided compliance with the rest of 230.205(C), which is that any such remote disconnecting provision be located in a readily accessible location. In effect, however unconscionable, it could have been considered acceptable to install a pole-top switch with no linkage to the pole base, thereby relying on personnel working with a hot stick out of a bucket truck to open the switch. This has all been corrected as of the 2011 edition. The operating handle must be readily accessible, or electronic control per 230.205(C) is another option.

Part (B), covering the electrical fault characteristics, requires that the service disconnect be *capable of closing*, safely and effectively, on a fault equal to or greater than the maximum short-circuit current that is available at the line terminals of the disconnect. The last sentence notes that where fuses are used within the disconnect or in conjunction with it, the fuse characteristics may contribute to fault-closing rating of the disconnect. This provision recognizes that some medium-voltage fuses have current-limiting characteristics, and that having them in place will make it possible to close the switch safely. This might be seen as a modification of 110.9, which normally requires equipment that will interrupt circuits under fault conditions to be rated for the available fault current

as their supply terminals. In this case, however, there is a distinction drawn between a fault clearing rating, which the fuse will have and is normally quite high, and covered in 230.208, and a fault closing rating, to which the fuse may safely contribute.

230.208. Protection Requirements. Service conductors operating at voltages over 1000 V must have a short-circuit (not overload) device in each ungrounded conductor, installed either (1) on load side of service disconnect, or (2) as an integral part of the service disconnect.

All devices must be able to detect and interrupt all values of current in excess of their rating or trip setting, which must be as shown in Fig. 230-57.

FUSED LOAD INTERRUPTER SWITCH

AIR, OIL, OR VACUUM CB

TYPES OF DEVICES PERMITTED

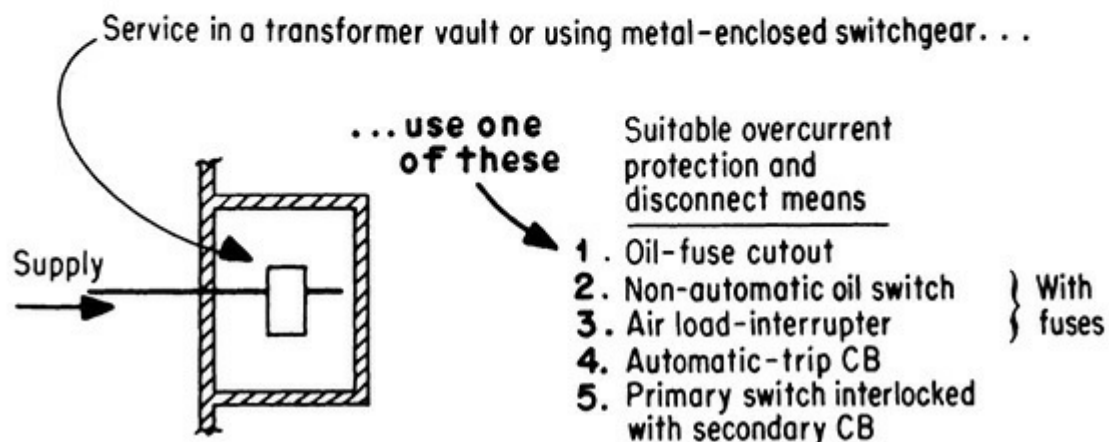

Fig. 230-57. Maximum permitted rating or setting of high-voltage overcurrent protection for service. (Sec. 230.208.)

The difference between 300 percent for fuses and 600 percent for CBs is explained as follows:

The American National Standards Institute (ANSI) publishes standards for power fuses. The continuous-current ratings of power fuses are given with the letter “E” following the number of continuous amps—for instance, 65E or 200E or 400E. The letter “E” indicates that the fuse has a melting time-current characteristic in accordance with the standard for E-rated fuses:

The melting time–current characteristics of fuse units, refill units, and links for power fuses shall be as follows:

- (1) The current-responsive element with ratings 100 amperes or below shall melt in 300 seconds at an rms current within the range of 200 or 240 percent of the continuous current rating of the fuse unit, refill unit, or fuse link.
- (2) The current-responsive element with ratings above 100 amperes shall melt in 600 seconds at an rms current within the range of 220–264 percent of the continuous current rating of the fuse unit, refill unit, or fuse link.
- (3) The melting time–current characteristic of a power fuse at any current higher than the 200 to 240 or 264 percent specified in (1) or (2) above shall be shown by each manufacturer’s published time current curves, since the current-responsive element is a distinctive feature of each manufacturer.
- (4) For any given melting time, the maximum steady-state rms current shall not exceed the minimum by more than 20 percent.

The fact that E-rated fuses are given melting times at 200 percent or more of their continuous-current rating explains why **NEC** 230.208 and 240.100 set 300 percent of conductor ampacity as the maximum fuse rating but permit CBs up to 600 percent. In effect, the 300 percent for fuses times 2 (200 percent) becomes 600 percent—the same as for CBs.

Part **(B)** of this section permits overcurrent protection for services over 1000 V to be loaded up to 100 percent of its rating even on continuous loads (operating for periods of 3 h or more). The greater spacings in medium-voltage equipment permit this latitude safely; see also 110.40 for allowances to use 90°C ratings on medium-voltage terminations for the same reason.

ARTICLE 240. OVERCURRENT PROTECTION

240.1. Scope. For any electrical system, required current-carrying capacities are determined for the various circuits—feeders, subfeeders, and branch circuits. Then these required capacities are converted into standard circuit conductors that have sufficient current-carrying capacities based on the size of the conductors, the type of insulation on the conductors, the ambient temperature at the place of installation, the number of conductors in each conduit, the type and continuity of load, and judicious determination of spare capacity to meet future load growth. Or if busway, armored cable, or other cable assemblies are to be used, similar considerations go into selection of conductors with required current-carrying capacities. In any case, the next step is to provide overcurrent protection for each and every circuit.

The overcurrent device for conductors or equipment must automatically open the circuit it protects if the current flowing in that circuit reaches a value that will cause an excessive or dangerous temperature in the conductor or conductor installation.

Overcurrent protection for conductors must also be rated for safe operation at the level of fault current obtainable at the point of their application. Every fuse and circuit breaker for short-circuit protection must be applied in such a way that the fault current produced by a bolted short circuit on its lead terminals will not damage or destroy the device. Specifically, this requires that a short-circuit overcurrent device have a proven interrupting capacity at least equal to the current that the electrical system can deliver into a short on its line terminals. That is, the calculation for the short-circuit interrupting rating must *not* include the impedance of the device itself. That impedance may only be applied to the calculation for the next device downstream.

But safe application of a protective device does not stop with adequate interrupting capacity for its own use at the point of installation in the system. The speed of operation of the device must then be analyzed in relation to the thermal and magnetic energy which the device permits to flow in the faulted circuit. A very important consideration is the provision of conductor size to meet the potential heating load of short-circuit currents in cables. With expanded use of circuit-breaker overcurrent protection, coordination of protection from loads back to the source has introduced time delays in operation of overcurrent devices. Cables in such systems must be able to withstand any impressed short-circuit currents for the durations of overcurrent delay. For example, a motor circuit to a 100-hp motor might be required to carry as much as 15,000 A for a number of seconds. To limit damage to the cable due to heating effect, a much larger size conductor than necessary for the load current alone may be required.

A device may be able to break a given short-circuit current without damaging itself in the operation; but in the time it takes to open the faulted circuit, enough energy may get through to damage or destroy other equipment in series with the fault. This other equipment might be a cable or busway or a switch or motor controller—any circuit component which simply cannot withstand the few cycles of short-circuit current that flows in the period of time between initiation of the fault and interruption of the current flow.

The informational note following Sec. 240.1 often raises questions about the approved use of conductors and overcurrent protection to withstand faults.

example Assume a panelboard with 20-A breakers rated 10,000 AIR (ampere interrupting rating) and No. 12 copper branch-circuit wiring. Available fault current at the point of breaker application is 8000 A. The short-circuit withstand capability of a No. 12 copper conductor with plastic or polyethylene insulation rated 60°C would be approximately 3000 A of fault or short-circuit current for one cycle.

question: Assuming that the CB (circuit breaker) will take at least one cycle to operate, would use of the conductor where exposed to 8000 A violate Sec. 110.9 or 110.10? These sections state that overcurrent protection for conductors and equipment is provided for the purpose of opening the electrical circuit if the current reaches a value that will cause an excessive or dangerous temperature in the conductor or conductor insulation. The 8000-A available fault current would seem to call for use of conductors with that rating of short-circuit withstand. This could mean that branch-circuit wiring from all 20-A CBs in this panelboard must be *No. 6 copper* (the next larger size suitable for an 8000-A fault current).

answer: As noted in UL Standard 489, a CB is required to operate safely in a circuit where the available fault current is up to the short-circuit current value for which the breaker is rated. The CB must clear the fault without damage to the insulation of conductors of proper size for the rating of the CB. A UL-listed, 20-A breaker is, therefore, tested and rated to be used with 20-A-rated wire (say, No. 12 THW) and will protect the wire in accordance with 240.4 when applied at a point in a circuit where the short-circuit current available does not exceed the value for which the breaker is rated. This is also true of a 15-A breaker on No. 14 (15-A) wire, for a 30-A breaker on No. 10 (30-A) wire, and all wire sizes.

UL 489 states:

A circuit breaker shall perform successfully when operated under conditions as described in paragraphs 21.2 and 21.3. There shall be no electrical or mechanical breakdown of the device, and the fuse that is indicated in paragraph 12.16 shall not have cleared. Cotton indicators as described in paragraphs 21.4 and 21.6 shall not be ignited. There shall be no damage to the insulation on conductors used to wire the device. After the final operation, the circuit breaker shall have continuity in the closed position at rated voltage.

240.2. Definitions. Here, the Code provides a number of additional definitions that apply to this article on overcurrent protection. These definitions must be considered when interpreting the requirements given in this Code article. They will be referred to in the context of subsequent discussion of the relevant topics.

240.3. Other Articles. Here, the Code reminds us that the rules given in Art. 240 are essentially general requirements for conductor protection. The individual articles for the equipment specifically indicated by this section have overcurrent protection requirements that are different from the “general rules” given in Art. 240 for protection of conductors and flexible cords. Where installing overcurrent protection for circuits for the equipment, and in the locations, identified here, the rules for overcurrent protection given in the indicated articles supersede the requirements given in Art. 240. In effect, compliance with those rules satisfies the rule of 240.3.

240.4. Protection of Conductors. Aside from flexible cords and fixture wires, conductors for all other circuits must conform to the rules of 240.4.

Clearly, the rule wants overcurrent devices to prevent conductors from being subjected to currents in excess of the ampacity values for which the conductors are rated by 310.15 and Tables 310.15(B)(16) through 310.15(B)(21).

The wording mentions 310.15, which includes Tables 310.15(B)(16) through 310.15(B)(21). That is important because it points out that when conductors have their ampacities derated because of conduit fill [310.15(B)(3)(a)] or because of elevated ambient temperature, the conductors must be protected at the *derated* ampacities and *not* at the values given in the tables.

As of the 2011 **NEC** there is a new informational note at this point referencing an ICEA paper (P-32-382-2007) providing information on allowable short-circuit currents for insulated conductors. The inclusion of this note was very controversial, with the NEMA, UL, and IAEI representatives all voting against its inclusion. The concerns in the voting involved lack of confidence in the validity of the data in the ICEA document relative to actual field conditions, and the fact that overcurrent devices are all tested with actual conductor samples attached to them; if the conductor is not protected under the worst-case fault condition for which the device is being rated, then the device fails the test. Finally, the note could be misapplied to require wire sizes above those given in Table 310.15(B)(16) although no substantiation was presented to invalidate the ampacity table, and Table 310.15(B)(16) is much easier to enforce than the calculations in the ICEA paper. Conductors do not have withstand ratings.

This information has been previously proposed on several occasions for general application in the **NEC**, including the 1987 cycle when it made it all the way through the normal process but was turned aside on the floor of the NFPA Annual Meeting. One reason was that the ICEA indicated that its paper was not appropriate for a reference in the **NEC**. A comparable effort on equipment grounding conductors failed in the 1996 **NEC** cycle. It does appear in Part **VIII** of Art. 240 (Supervised Industrial Installations), but this is a more appropriate context because it is not generally applicable and primarily addresses taps, which by definition have overcurrent protection that is either beyond the conductor rating or absent.

The basic rule of Sec. 240.4(A) represents a basic concept in Code application. When conductors supply a load to which loss of power would create a hazard, this rule states it is not necessary to provide “overload protection” for such conductors, *but* “short-circuit protection” *must* be provided. By “overload protection,” this means “protection at the conductors’ ampacity”—that is, protection that would prevent overload ([Fig. 240-1](#)).

Fig. 240-1. If “overload protection” creates a hazard, it *may* be eliminated. (Sec. 240.4.)

Several points should be noted about this rule.

1. This requirement is reserved only for applications where circuit opening on “overload” would be more objectionable than the overload itself, “such as in a material handling magnet circuit.” In that example mentioned in the rule, loss of power to such a magnet while it is lifting a heavy load of steel would cause the steel to fall and would certainly be a serious hazard to personnel working below or near the lifting magnet. To minimize the hazard created by such power loss, the circuit to it *need not* be protected at the conductor ampacity. A higher value of protection may be used—letting the circuit sustain an overload rather than opening on it and dropping the steel. Because such lifting operations are usually short-time, intermittent tasks, occasional overload is far less a safety concern than the dropping of the magnet’s load.
2. The rule to eliminate *only* “overload protection” is not limited to a lifting-magnet circuit, which is mentioned simply as an example. Other electrical applications that present a similar concern for “hazard” would be equally open to use of this rule. Fire pump circuits are required to implement this principle.
3. Although 240.4(A) *allows* elimination of overload protection and requires short-circuit protection, it gives no guidance on selecting the actual rating of protection that must be used. For such circuits, fuses or a CB rated, say, 200 to 400 percent of the full-load operating current would give freedom from overload opening. Of course, the protective device ought to be selected with as low a rating as would be compatible with the operating characteristics of the electrical load. And it must have sufficient interrupting capacity for the circuit’s available short-circuit current.
4. Finally, it should be noted that this is *not* a mandatory rule but a *permissible* application. It says “... overload protection *shall not be required* ...”; it does not say that overload protection “*shall not be used.*” Overload protection *may be used*, or it *may be eliminated*. Obviously, careful study should always go into application of this requirement.

Specifically, the general rule is that the device must be rated to protect conductors in accordance with their safe allowable current-carrying capacities. Of course, there will be cases where standard ampere ratings and settings of overcurrent devices will not correspond with conductor capacities. In such cases, part (B) permits the next larger standard size of overcurrent device to be used where the rating of the protective device is 800 A or less, unless the circuit in question is a multioutlet

receptacle circuit for cord- and plug-connected portable loads, in which case the next smaller standard size overcurrent device *must* be used. Therefore, a basic guide to effective selection of the amp rating of overcurrent devices for any feeder or service application is given in various subsections [(A) through (G)].

For example, if a circuit conductor of, say, 500-kcmil THW copper (not more than three in a conduit at not over 86°F [30°C] ambient) satisfies design requirements and **NEC** rules for a particular load current not in excess of the conductor's table ampacity of 380 A, then the conductor *may* be protected by a 400-A rated fuse or CB.

240.6, which gives the “Standard Ampere Ratings” of protective devices to correspond to the word “standard” in part (B), shows devices rated at 350 and 400 A, but none at 380 A. In such a case, the **NEC** accepts a 400-A-rated device as “the next higher standard device rating” above the conductor ampacity of 380 A.

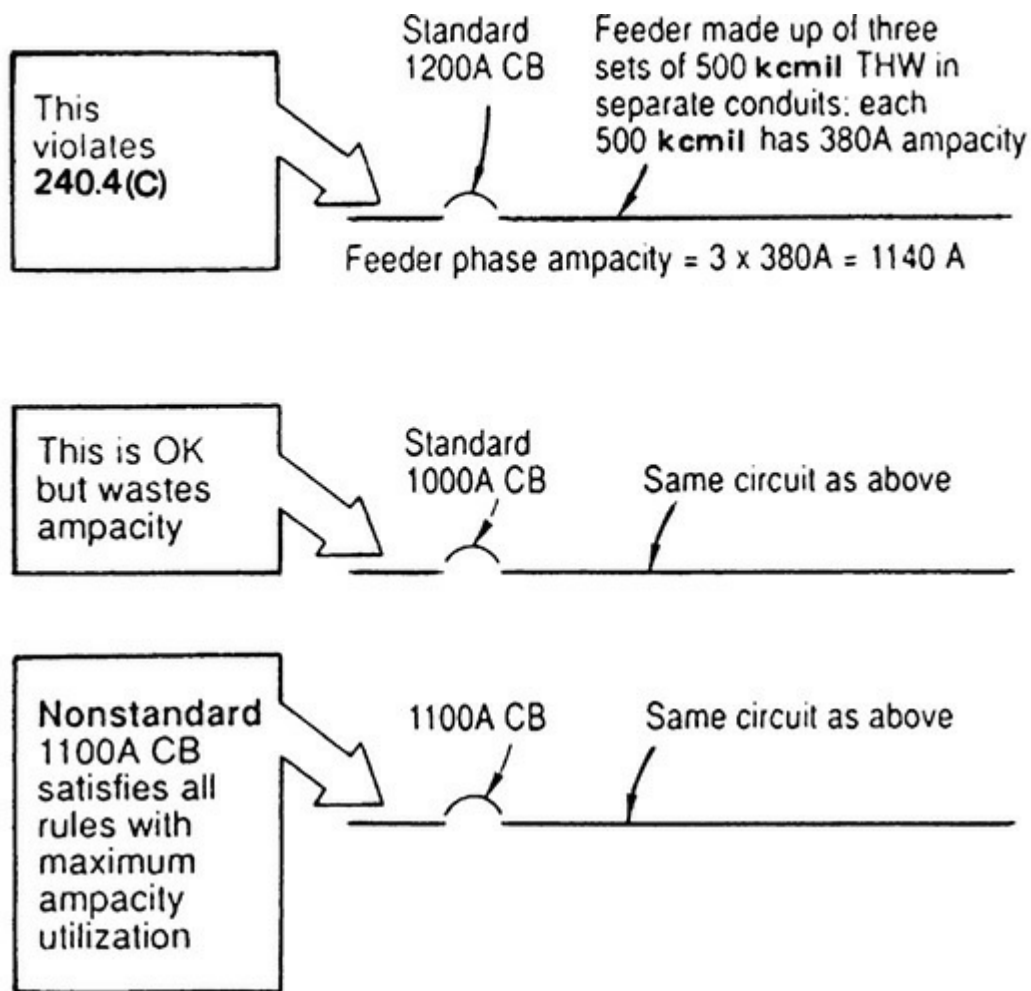

But, such a 400-A device would permit load increase above the 380 A that is the safe maximum limit for the conductor. Better conductor protection could be achieved by using a 350-A-rated device, which will prevent such overload.

For application of fuses and CBs, parts (B) and (C) have this effect:

1. If the ampacity of a conductor does not correspond to the rating of a standard-size fuse, the next *larger* rating of fuse may be used only where that rating is 800 A or less. Over 800 A, the next *smaller* fuse must be used, as covered in part (C). For any circuit over 800 A, 240.4(C) prohibits the use of “the next higher standard” rating of protective device (fuse or CB) when the ampacity of the circuit conductors does not correspond with a standard ampere rating of fuse or CB. The rating of the protection may not exceed the conductor ampacity. Although it would be acceptable to use a protective device of the next lower standard rating (from 240.6) below the conductor ampacity, there are many times when greater use of the conductor ampacity may be made by using a fuse or CB of rating lower than the conductor ampacity but not as low as the next lower standard rating. Listed fuses and CBs are made with ratings between the standard values shown in 240.6.

For example, if the ampacity of conductors for a feeder circuit is calculated to be 1540 A, 240.4(C) does not permit protecting such a conductor by using the next higher standard rating above 1540–1600 A. The next lower standard rating of fuse or CB shown in 240.6 is 1200 A. Such protection could be used, but that would sacrifice 340 A (1540 - 1200) of conductor ampacity. Because listed 1500-A protective devices are available and would provide for effective use of almost all the conductor's 1540-A capacity, this rule specifically recognizes such an application as safe and sound practice. Such application is specifically recognized by the second sentence of 240.6.

In general, 240.6 is not intended to require that all fuses or CBs be of the standard ratings shown. Intermediate values of protective device ratings may be used, provided all Code rules on protection—especially, the basic first sentence of 240.4, which requires conductors to be protected at their ampacities—are satisfied (Fig. 240-2).

PROTECTING TWO SIZES OF CONDUCTORS [240.4]

Fig. 240-2. Protection in accordance with 240.4(C) may use standard or nonstandard rated fuses or circuit breakers. And, smaller conductors are considered protected as covered in 240.4(D). (Secs. 240.4 and 240.6.)

2. A nonadjustable-trip breaker (one without overload trip adjustment above its rating—although it may have adjustable short-circuit trip) must be rated in accordance with the current-carrying capacity of the conductors it protects—except that the next higher standard rating of CB may be used if the ampacity of the conductor does not correspond to a standard unit rating. In such a case, the next higher standard setting may be used only where the rating is 800 A or less. An example of such application is shown in Fig. 240-1, where a nonadjustable CB with a rating of

1200 A is used to protect the conductors of a feeder circuit, which are rated at 1140 A. As shown there, use of that size CB to protect a circuit rated at 1140 A ($3 \times 380 \text{ A} = 1140 \text{ A}$) clearly violates 240.4(C) because the CB is the next higher rating above the ampacity of the conductors—on a circuit rated over 800 A. With a feeder circuit as shown (three 500-kcmil THW, each rated at 380 A), the CB must *not* be rated over 1140 A. A standard 1000-A CB would satisfy the Code rule—being the *next lower* rated protective device from 240.6. Or a 1100-A fuse could be used. Of course, if 500-kcmil THHN or XHHW conductors are used instead of THW conductors, then each 500 is rated at 430 A, three per phase would give the circuit an ampacity of 1290 A (3×430), and the 1200-A CB would satisfy the basic rule in 240.4(C). *But*, given that 500-kcmil conductors would be operating at 90°C when carrying the 430 A of current, such conductors could never be loaded to that value as there is no equipment rated for use with conductors operating at 90°C. To satisfy the termination temperature limitations of 110.14(C), the load would be prohibited from exceeding the 75°C value, or $3 \times 380 \text{ A} = 1140 \text{ A}$. Alternatively, a circuit breaker listed for terminations operating at 90°C could be used. These are only available in very large frame sizes, such as those in this example.

It should be noted, however, that 240.4(B) requires that the rating of overcurrent protection must *never* exceed the ampacity of circuit conductors supplying one or more receptacle outlets on a branch circuit with more than one outlet. This wording in 240.4(B) coordinates with the rules described under 210.19(A)(2) on conductor ampacity. The effect of that rule is to require that the rating of the overcurrent protection must not exceed the Code-table ampacity [NEC Table 310.15(B)(16)] or the derated ampacity dictated by 310.15(B)(3)(a) for any conductor of a multioutlet branch circuit supplying any receptacles for cord-and-plug-connected portable loads. If a standard rating of fuse or CB does not match the ampacity (or derated ampacity) of such a circuit, the next lower standard rating of protective device must be used. *But*, where branch-circuit conductors of an individual circuit to a single load or a multioutlet circuit supply *only* fixed connected (hard-wired) loads—such as lighting outlets or permanently connected appliances—the next larger standard rating of protective device *may* be used in those cases where the ampacity (or derated ampacity) of the conductor does not correspond to a standard rating of protective device—but, again, that is permitted only up to 800 A, above which the next lower rating of fuse or CB must be used, as described under 210.19(A)(2).

The rules of 240.4 must also be correlated with the requirement for minimum conductor size where continuous loading or a combination of continuous and noncontinuous loading is supplied. Where such loads are supplied, 210.19(A), 210.20(A), 215.2(A), 215.3(A), and 230.42 require that additional capacity be provided where the branch-circuit, feeder, or service conductors and overcurrent devices supply continuous loads. After that minimum size has been established, the OCPD must be rated such that it either protects the conductors in accordance with their ampacity, or is the next larger rated overcurrent device—up to 800 A. Above 800 A, 240.4(C) would mandate use of the next smaller rated overcurrent device, which may not be adequately rated to supply the continuous load. Careful correlation of the rules here and in 210.19, 210.20, 215.2, 215.3, and 230.42 is especially important to ensure that the selected conductors and OC protection are properly rated.

At the end of this book, as part of the detailed coverage of ampacity calculations, all of these code requirements are integrated in one location. The coverage focuses on Annex D, Example D3(a), which is the new example devoted to ampacity calculations as distinguished from load calculations.

Part (D) of 240.4 covers a long-standing requirement for protection of the smaller sizes of conductors, that is, No. 14, No. 12, and No. 10. Although such conductors have greater ampacities, as

shown in Table 310.15(B)(16), this rule requires that the maximum rating of overcurrent protection be 15, 20, and 30 A, respectively. This limitation on the rating of overcurrent devices is related to the fact that listed overcurrent devices cannot protect against conductor damage under short-circuit testing where, say, a No. 12 copper THW conductor is protected by a 25-A CB. Although the No. 12 has an ampacity of 25 A and can carry that current when used under the conditions described in the heading of Table 310.15(B)(16), a 25-A CB will not operate fast enough to prevent the conductor from burning open during the short-circuit test. It was established that lower-rated breakers, such as a 20-A CB, can protect the No. 12 conductor from damage under short-circuit conditions. Because this is not a problem with CBs rated for protection of conductor sizes No. 8 and larger, only No. 14, No. 12, and No. 10, copper, as well as No. 12 and No. 10 aluminum and copper-clad aluminum conductors, are specially limited with regard to the maximum rating of their overcurrent protection, where they are required to be protected in accordance with their ampacity. The 2011 **NEC** changed the 60°C column ampacities for these conductors so they now agree with the limits in these paragraphs, and is true that 110.14(C)(1)(a) uses this temperature as the default termination temperature starting points for these wire sizes. However, the limitations here need to stay in place because other columns can be used in some cases, and unlike the ampacity tables, these limits do not vary with insulation temperature ratings.

In the 2008 **NEC**, this part of 240.4 was expanded to cover even smaller conductors (18 and 16 AWG) and the allowable overcurrent devices that can be used to protect them when they are not considered to be protected by ordinary branch-circuit protective devices due to special provisions in various Code rules. The principal application of these ampacities involves industrial machinery covered by *NFPA 79* where international competition dictates smaller wires for small motors that are components of complicated equipment. See 430.22(G).

240.4(G) gives a list of “specific conductor applications” that are exempt from the basic rules of 240.4. For example, this rule refers the matter of protecting motor-control circuits to Art. 430 on motors.

Table 240.4(G) also applies to the protection of the remote-control circuit that energizes the operating coil of a magnetic contactor, as distinguished from a magnetic motor starter ([Fig. 240-3](#)).

Fig. 240-3. Coil-circuit wires of magnetic contactor must be protected as required by 725.43. (Sec. 240.4.)

725.45(C) covers control wires for magnetic contactors used for control of lighting or heating loads, but not motor loads. 430.72 covers that requirement for motor-control circuits. In Fig. 240-4, the remote-control conductors may be considered properly protected by the branch-circuit overcurrent devices (A) if these devices are rated or set at not more than 300 percent of (3 times) the current rating of the control conductors. If the branch-circuit overcurrent devices were rated or set at more than 300 percent of the rating of the control conductors, the control conductors would have to be protected by a separate protective device located at the point (B) where the conductor to be protected receives its supply. [See 725.45(C).]

For instance, 30-amp fuses at A would be adequate protection if No. 14 wire, rated at 15 amps, is used for the remote-control circuit because 30 amps is less than 3 X 15 amps. If fuses at A were over 45 amps, then 15-amp protection would be required at B for No. 14 wire.

Fig. 240-4. Protecting a remote-control circuit in accordance with 725.43. (Sec. 240.4.)

240.4(F) permits the secondary circuit from a transformer to be protected by means of fuses or a CB in the primary circuit to the transformer—if the transformer has no more than a 2-wire primary circuit *and* a 2-wire secondary circuit. As shown in Fig. 240-5, by using the 2-to-1 primary-to-secondary turns ratio of the transformer, 20-A primary protection will protect against any secondary current in excess of 40 A—thereby protecting, say, secondary No. 8 TW wires rated at 40 A. As the wording of the rule states, the protection on the primary (20 A) must not exceed the value of the secondary conductor ampacity (40 A) multiplied by the secondary-to-primary transformer voltage ratio ($120 \div 240 = 0.5$). Thus, $40 \text{ A} \times 0.5 = 20 \text{ A}$. But it should be carefully noted that the rating of the primary protection must comply with the rules of 450.3(B).

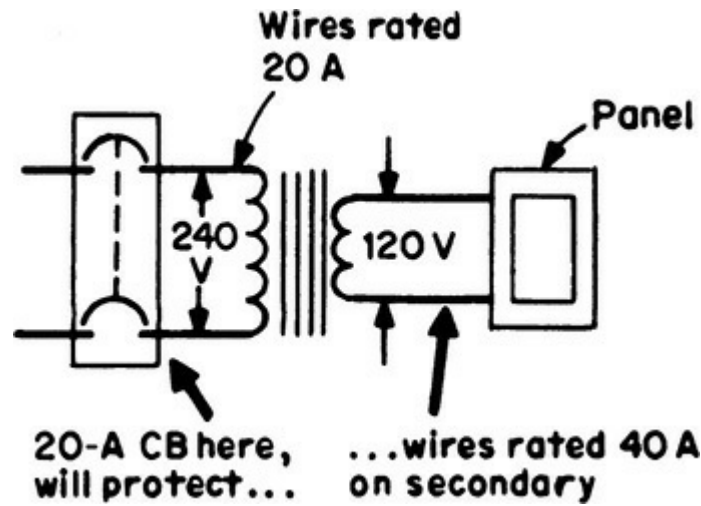

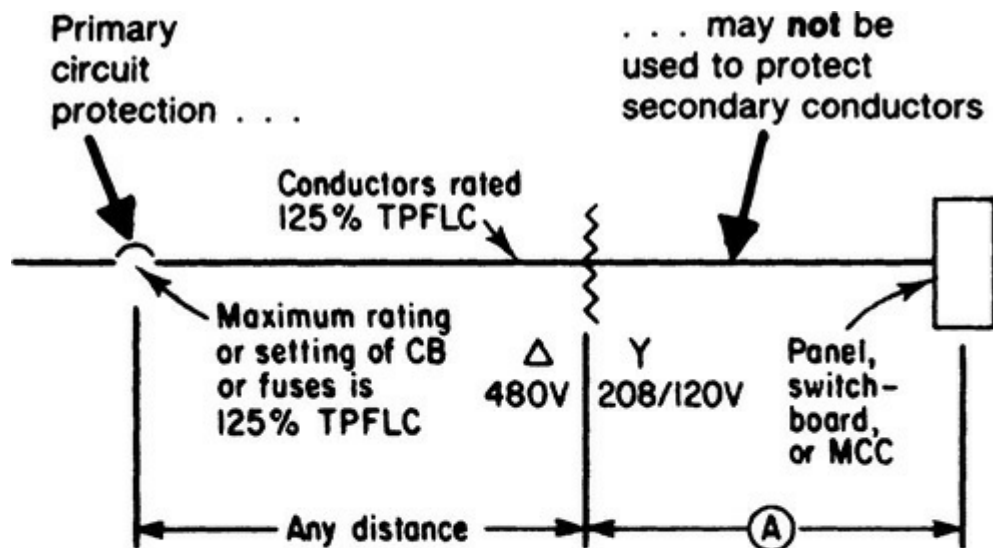

Fig. 240-5. Primary fuses or CB may protect secondary circuit for 2-wire to 2-wire transformer. (Sec. 240.4.)

The rule of part (F) also recognizes protection of the secondary conductors by the primary OCPD for delta-delta-wound transformers. This permission recognizes that the “per-unit” current value on the secondary side will be equal to or less than the per-unit current value on the primary conductors. And, because a directly proportional current will be carried by both conductors, the overcurrent device on the primary side can protect both sets of conductors, the primary and secondary. For 3- and 4-wire delta-wye-wound transformers, separate overcurrent protection is required for the primary conductors and secondary conductors.

To put this another way, no conductors connected to a dual-voltage transformer secondary can be protected on the primary side by relying on a turns ratio. Consider a 480-V to 120/240-V transformer of the type commonly used to create separately derived single-phase systems for local lighting and receptacles. Suppose the panel on the secondary side is rated 100 A, the secondary conductors are 3 AWG, and the primary-side circuit breaker is rated 50 A. The winding ratio from 480 to 240 V is 2:1, so the maximum current that could flow over the secondary conductors is 100 A, right?

Wrong. If the load in the panel is perfectly balanced, then when the load on the panel exceeds 100 A, the primary side protection will open, true enough. But now suppose the panel load is not balanced. In fact, suppose the worst case happens, and 100 percent of the line-to-neutral load is on only one of the line legs. Now the transformer is, in effect, operating as a 4:1 (480:120 V) transformer. At this point, 100 A of load on the secondary, at 120 V, will cause only 25 A of current to flow in the primary. The transformer will be quite happy, and the primary side protection will be nowhere close to opening. Meanwhile, up to 200 percent of rated current (in this case 200 A) could be drawn on the secondary side before the primary side would open. The so-called protection on the primary side does protect the transformer, but it is absolutely useless in terms of reliably protecting the conductors and other equipment on the secondary side. 725.45(D) clearly makes this point regarding Class 1 control circuit conductors, and 240.21(C)(1) reiterates the point made here in 240.4(F) for power circuits. [Figure 240-6](#) previews the rules in 240.21(C) and [Fig. 240-7](#) gives another example of the problems with potential imbalances on a multiwire transformer secondary.

Distance "A" from transformer to first protection on the secondary side is limited to 10 or 25 ft, subject to the requirements of part (C) of 240.21. If overcurrent protection is placed at the transformer secondary connection to protect secondary conductors, the circuit can run any distance to the panel.

Fig. 240-6. Part (C) clearly resolves long-standing controversy. (Sec. 240.4.)

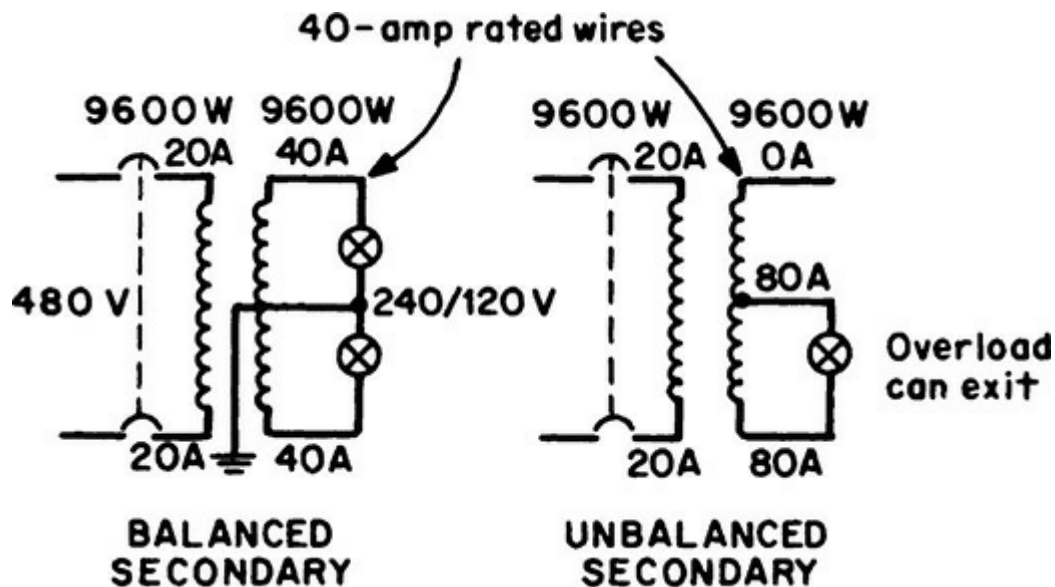

Fig. 240-7. Why primary protection may not do the job for 3-wire or 4-wire secondary 40-A-rated wires. (Sec. 240.4.)

240.5. Protection of Flexible Cords, Flexible Cables, and Fixture Wires. The basic rules of part (A) are that

1. All flexible cords and extension cords must be protected at the ampacity given for each size and type of cord or cable in **NEC** Tables 400.5(A)(1) and 400.5(A)(2). "Flexible cords" includes "insel cord"—No. 27 AWG wires in a cord that is attached directly or by a special plug to a portable appliance rated not over 50 W.
2. All fixture wires must be protected in accordance with their ampacities, as given in Table

402.5.

3. The required protection may be provided by use of supplementary OCPD (usually fuses), instead of having branch-circuit protection rated at the low values involved.

Then, the basic rules are modified by the rules in parts **(B)(1)** and **(B)(2)** applying to each of the preceding rules:

Part **(B)(1)** applies only to a flexible cord or a tinsel cord (not an “extension cord”) that is “approved for and used with a specific *listed* (by UL or other recognized test lab) appliance or luminaire.” Such a cord, under the conditions stated, is not required to be protected at its ampacity from **NEC** Table 400.5. The 2008 **NEC** removed the qualifier “portable” as a descriptive term for the light, thereby removing a direct conflict with cord-supplied luminaires that rely on flexible cord dropping out of a canopy because the luminaire is supported with aircraft cable that can be adjusted in the field to change the mounting height. Such luminaires are not portable and they are necessarily connected with flexible cord, but they need not be provided with overcurrent protection.

Note that “extension cords” are *not* covered by part **(B)(1)** because they are *not* “approved for and used with a specific listed appliance.” They are covered in part **(B)(3)** and **(B)(4)**, depending on whether they are a listed extension cord set or field assembled. If they are listed, then there are no longer any prescriptive rules and they are only limited by the listing requirements. If they are field assembled from listed components, then they are only limited by the rules in 400.5, but only where constructed from 14 AWG and larger cord. If they employ 16 AWG cord they can be connected to up to a 20-A (and no larger) branch circuit, and if they are 18 AWG they revert to the default limits of 7 or 10 A (from Table 400.5). Refer to the bottom half of [Fig. 240-8](#). Some cords are now available with 18 AWG cord, but such cords have supplementary overcurrent protection in the form of fuses in their plugs, in deference to these rules and in accordance with the requirements of 240.4(D)(1).

Part **(B)(2)** gives the conditions under which fixture wire does not have to be protected at the ampacity value given in Table 402.5 for its particular size *if* the fixture wire is any one of the following:

- No. 18 wire, not over 15 m (50 ft) long, connected to a branch circuit rated not over 20 A
- No. 16 wire, not over 30 m (100 ft) long, connected to a branch circuit rated not over 20 A
- No. 14 or larger wire, of any length, connected to a branch circuit rated not over 30 A
- No. 12 or larger wire, of any length, connected to a branch circuit rated not over 50 A

From those rules, No. 16 or No. 18 fixture wire may be connected on any 20-A branch circuit, provided the “run length” (the length of any one of the wires used in the raceway) is not more than 15 m (50 ft)—such as for 450 mm to 1.8 m (1½ to 6-ft) fixture whips [410.117(C)], as illustrated in the top part of [Fig. 240-8](#). *But*, for remote-control circuits run in a raceway from a magnetic motor starter or contactor to a remote pushbutton station or other pilot-control device, 430.72(B) and 725.43 require that a No. 18 wire be protected at not over 7 A and a No. 16 wire at not over 10 A—where fixture wires are used for remote-control circuit wiring, as permitted by Sec. 725.49(A) and (B).

240.5 (B)(2)

Typical use of fixture wire:
4-to-6-ft length of flex for
fixture whip in ceiling, containing
two No. 18 Type FEP wires (for 6-A
fixture load, see Section 402-5)
or two No. 16 Type FEP wires (for
8-A fixture load). 240.5 permits
No. 16 and No. 18 fixture wire
to be protected at 20 A.

IMPORTANT!! Flex is equipment grounding conductor because FEP wires in flex are tapped from circuit protected at not over 20-A as permitted in 250.118(5).

240.5 (B)(3)

Listed extension cord sets
now protected per listing
instructions; no prescrip-
tive NEC OCPD rules.

Field assemblies require
fusing per 400.5 if 18 AWG
or if 16 AWG and used over
20A.

NOTE: Listed components required for field assembled
16 AWG extension cord sets in order to use the 20 ampere
circuit allowance.

Fig. 240-8. Separate rules cover fixture wires and extension cords. (Sec. 240.5.)

240.6. Standard Ampere Ratings. This is a listing of the “standard ampere ratings” of fuses and CBs for purposes of Code application, now presented in a tabular form. However, an important qualification is made by the second sentence of this section. Although this **NEC** section designates “STANDARD ampere ratings” for fuses and circuit breakers, UL-listed fuses and circuit breakers of other intermediate ratings are available and may be used if their ratings satisfy Code rules on protection. For instance, 240.6 shows standard rated fuses at 1200 A, then 1600 A. But if a circuit was found to have an ampacity of, say, 1530 A and, because 240.4(C) says such a circuit may not be protected by 1600-A fuses, it is not necessary to drop down to 1200-A fuses (the next lower standard size). This final sentence fully intends to recognize use of 1500-A fuses—which would satisfy the basic rule of 240.4(C) for protection rated over 800 A. (Fig. 240-1.)

The last sentence in part (A) of 240.6 designates specific “additional standard ratings” of *fuses* at 1, 3, 6, 10, and 601 A. These values apply *only* to fuses and *not* to CBs. The 601-A rating gives Code recognition to use of Class L fuses rated less than 700 A. The reasoning of the Code panel was:

An examination of fuse manufacturers’ catalogs will show that 601 amperes is a commonly listed current rating for the Class L nontime-delay fuse. Section [430.52(C)(1) (Exception No. 2d)] also lists this current rating as a break point in application rules.

Without a 601 ampere rating, the smallest standard fuse which can be used in Class L fuse clips is rated 700 amperes. Since the intent of Table 430.152 and 430.52 is to encourage closer short-circuit protection, it seems prudent to encourage availability and use of 601-ampere fuses in combination motor controllers having Class L fuse clips.

Because ratings of inverse time circuit breakers are not related to fuse clip size, a distinction between 600 and 601 amperes in circuit breakers would serve no useful purpose. Hence, inverse-time circuit breaker ratings are listed separately. Such separation also facilitates recognition of other fuse ratings as standard.

The smaller sizes of fuses (1, 3, 6, and 10 A) listed as “standard ratings” provide more effective short-circuit and ground-fault protection for motor circuits—in accordance with 430.52, 430.40, and UL requirements for protecting the overload relays in controllers for very small motors. The Code panel reasoning was as follows:

Fuses rated less than 15 amperes are often required to provide short circuit and ground-fault protection for motor branch circuits in accordance with 430.52.

Tests indicate that fuses rated 1, 3, 6 and 10 amperes can provide the intended protection in motor branch circuits for motors having full load currents less than 3.75 amperes ($3.75 \times 400\% = 15$). These ratings are also those most commonly shown on control manufacturers’ overload relay tables. Overload relay elements for very small full load motor currents have such a high resistance that a bolted fault at the controller load terminals produces a short-circuit current of less than 15 amperes, regardless of the available current at the line terminals. An overcurrent protective device rated or set for 15 amperes is unable to offer the short circuit or ground fault protection required by 110.10 in such circuits.

An examination of fuse manufacturers’ catalogs will show that fuses with these ratings are commercially available. Having these ampere ratings established as standard should improve product availability at the user level and result in better overcurrent protection.

Since inverse time circuit breakers are not readily available in the sizes added, it seems appropriate to list them separately.

Listing of those smaller fuse ratings has a significant effect on use of several small motors (fractional and small-integral-horsepower sizes) on a single branch circuit as described under 430.53(B).

240.6(B) states that if a circuit breaker has external means for changing its continuous-current rating (the value of current above which the inverse-time overload—or longtime delay—trip mechanism would be activated), the breaker must be considered to be a protective device of the maximum continuous current (or overload trip rating) for which it might be set. This type of CB

adjustment is available on molded-case, insulated-case, and air power circuit breakers. As a result of that rule and 240.4, the circuit conductors connected to the load terminals of such a circuit breaker must be of sufficient ampacity as to be properly protected by the maximum current value to which the adjustable trip might be set. That means that the CB rating must not exceed the ampacity of the circuit conductors, except that where the ampacity of the conductor does not correspond to a standard rating of CB, the next higher standard rating of CB may be used, up to 800 A (Fig. 240-9).

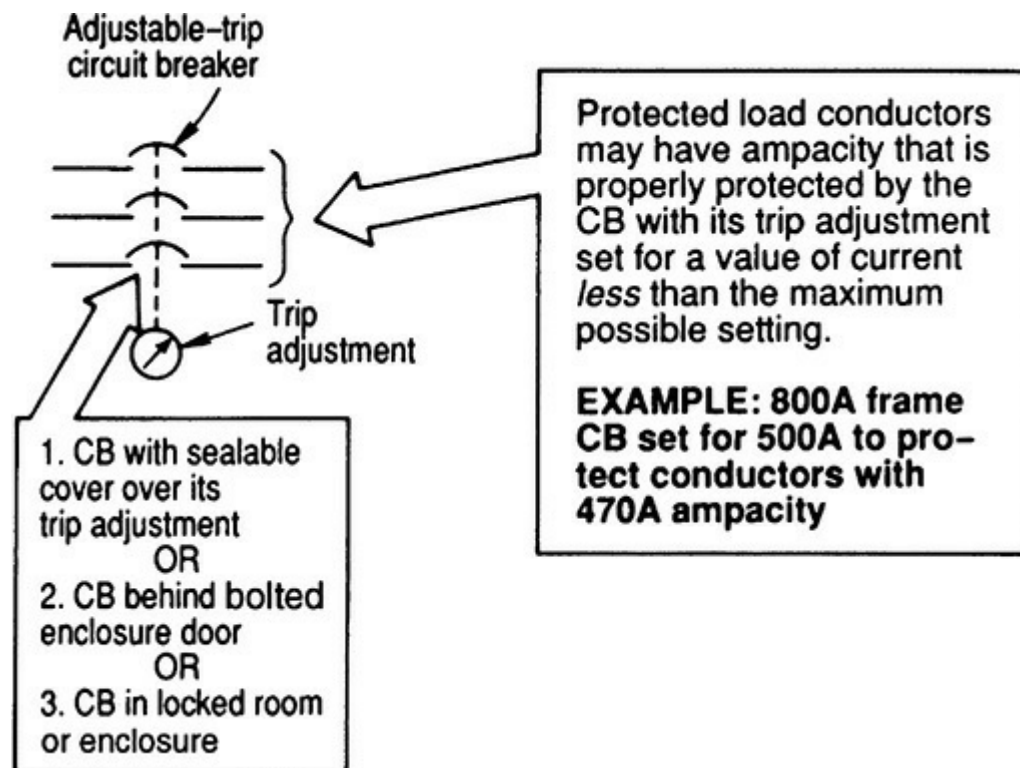

Fig. 240-9. An adjustable-trip circuit breaker that has access to its trip adjustment limited only to qualified persons may be taken to have a rating less than the maximum value to which the continuous rating (the longtime or overload adjustment) might be set. (Sec. 240.6.)

Prior to the 1987 edition, the **NEC** did not require that a circuit breaker with adjustable or changeable trip rating must have load-circuit conductors of an ampacity at least equal to the highest trip rating at which the breaker might be used. Conductors of an ampacity less than the highest possible trip rating could be used, provided that the actual trip setting being used did protect the conductor in accordance with its ampacity, as required in **NEC** 240.4. Since the 1990 edition, such application may be made only in accordance with the rule in part (C), which says that an adjustable-trip circuit breaker may be used as a protective device of a rating lower than its maximum setting and used to protect conductors of a corresponding ampacity in accordance with 240.4(B) *if* the trip-adjustment is

1. Located behind a removable and sealable cover, or
2. Part of a circuit breaker which is itself located behind bolted equipment enclosure doors accessible only to qualified persons, or
3. Part of a circuit breaker that is locked behind doors (such as in a room) accessible only to qualified persons

Although this rule permits use of conductors with ampacity lower than the maximum possible trip setting of a CB under the conditions given, this does not apply to fusible switches, and it is never

necessary for a fusible switch to have its connected load-circuit conductors of ampacity equal to the maximum rating of a fuse that might be installed in the switch—provided that the actual rating of the fuse used in the switch does protect the conductor at its ampacity.

240.8. Fuses or Circuit Breakers in Parallel. This rule allows fuses or CBs in parallel where “factory assembled” and “listed as a unit.” Such units are used to increase the rating of overcurrent protection in marine, over-the-road, off-road, commercial, and industrial installations. Use of other than listed units, including any composed of field assembled devices, is a clear and direct violation.

240.10. Supplementary Overcurrent Protection. Supplementary overcurrent protection is commonly used in lighting fixtures, heating circuits, appliances, or other utilization equipment to provide individual protection for specific components within the equipment itself. Such protection is not branch-circuit protection and *the NEC does not require supplemental overcurrent protective devices to be readily accessible*. Typical applications of supplemental overcurrent protection are fuses installed in fluorescent fixtures and cooking or heating equipment where the devices are sized to provide lower overcurrent protection than that of the branch circuit supplying such equipment. This is discussed under 424.19 and 424.22 on electric space-heating equipment.

Years ago there was no allowance for conventional OCPDs to be in locations that were not readily accessible, and so they were classified, essentially at the convenience of the engineer, as supplementary. One common example is the combination plug fuse and snap switch assemblies that come premounted in box covers or handy box covers, particularly where mounted in not-readily-accessible locations such as adjacent to ceiling-mounted equipment and/or fractional-horsepower motors. Since the plug fuse is actually rated for branch-circuit protection, this wasn't really correct until the rule in 240.24(A)(4) caught up with the very long-standing allowance in 404.8(A) Exception No. 2. Now that 240.24(A)(4) allows this openly (although only adjacent to the equipment supplied), the need to artificially classify branch-circuit rated protective devices as supplementary devices has largely gone away.

240.12. Electrical System Coordination. This rule applies to any electrical installation where hazard to personnel would result from disorderly shutdown of electrical equipment under fault conditions. The purpose of this rule is to permit elimination of “overload” protection—that is, protection of conductors at their ampacities—and to eliminate unknown or random relation between operating time of overcurrent devices connected in series.

The section recognizes two requirements, both of which must be fulfilled to perform the task of “orderly shutdown.”

One is selective coordination of the time-current characteristics of the short-circuit protective devices in series from the service to any load—so that, automatically, any fault will actuate only the short-circuit protective device closest to the fault on the line side of the fault, thereby minimizing the extent of electrical outage due to a fault.

The other technique that must also be included if *overload* protection is eliminated is “overload indication based on monitoring systems or devices.” A note to this section gives brief descriptions of both requirements and establishes only a generalized understanding of “overload indication.” Effective application of this rule depends on careful design and coordination with inspection authorities.

It should be noted, however, that it says that the technique of eliminating overload protection to afford orderly shutdown “shall be permitted”—but does *not require* such application. Although it

could be argued that the wording implies a mandatory rule, consultation with electrical inspection authorities on this matter is advisable because of the safety implications in nonorderly shutdown due to overload. Emergency systems (700.32), legally required standby systems (701.27), critical operations power systems (708.54), fire pump protective devices connected to campus-style multibuilding distributions [695.3(C)(3)], and main elevator feeders, and multiple elevator driving machines on a single feeder (620.62) now require selective coordination, a specifically defined term in Art. 100, within their scope.

240.13. Ground-Fault Protection of Equipment (GFPE). Equipment ground-fault protection—of the type required for 480Y/227-V service disconnects—is now required for each disconnect rated 1000 A or more that serves as a main disconnect for a building or structure. Like 215.10, this section expands the application of protection against destructive arcing burndowns of electrical equipment. The intent is to equip a main building disconnect with GFPE whether the disconnect is technically a service disconnect or a building disconnect on the load side of service equipment located elsewhere. This was specifically devised to cover those cases where a building or structure is supplied by a 480Y/277-V feeder from another building or from outdoor service equipment. Because the main disconnect (or disconnects) for such a building serves essentially the same function as a service disconnect, this requirement makes such disconnects subject to all of the rules of 230.95, covering GFPE for services (Fig. 240-10).

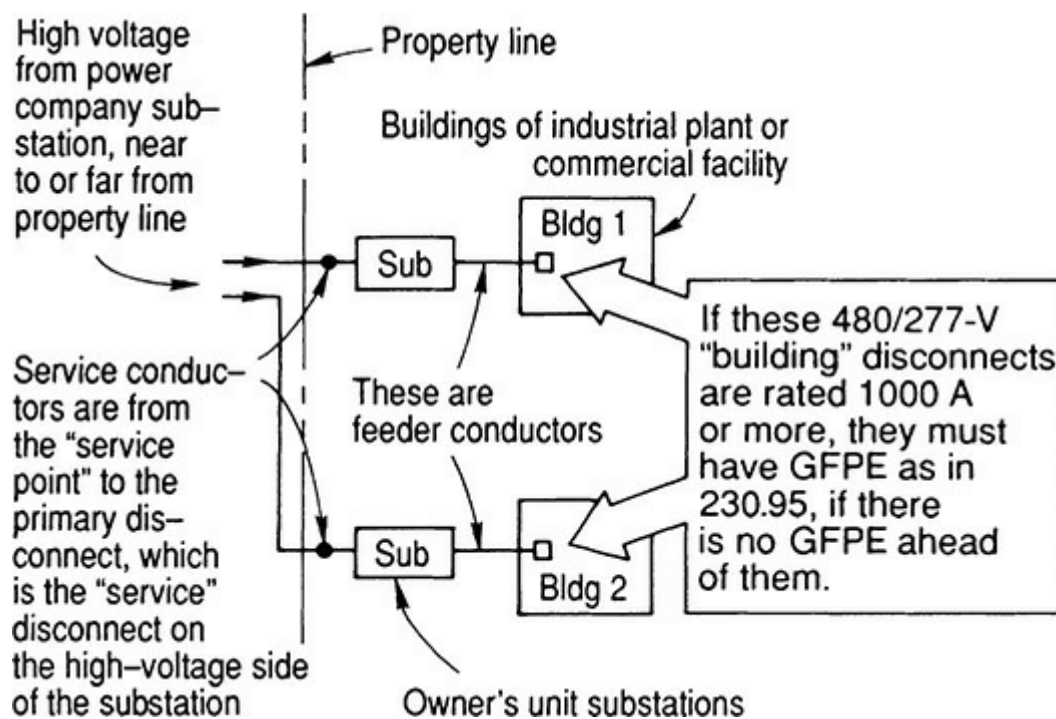

Fig. 240-10. Ground-fault protection is required for the feeder disconnect for each building—either at the building or at the substation secondary. (Sec. 240.13.)

The last part of this section is intended to clarify that the rule applies to the rating of *individual* disconnects and *not* to the sum of disconnects. Where an individual disconnect is rated 1000 A, or more, GFPE must be provided.

There are three conditions under which GFPE may be omitted. The first condition here excluded from the need for such GFPE disconnects for critical processes where automatic shutdown would introduce additional or different hazards. And as with service GFPE, the requirement does not apply

to fire-pump disconnects.

As covered in 240.13(2), the need for GFPE on a building or structure disconnect is suspended *if* such protection is provided on the upstream (line) side—either service or feeder disconnect GFPE—of the feeder disconnect. The rule (eliminated in the 1996 **NEC**) used to stipulate that there must not be any desensitizing of the ground-fault protection because of downstream neutral regrounding, that is, bonding to the equipment grounding conductor and grounding electrode conductor in the downstream building disconnect. If this were done, and it is now prohibited in these cases by 250.32(B)(1) Exception No. 1, any ground-fault current in the downstream building that develops will pass over the bonding connection and return to the upstream GFPE not as unbalanced and detectable fault current, but rather as perfectly balanced and undetectable neutral load current.

The problem with this was that the rule recognizing the upstream protection was in the form of an exception. The “requirement” to avoid desensitization was added to the exception. However, since it was part of an exception, it was unenforceable. If someone desensitized the upstream GFPE, what rule was broken? True, the exception became inoperable and therefore GFPE was now required at the building disconnect. However, if there were additional downstream cross-connections, then neither GFPE device would work properly. The real solution was to address the problem in the second-building regrounding rules in Art. 250. This was successfully done in the 1999 **NEC**, eliminating the problem.

240.15. Ungrounded Conductors. A fuse or circuit breaker must be connected in series with each ungrounded circuit conductor—usually at the supply end of the conductor. A current transformer and relay that actuates contacts of a CB is considered to be an overcurrent trip unit, like a fuse or a direct-acting CB ([Fig. 240-11](#)).

PROTECTIVE DEVICE IN SERIES

CT-RELAY RESPONDS TO LOAD CURRENT

Overcurrent device

3-wire 3-phase delta

Grounded 3-wire 3-phase delta

Fig. 240-11. A fuse or overcurrent trip unit must be connected in series with each ungrounded conductor. (Sec. 240.20.)

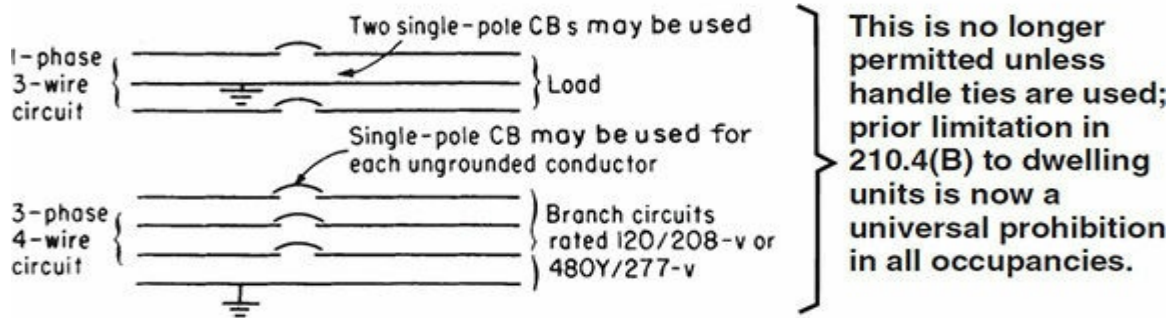

Although part **(B)** basically requires a CB to open all ungrounded conductors of a circuit simultaneously, that is, to be a multipole circuit breaker, parts **(1)**, **(2)**, **(3)**, and **(4)** cover acceptable uses of a number of single-pole CBs instead of multipole CBs.

The permission in (1) for use of single-pole breakers on multiwire branch circuits requires handle-ties on all such applications, thereby correlating with 210.4(B). Note that for 277-V multiwire branch circuits originating from a 480-V distribution, handle ties are not an option because the UL Guide Card entry does not recognize voltages above 120/240 for this application. Therefore, actual two- or three-pole breakers (or fused switches) are required for these circuits. In addition, a multipole circuit breaker that simultaneously opens all ungrounded conductors is required for multiwire branch circuits that supply both line-to-line loads and line-to-neutral loads as permitted by 210.4(C) Exception No. 2.

The next three paragraphs allow handle-tied breakers for exclusively line-to-line loads such as baseboard electric heaters on grounded single-phase ac systems **(2)** and three-phase ac systems **(3)** (which also includes 5-wire 2-phase systems). In both cases the circuit must be derived from a grounded distribution and use a slash voltage rated circuit breaker, as covered in the second paragraph of 240.85. Paragraph **(4)** imposes a similar limitation on dc circuits, namely, that they be supplied from a system with a grounded neutral.

In all three cases [**(2)**, **(3)**, and **(4)**] the systems must be grounded, but it is not necessary for the neutral to be running to the load supplied. In addition, as of the 2011 edition, there is an express rather than implied voltage system limit in the **NEC** for these applications. Line-to-line loads that employ single-pole breakers with handle ties are limited to 120/240-V applications, or 125/250-V dc applications, or both if dual rated. Prior codes (going back to the 1959 edition) referred to the voltage limitations of 210.6. Now these three paragraphs line up with the UL Guide Card information on circuit breakers.

Note: Two single-pole circuit breakers may not be used on “ungrounded 2-wire circuits”—such as 240-, 480-, or 600-V single-phase, 2-wire circuits. A 2-pole CB must be used if protection is provided by CBs. Use of single-pole CBs with handle ties but not common-trip is not allowed. These circuits become corner grounded on the first ground fault, and must then clear on a ground fault elsewhere in a different phase connection; only the straight two-pole breaker will have been tested without the assistance of a reduced voltage to ground. However, use of fuses for protection of such a circuit is permitted even though it will present the same chance of a fault condition as shown in [Fig. 240-12](#).

THIS IS THE POSSIBLE HAZARDOUS CONDITION —

NOTE: A similar faulty condition could develop if the above hookup consisted of two single-pole breakers supplying 480 volts to the primary of a single-phase 480-240/120-volt transformer.

SINGLE-POLE BREAKERS MAY NOT BE USED LIKE THIS —

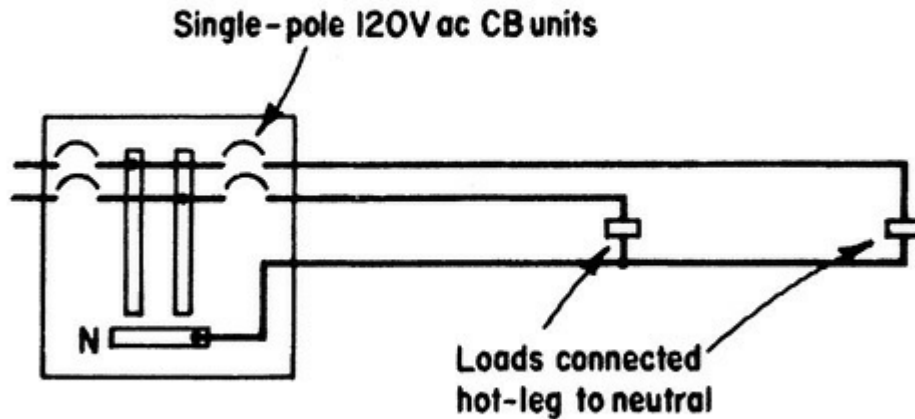

Fig. 240-12. Single-pole versus multipole breakers. (Sec. 240.15.)

Although 1-pole CBs may be used, as noted, it is better practice to use multipole CBs for circuits to individual load devices that are supplied by two or more ungrounded conductors. It is never wrong to use a multipole CB; but, based on the rules given here and in 210.4, it may be a violation to use two single-pole CB units (see Fig. 240-13). A 3-pole CB must always be used for a 3-phase, 3-wire circuit supplying phase-to-phase loads fed from an ungrounded delta system, such as 480-V outdoor lighting for a parking lot, as permitted by 210.6(B). In addition, there is a significant problem with availability of handle ties for three single-pole breakers used on three-phase wye multiwire branch circuits.

1. Single-pole CBs rated 120 volts ac are suitable for use on circuits rated 120 V to ground.

2. Single-pole circuit breakers with handle ties rated 120/240 volts ac are suitable for use in a single-phase circuit with or without the neutral connected to the load.

Fig. 240-13. NEC rules must be correlated with these UL requirements. (Sec. 240.20.)

BASIC RULE

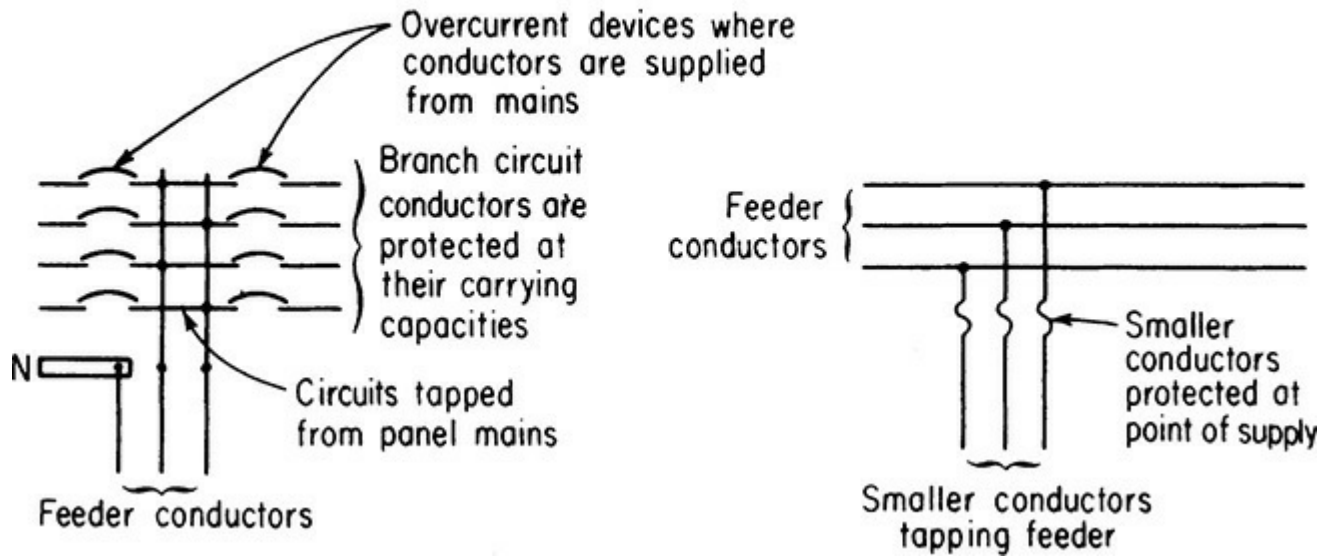

Fig. 240-14. Conductors must be protected at their supply ends. (Sec. 240.21.)

Just because a two-pole breaker ships as a single unit from a manufacturer does not necessarily mean that it is actually a common-trip device; to be so it must have an actual internal common trip, and an external handle tie, no matter how robust, does not qualify the breaker as a common-trip device. UL requires such breakers to be marked as “independent trip” or “no common trip” where directly visible when the dead-front is removed.

240.21. Location in Circuit. The basic rule of this section is shown in [Fig. 240-14](#). A very important qualification that applies to all tap conductors is this: A tap cannot be tapped. Any conductor that originates under one of the provisions of 240.21(A through H) cannot supply any other conductor unless the next conductor has protection at its supply end with a conventional overcurrent device meeting all the rules in 240.4.

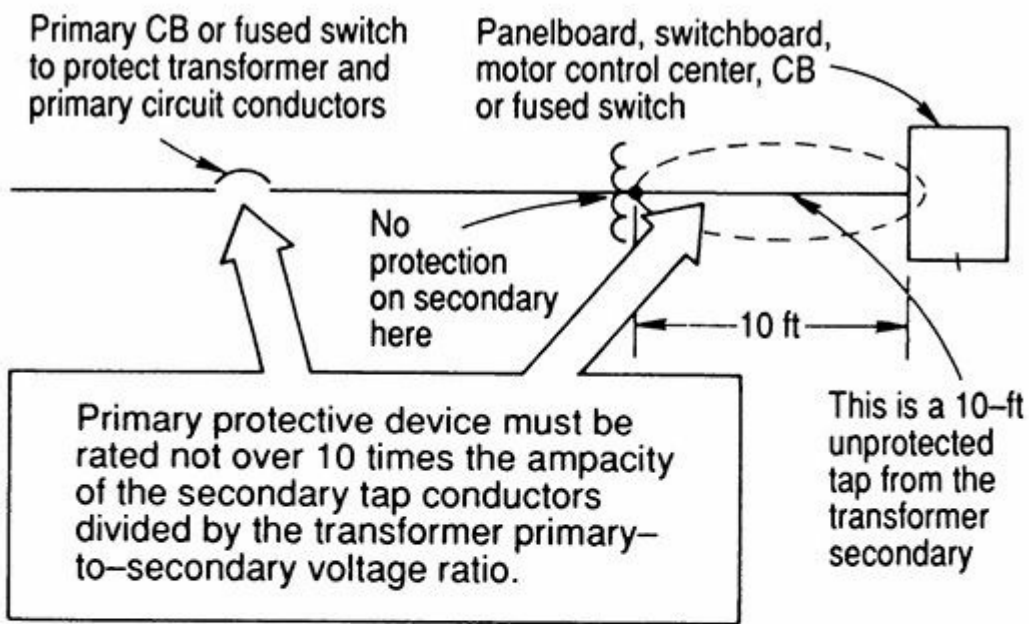

Although basic Code requirements dictate the use of an overcurrent device at the point at which a conductor received its supply, subparts (A) through (H) effectively present exceptions to this rule in the case of taps to feeders. That is, to meet the practical demands of field application, certain lengths of unprotected conductors may be used to tap energy from protected feeder conductors.

These “exceptions” to the rule for protecting conductors at their points of supply are made in the case of 10-, 25-, and 100-ft (3.0-, 7.5-, and 30.0-m) taps from a feeder, as described in 240.21, parts (B)(1), (B)(2), and (B)(4). Application of the tap rules should be made carefully to effectively minimize any sacrifice in safety. The taps are permitted without OCPDs at the point of supply.

240.21(B)(1) says that unprotected taps not over 10 ft (3.0 m) long ([Fig. 240-15](#)) may be made from feeders, and 240.21(C)(2) for transformer secondaries, provided:

240.21(B)(1)

240.21(C)(2)

EXAMPLE: If the above transformer is stepping 480V single phase down to 240/120V single phase, and the 10-ft tap conductors on the transformer secondary have an ampacity of 100A, the primary feeder CB must be rated not more than 10 times 100A divided by two (480/240), or 500A.

Fig. 240-15. Ten-foot taps may be made from a feeder or a transformer secondary. (Sec. 240.21.)

1. The smaller conductors have a current rating that is not less than the combined computed loads of the circuits supplied by the tap conductors and must have ampacity of—
Not less than the rating of the equipment containing an overcurrent device(s) supplied

by the tap conductors, or (which formerly included the bus structure of a main lug only panelboard but given changes in 408.36, an overcurrent device is now generally required) and

Not less than the rating of the overcurrent device (fuses or CB) that is installed at the termination of the tap conductors. This provision does not apply to listed equipment such as some surge protective devices that include specific instructions covering minimum conductor sizing; in such cases, the manufacturer's instructions apply.

Important Limitation: For any 10-ft (3-m) unprotected feeder tap installed in the field, the rule limits its connection to a feeder that has protection rated *not* more than 1000 percent of (10 times) the ampacity of the tap conductor where the tap conductors do not remain within the enclosure or vault in which the tap is made. This provision recognizes that taps present little threat while they remain within the confines of a transformer vault. It also recognizes the practical issues of sensor wiring within enclosures. For example, if a voltmeter is installed in the enclosure door of a 2000 A switchboard, 10 percent of 2000 A would otherwise require 3/0 conductors to run to the meter. Under the rule, unprotected No. 14 tap conductors are not permitted to tap a feeder any larger than 1000 percent of the 20-A ampacity of No. 14 copper conductors—which would limit such a tap for use with a maximum feeder protective device of not over 10×20 A, or 200 A.

2. The tap does not extend beyond the switchboard, panelboard, disconnect, or control device which it supplies.
3. The tap conductors are enclosed in conduit, EMT, metal gutter, or other approved raceway when not a part of the switchboard or panelboard.

240.21(C)(2) specifically recognizes that a 10-ft (3-m) tap may be made from a transformer secondary in the same way it has always been permitted from a feeder. In either case, the tap conductors must not be over 10 ft (3 m) long and must have ampacity not less than the amp rating of the switchboard, panelboard, disconnect, or control device—or the tap conductors may be terminated in an overcurrent protective device rated not more than the ampacity of the tap conductors. As in the case of the equivalent feeder tap, this provision does not apply to listed equipment, such as some surge protective devices, that includes specific instructions covering minimum conductor sizing; in such cases the manufacturer's instructions apply.

In the case of an unprotected tap from a transformer secondary, the ampacity of the 10-ft (3-m) tap conductors would have to be related through the transformer voltage ratio to the size of the transformer primary protective device—which in such a case would be “the device on the line side of the tap conductors.” Just as in the case of the feeder tap, there is a 1000 percent ratio limitation (in this case multiplied by the applicable transformer winding ratio) except once again where the secondary conductors don't leave the vault or the enclosure where they originate the 1000 percent (10 times) factor does not apply.

Taps not over 25 ft (7.5 m) long (Fig. 240-16) may be made from feeders, as noted in part **(B)(2)** of 240.21, provided:

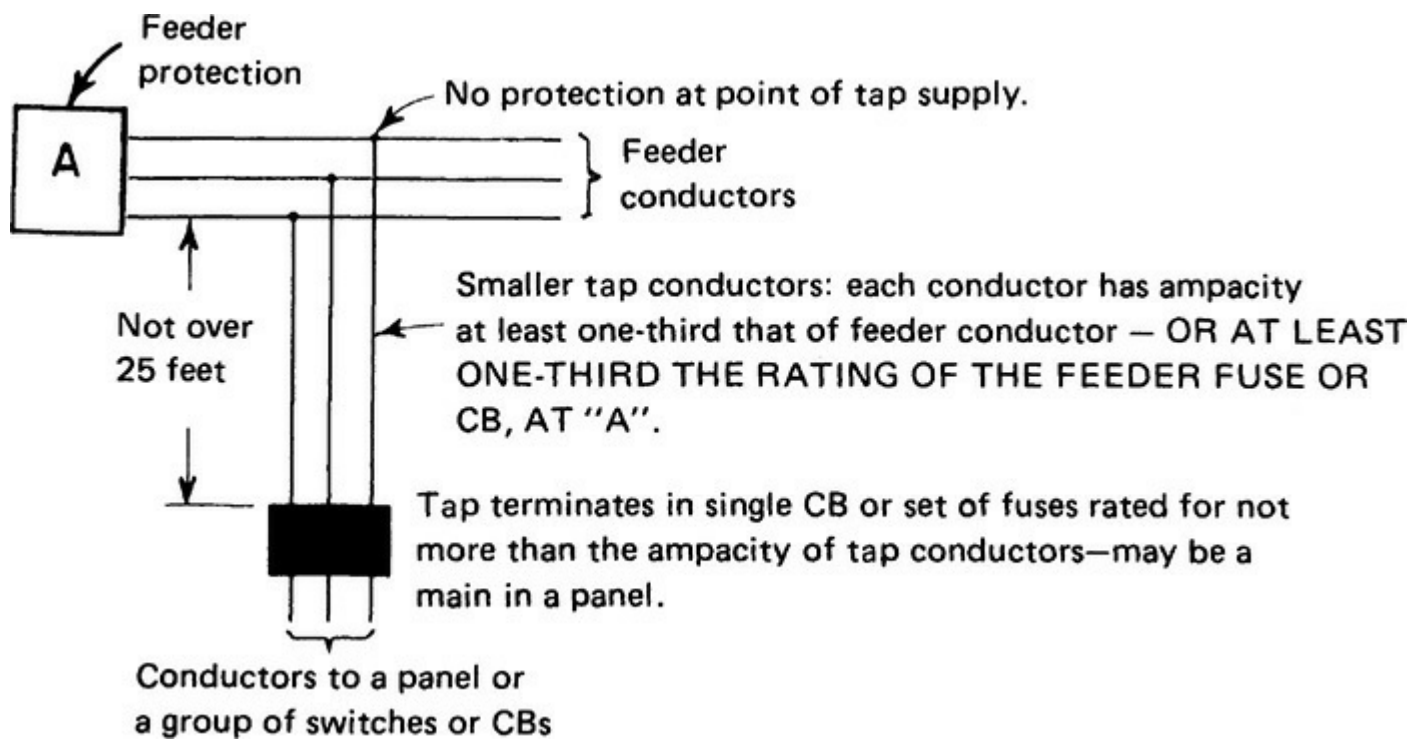

Fig. 240-16. Sizing feeder taps not over 25 ft (7.5 m) long. (Sec. 240.21.)

1. The smaller conductors have a current rating at least one-third that of the feeder overcurrent device rating or of the conductors from which they are tapped.
2. The tap conductors are suitably protected from mechanical damage. In previous Code editions, the 25-ft (7.5-m) feeder tap without overcurrent protection at its supply end simply had to be “suitably protected from physical damage”—which could accept use of cable for such a tap. Now, the rule requires such tap conductors to be “enclosed in an approved raceway or by other approved means”—strongly suggesting, but not quite mandating a raceway as has always been required for 10-ft (3-m) tap conductors.
3. The tap is terminated in a single CB or set of fuses, which will limit the load on the tap to the ampacity of the tap conductors.

Examples of Taps

Figure 240-17 shows use of a 10-ft (3-m) feeder tap to supply a single motor branch circuit. The conduit feeder may be a horizontal run or a vertical run, such as a riser. If the tap conductors are of such size that they have a current rating at least one-third that of the feeder conductors (or protection rating) from which they are tapped, they could be run a distance of 25 ft (7.5 m) without protection at the point of tap-off from the feeder because they would comply with the rules of 240.21(B)(2), which permit a 25-ft (7.5-m) feeder tap if the conductors terminate in a single protective device rated not more than the conductor ampacity. 368.17(C) generally requires that any busway used as a feeder must have overcurrent protection on the busway for any subfeeder or branch circuit tapped from the busway. The use of a cable-tap box on a busway without overcurrent protection (as shown in the conduit installation of [Fig. 240-17](#)) would usually be a violation. But, Exception No. 1 to 368.17(C) clearly eliminates such protection where making taps. Refer to 240.24 and 368.17.

Fig. 240-17. A 10-ft (3-m) tap for a single motor circuit. (Sec. 240.21.)

A common application of the 10-ft (3.0-m) tap is the supply of panelboards from conduit feeders or busways, as shown in Fig. 240-18. The case shows an interesting requirement that arises from 408.36, which requires that all panelboards be protected on their supply side by overcurrent protection rated not more than the rating of the panelboard busbars. If the feeder is a busway, the protection must be placed [a requirement of 368.17(C)] at the point of tap on the busway. In that case a 100-A CB or fused switch on the busway would provide the required protection of the panel, and the panel would not require a main in it. But, if the feeder circuit is in conduit, the 100-A panel protection would have to be in the panel or just ahead of it.

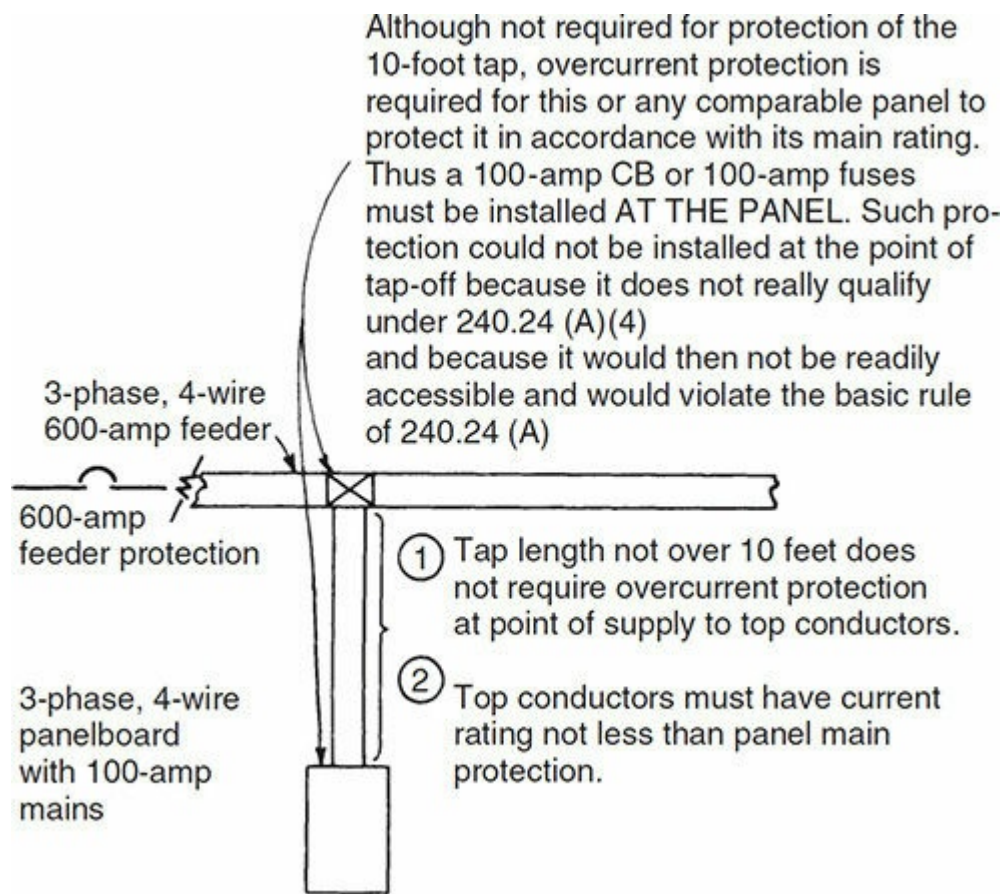

Fig. 240-18. A 10-ft (3.0 m) tap to lighting panel with unprotected conductors. (Sec. 240.21.)

For transformer applications, typical 10- and 25-ft (3.0- and 7.5-m) tap considerations are shown in [Fig. 240-19](#).

10-FT TAP

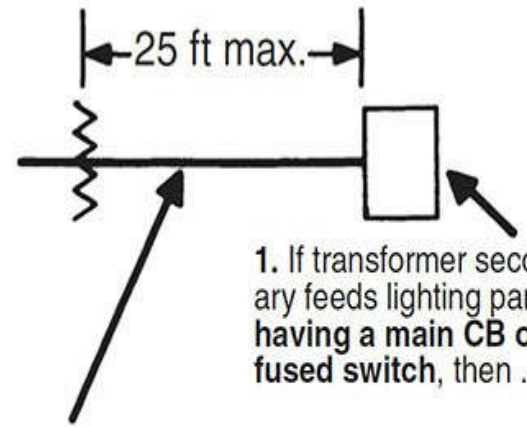

1. A 10-ft tap may be made from transformer secondary to a panel, switchboard, MCC, etc.

2. If this is a lighting panel that requires main protection, a fused switch or CB must be installed as a main protective device in the panel or just ahead of it, at the end of the 10-ft tap.

3. Effective with the 2008 NEC, all panelboards require this type of individual protection.

25-FT TAP

1. If transformer secondary feeds lighting panel having a main CB or fused switch, then ...

2. ... secondary tap conductors from transformer may be 25 ft long, as permitted by 240.21(C)(4), but only where the tap terminates in a single CB or set of fuses.

3. Or, a 25-ft tap may be made from a transformer to a CB or fused switch in an individual enclosure or serving as a main in a switchboard or MCC.

NOTE: From a single transformer secondary of adequate capacity, more than one set of 10-ft tap conductors may be run to more than one panel or other distribution equipment.

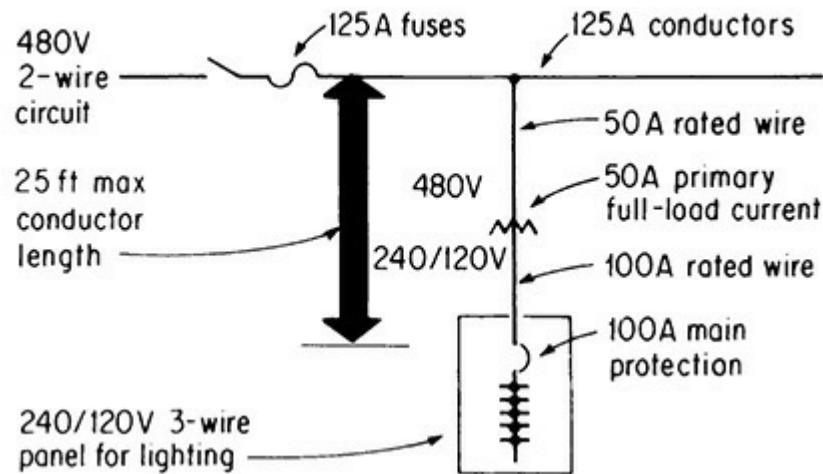

Fig. 240-19. Taps from transformer secondaries. (Sec. 240.21.)

The bottom half of [Fig. 240-19](#) illustrates an important concept that was just clarified in the 2008 **NEC**. A transformer (assuming appropriate capacity and primary-side protection) can supply any number of sets of secondary conductors, each of which is considered independently when applying the various rules for transformer secondary conductors covered in 240.21(C). If five sets of secondary conductors were supplied from a common secondary, in raceway and feeding a suitable overcurrent device at their load end, each could be 7.5 m (25 ft) long. It would not be necessary to keep them all 1.5 m (5 ft) long or other lengths such that the total did not exceed the 7.5 m (25 ft) limit overall.

Figure 240-20 shows application of part **(B)(3)** of 240.21 in conjunction with the rule of 450.3(B), covering transformer protection. As shown in Example 1, the 100-A main protection in the panel is sufficient protection for the transformer and the primary and secondary conductors when these conditions are met:

EXAMPLE 1:

EXAMPLE 2:

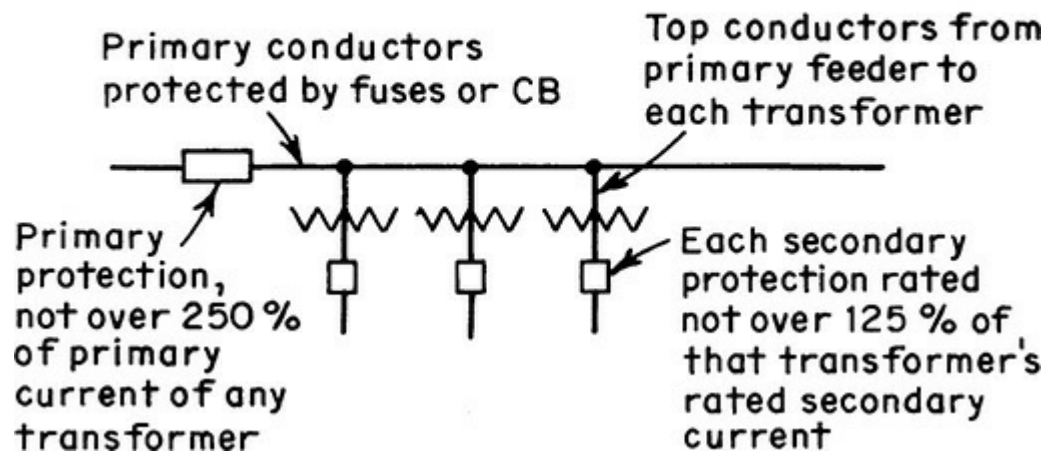

Fig. 240-20. Feeder tap of primary-plus-secondary not over 25 ft (7.5 m) long. (Sec. 240.21.)

1. Tap conductors have ampacity at least one-third that of the 125-A feeder conductors.
2. Secondary conductors are rated at least one-third the ampacity of the 125-A feeder conductors, based on the primary-to-secondary transformer ratio.
3. Total tap is not over 25 ft (7.5 m), primary plus secondary.
4. All conductors are in “approved raceway or other approved means.”
5. Secondary conductors terminate in the 100-A main protection that limits secondary load to the ampacity of the secondary conductors and simultaneously provides the protection required by the lighting panel.
6. Primary feeder protection is not over 250 percent of transformer rated primary current, as recognized by 450.3(B), and the 100-A main breaker in the panel satisfies as the required “overcurrent device on the secondary side rated or set at not more than 125 percent of the rated secondary current of the transformer.” Alternatively, if the primary protection meets the 125 percent rule in 450.3(B), the secondary protection would not be required for the transformer, and would therefore be limited only by the requirements of protecting the secondary conductors and of protecting the panelboard.

Frequently the wiring under this rule uses conductors on the line side of the transformer that are not reduced in any way from the size of the conductors of the feeder to which they are connected. In this

case, the length of wire on the primary side that has to be figured in to the 7.5 m (25 ft) limitation under this rule is zero, and the secondary conductors can take the full 7.5 m (25 ft) if necessary.

Example 2 of Fig. 240-20 shows multiple sets of tap conductors from the primary feeder to a group of transformers. In such cases the primary taps are frequently reduced because the primary feeder must have the capacity for several load groups. In such cases the length of the primary side is not zero, and must be subtracted from the permitted overall total. The allowable protection for that parent feeder must meet both 240.4 for the feeder conductors employed, and also provide protection for *each* of the transformers supplied, at a value therefore based on 250 percent of the primary rating of the *smallest* transformer served. Figure 240-21 shows this process at work, although in this example the primary conductors were not reduced in size, allowing a full-length secondary.

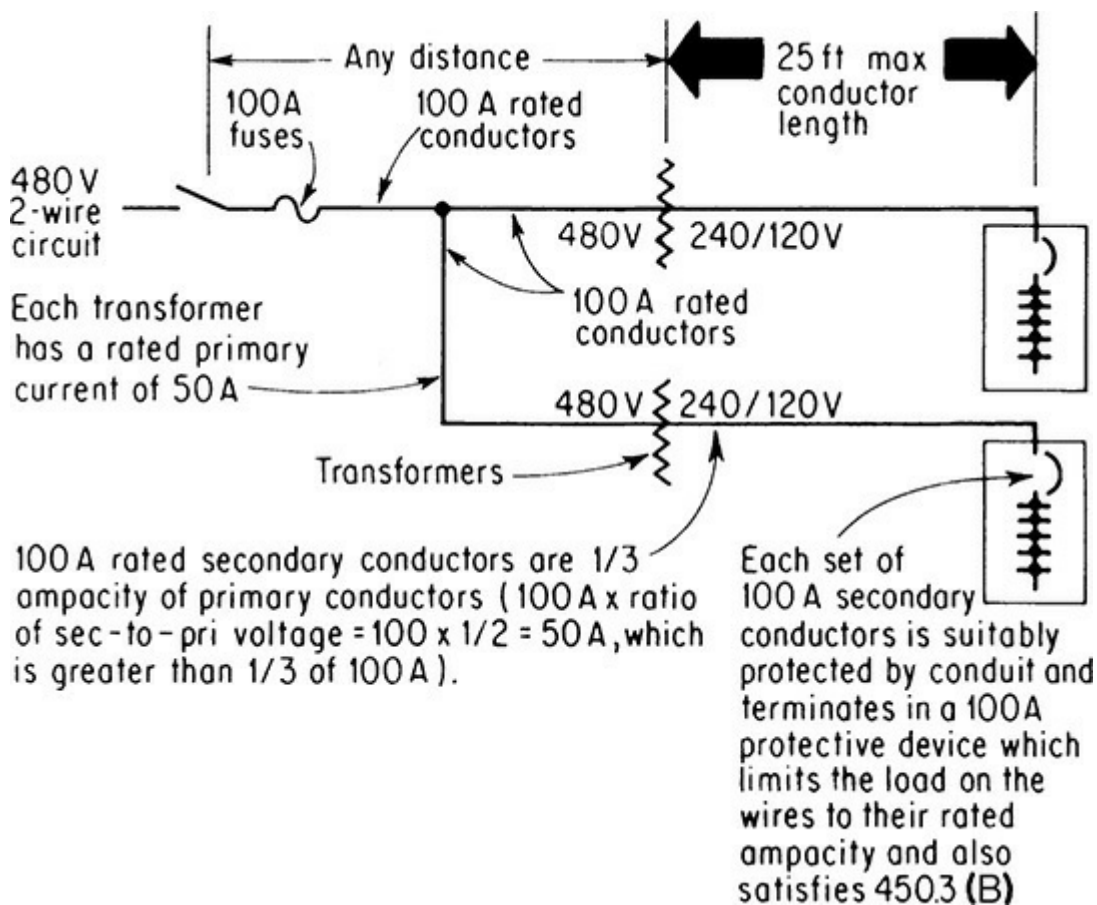

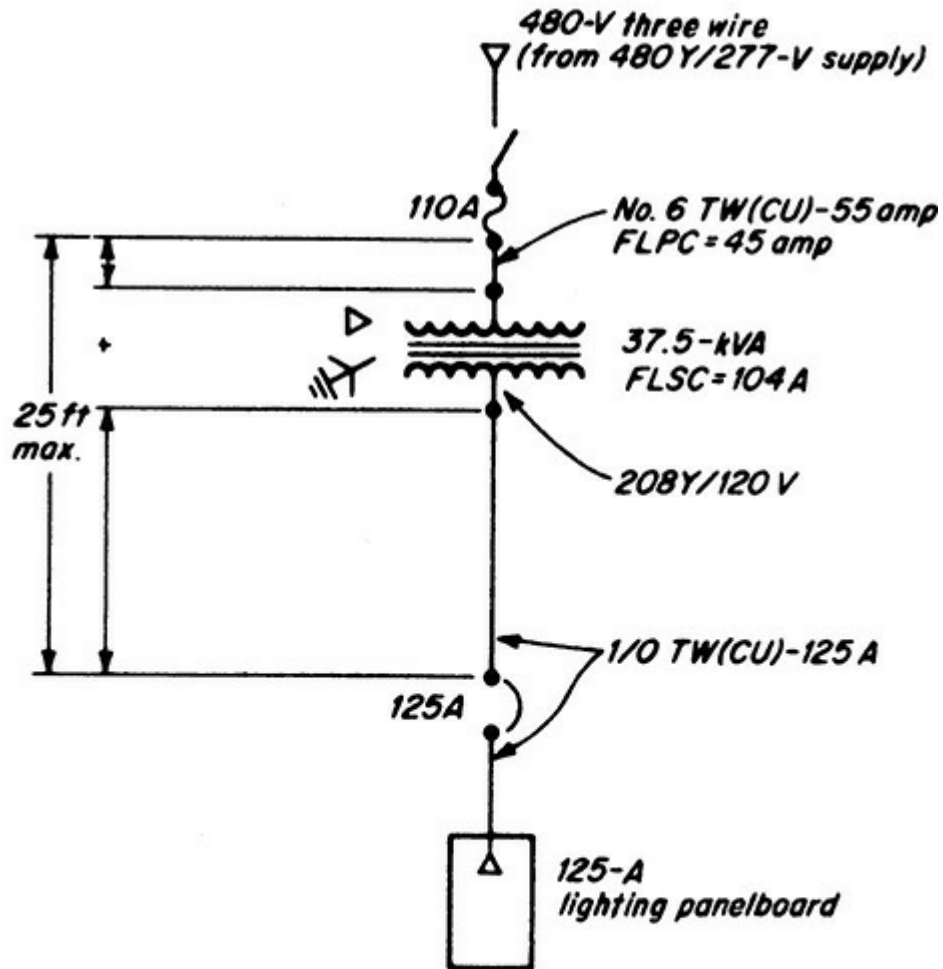

Fig. 240-21. Sizing a 25-ft (7.5-m) tap and transformer protection. (Sec. 240.21.)

This is as good an illustration as any of a crucial principle that we will discuss again in 450.3, namely, the rules in Art. 240 for conductor protection stand alone from the rules in Art. 450 for transformer protection. However, if it is intended that a single protective device perform both functions, then both sets of rules must be applied. Make separate calculations, and select for the worst case. If the result is one you don't want to live with, add additional devices until you do meet all the rules.

Figure 240-22 compares the two different 25-ft (7.5-m) tap techniques covered by part (B)(2) and the equivalent distance with a transformer secondary interposed, 240.21(C)(5), as just covered in 240.21(B)(3). This rule in part (C) simply provides correlation with 240.21(B)(3) because that other rule also covers a transformer secondary.

25-ft tap – 240.21(B)(2)

*Taps protected from physical damage.
 Secondary-to-primary voltage ratio = 208:480 = 1:2.3*

25-ft tap – 240.21(C)(5)

Fig. 240-22. Examples show difference between the two types of 25-ft (7.5-m) taps covered by parts (C) and (C)(5). (Sec. 240.21.)

Part (B)(4) is another departure from the rule that conductors must be provided with overcurrent protection at their supply ends, where they receive current from larger feeder conductors. 240.21(B)(4) permits a longer length than the 10-ft unprotected tap of part (B)(1) and the 25-ft (7.5-m) tap of part (B)(2). Under specified conditions that are similar to the requirements of the 25-ft-tap exception, an unprotected tap up to 100 ft (30.0 m) in length may be used in “high-bay manufacturing buildings” that are over 35 ft (11.0 m) high *at the walls*—but only “where conditions of maintenance and supervision assure that only qualified persons will service the system.” Obviously, that last phrase can lead to some very subjective and individualistic determinations by the authorities enforcing the Code. And the phrase “35 ft (11.0 m) high at the walls” means that this rule cannot be applied where the height is over 35 ft (11.0 m) at the peak of a triangular or curved roof section but less than 35 ft (11.0 m) at the walls.

The 100-ft (30.0-m) tap exception must meet specific conditions:

1. “Qualified” persons must maintain the system.
2. From the point at which the tap is made to a larger feeder, the tap run must not have more than 25 ft (7.5 m) of its length run horizontally, and the sum of horizontal run and vertical run must not exceed 100 ft (30.0 m). [Figure 240-23](#) shows some of the almost limitless configurations of tap layout that would fall within the dimension limitations.

NO PROTECTION AT POINT OF TAP, WHICH MUST BE AT LEAST 30 FT ABOVE FLOOR

ALL TAP CONDUCTORS IN RACEWAY AND RATED NOT LESS THAN $\frac{1}{3} \times 1200 A$, OR 400 A

CONDUCTOR LENGTHS:

- A + B = not over 100 ft**
- B = not over 25 ft**
- C = not over 100 ft**
- D + E + F + G = not over 100 ft**
- E + G = not over 25 ft**

Fig. 240-23. Unprotected taps up to 100 ft long may be used in “high-bay manufacturing buildings.”

3. The tap conductors must have an ampacity equal to at least one-third of the rating of the overcurrent device protecting the larger feeder conductors from which the tap is made.
4. The tap conductors must terminate in a circuit breaker or fused switch, where the rating of overcurrent protection is not greater than the tap-conductor ampacity.
5. The tap conductors must be protected from physical damage and must be installed in “an approved raceway or other approved means.”
6. There must be no splices in the total length of each of the conductors of the tap.
7. The tap conductors must not be smaller than 6 AWG copper or 4 AWG aluminum.
8. The tap conductors must not pass through walls, floors, or ceilings.
9. The point at which the tap conductors connect to the feeder conductors must be at least 30 ft (9.0 m) above the floor of the building.

As shown in Fig. 240-23, the tap conductors from a feeder protected at 1200 A are rated at not less than one-third the protection rating, or 400 A. Although 500-kcmil THW copper is rated at 380 A, that value does not satisfy the minimum requirement for 400 A. But if 500-kcmil THHN or XHHW copper, with an ampacity of 430 A, were used for the tap conductors, the rule would be satisfied. However, in such a case, those conductors would have to be used as if their ampacity were 380 A for the purpose of load calculation because of the general UL rule of 75°C conductor terminations for connecting to equipment rated over 100 A—such as the panelboard, switch, motor-control center, or other equipment fed by the taps. And the conductors for the main feeder being tapped could be rated less than the 1200 A shown in the sketch if the 1200-A protection on the feeder was selected in accordance with 430.62 or 430.63 for supplying a motor load or motor and lighting load. In such cases, the overcurrent protection may be rated considerably higher than the feeder conductor ampacity. But the tap conductors must have ampacity at least equal to one-third the *feeder protection rating*.

The 1200-A feeder that was tapped in this example raises another point of discussion. That feeder, unless from a busway, almost certainly was run with multiple conductors in parallel. For the sake of argument, suppose the feeder consists of three sets of 600-kcmil conductors. The 400-A tap, as noted, could be 500 kcmil THHN. The question constantly arises in the field, is it necessary to connect each phase of the tap to all of the corresponding phase conductors in the overhead feeder? Certainly tapping only one of those conductors would be a far simpler task. The answer is no.

The feeder as connected to its overcurrent protective device is all three runs. Separating one of the sets of the supplied conductors means that the tap is being applied to only one-third of the feeder. In effect the tap is being made to another tap, namely, one that begins at the 1200 A breaker. That tap would not comply with any known allowance in the **NEC** given its length, location, etc. Further, the actual field tap covered here would then be made from this undefined tap, in violation of the clear prohibition of making taps from other taps.

240.21(C)(3) applies exclusively to industrial electrical systems. Conductors up to 25 ft (7.5 m) long may be tapped from a transformer secondary without overcurrent protection at their supply end and without need for a single-circuit breaker or set of fuses at their load end. Normally, a transformer secondary tap over 10 ft (3 m) long and up to 25 ft (7.5 m) long must comply with the rules of 240.21(C)(5) or (C)(6)—which call for such a transformer secondary tap to be made with conductors

that require no overcurrent protection at their supply end but are required to terminate at their load end in a single CB or single set of fuses with a setting or rating not over the conductor ampacity. However, 240.21(C)(3) permits a 10- to 25-ft (3- to 7.5-m) tap from a transformer secondary without termination in a single main overcurrent device—but it limits the application to “industrial installations.” The tap conductor ampacity must be at least equal to the transformer’s secondary current rating and must be at least equal to the sum of the ratings of overcurrent devices supplied by the tap conductors.

As clarified in the 2014 **NEC**, this provision is limited to tap conductors arriving at the main lugs of a switchboard, as in Fig. 240-24. A motor control center could never have qualified, because overcurrent protection in the form of a singular device is required in accordance with the rating of the common power bus, as covered in 430.94. Power panels no longer comply because all panelboards now require individual overcurrent protection, with exceptions that would not apply here (see 408.36). If the tap arrived at a wireway or auxiliary gutter over the collection of loads intended to be supplied, as shown at the bottom of Fig. 240-24, the individual taps to each of the loads would almost certainly have violated the prohibition against tapping taps, certainly so if they were reduced in size to meet the likely termination limitations of the smaller equipment.

Fig. 240-24. These tap applications are permitted for transformer secondaries only in “industrial”

electrical systems. The setup at the bottom of the figure would always have been a virtual impossibility to wire given the terminations limitations of the supplied devices, and as of the 2014 NEC the wiring must be as shown in the upper drawing.

The rule of parts **(B)(5)** and **(C)(4)** allows outdoor feeder taps and unprotected secondary conductors from outdoor transformers to run for any distance *outdoors*. Physical protection for the conductors must be provided and they must terminate in a single CB or set of fuses. The CB or set of fuses must be part of, or adjacent to, the disconnect, which may be installed anywhere outdoors or indoors as close as possible to the point of conductor entry. Both sections emphasize that such unprotected conductors must not be run within any building or structure. As is the case with service conductors, these tap conductors must be terminated at an OC device as soon as they enter. Also, as in the case of services, the rules of 230.6 (concrete encasement, etc.) can be used to artificially extend the point of entrance if necessary.

As shown in [Fig. 240-25](#), 240.21(G) gives permission for unprotected taps to be made from generator terminals to the first overcurrent device it supplies—such as in the fusible switch or circuit breakers used for control and protection of the circuit that the generator supplies. No maximum length is specified for the generator tap conductors, although various limits have been proposed over the years. Note also that 445.13, which is referenced, requires the tap conductors to have an ampacity of at least 115 percent of the generator nameplate current rating.

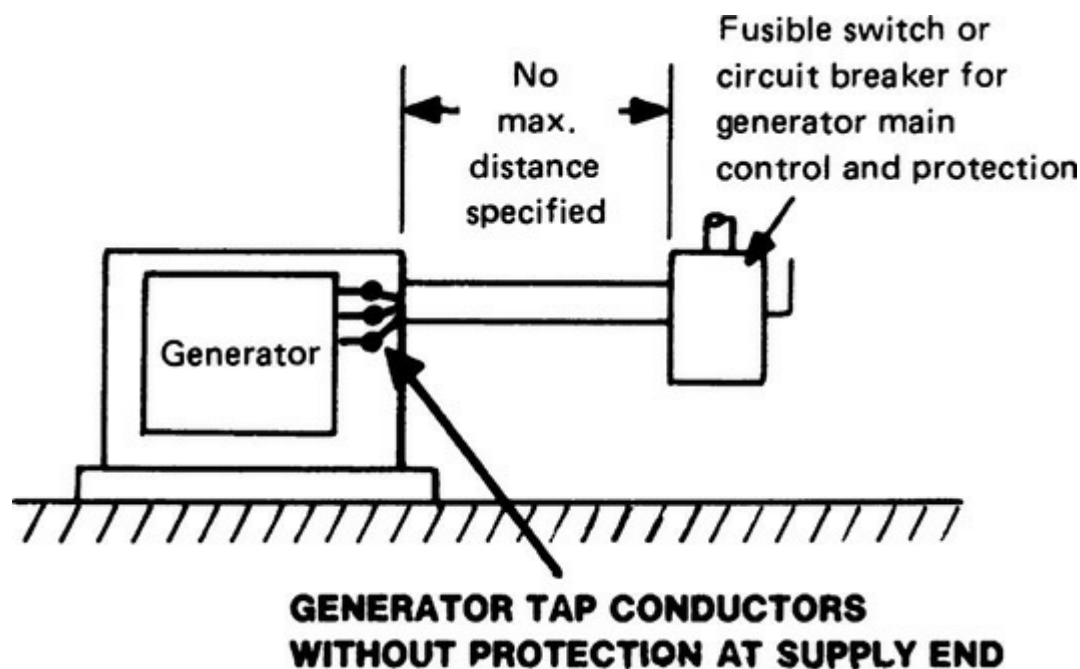

Fig. 240-25. Unprotected tap may be made from a generator's output terminals to the first overcurrent device. [Sec. 240.21(G).]

Section 240.21(H), new in the 2008 **NEC**, allows the location of overcurrent protection for battery output conductors to be as close as practicable to the battery room and still be out of range of the hazardous location boundary, if such a classification has been established. Note that 480.5 requires the disconnecting means for conductors supplied from a stationary battery system operating over 30 V to be readily accessible and within sight of the battery system. While batteries are charging, the current flowing over the conductors is controlled by the charging system, but when the

batteries are actually supplying power overcurrent protection is necessary.

240.22. Grounded Conductor. The basic rule prohibits use of a fuse or CB in any conductor that is intentionally grounded—such as a grounded neutral or a grounded phase leg of a delta system.

Figure 240-26 shows the two “exceptions” to that rule and a clear violation of the basic rule.

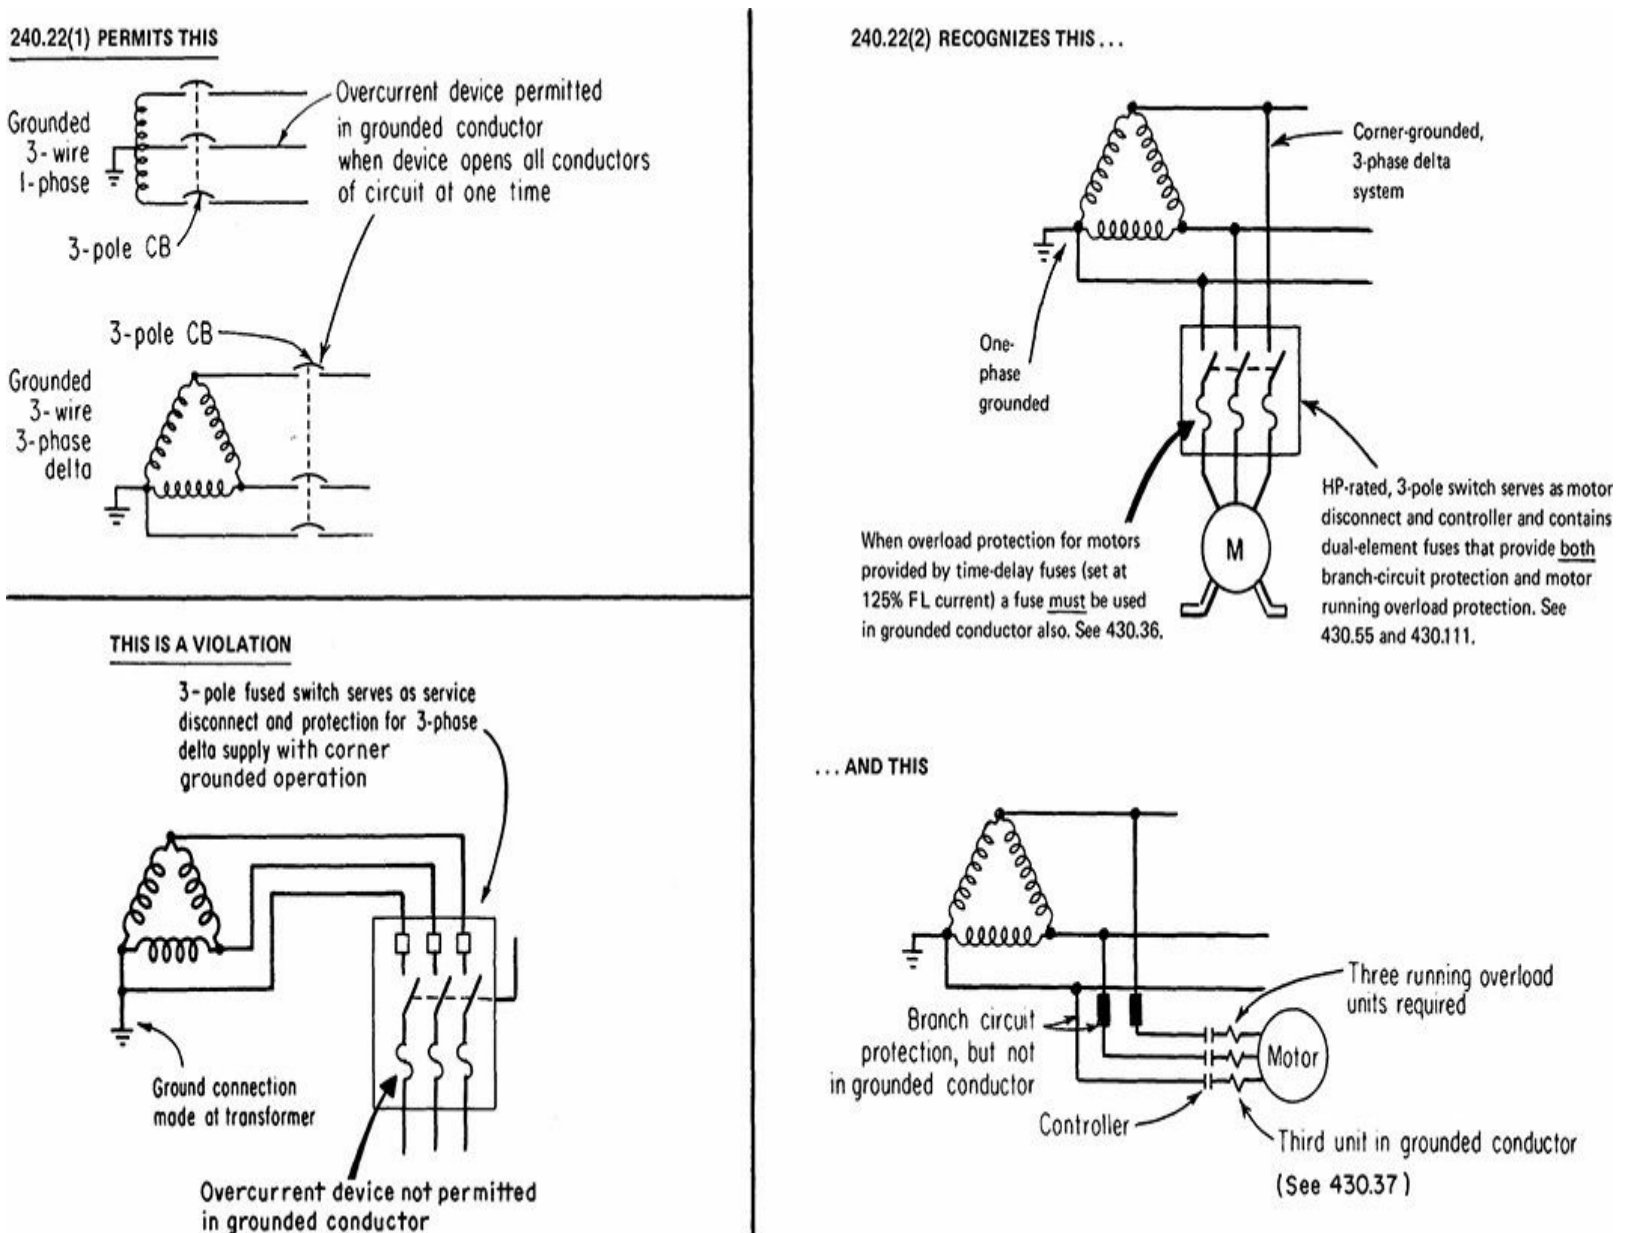

Fig. 240-26. Overcurrent protection in grounded conductor. (Sec. 240.22.)

240.23. Change in Size of Grounded Conductor. In effect, this recognizes the fact that if the neutral is the same size as the ungrounded conductor, it will be protected wherever the ungrounded conductor is protected. One of the most obvious places where this is encountered is in a distribution center where a small grounded conductor may be connected directly to a large grounded feeder conductor.

240.24. Location in or on Premises. According to part (A), overcurrent devices must be readily accessible. And in accordance with the definition of “readily accessible” in Art. 100, they must be “capable of being reached quickly for operation, renewal, or inspections, without requiring those to whom ready access is requisite to climb over or remove obstacles or to resort to portable ladders, chairs, etc.” (Fig. 240-27).

Overcurrent device in a panel, switch, CB, switchboard, MCC is not readily accessible . . .

Fig. 240-27. Overcurrent devices must be "readily accessible." (Sec. 240.24.)

Although the Code gives no maximum heights at which OCPDs are considered readily accessible, some guidance can be obtained from 404.8, which provides detailed requirements for location of switches and CBs. This section states that switches and CBs shall be so installed that the center of the grip of the operating handle, when in its highest position, will not be more than 6 ft 7 in. (2.0 m) above the floor or working platform.

There are certain applications where the rules for ready accessibility are waived.

Part (A)(1) covers any case where an overcurrent device is used in a busway plug-in unit to tap a branch circuit from the busway. 368.12 requires that such devices consist of an externally operable CB or an externally operable fusible switch. These devices must be capable of being operated from the floor by means of ropes, chains, or sticks. Part (A)(2) refers to 240.10, which states that where supplementary overcurrent protection is used, such as for lighting fixtures, appliances, or internal circuits or components of equipment, this supplementary protection is not required to be readily

accessible. An example of this would be an overcurrent device mounted in the cord plug of a fixed or semifixed luminaire supplied from a trolley busway or mounted on a luminaire that is plugged directly into a busway. Part **(A)(3)** acknowledges that 230.92 permits service overcurrent protection to be sealed, locked, or otherwise made not readily accessible. [Figure 240-28](#) shows these details.

Part (A)

FEEDER TAP FROM BUSWAY

BRANCH-CIRCUIT TAP FROM BUSWAY

LUMINAIRE FED BY CORD FROM BUSWAY

FOR SERVICE OR OUTBUILDING MAIN DISCONNECT OR FEEDER FROM SERVICE IN ANOTHER BUILDING

Part (B)

Overcurrent protection for feeder to each apartment or office may be in locked basement room or other room accessible only to superintendent or building management

Service equipment grouped in basement

Fig. 240-28. Fuses or CBs that are permitted to be *not* readily accessible. (Sec. 240.24.)

240.24 clarifies the use of plug-in OCPDs on busways for protection of circuits tapped from the busway. After making the general rule that OCPDs must be readily accessible (capable of being reached without stepping on a chair or table or resorting to a portable ladder), part **(A)(1)** notes that it is not only *permissible* to use busway protective devices up on the busway—it is *required* by 368.17(C). Such devices on high-mounted busways are not “readily accessible” (not within reach of a person standing on the floor). The wording of 368.17(C) makes clear that this requirement for overcurrent protection in the device on the busway applies to subfeeders tapped from the busway as well as branch circuits tapped from the busway.

The rule of **(A)(4)** recognizes the installation of an OC device in an inaccessible location where mounted adjacent to “utilization equipment they supply.” The term “equipment” is defined in Art. 100. That definition seems to give broad permission for application of this rule. It seems that locating OC devices for conductor protection in other than a readily accessible location would not be permitted. Clearly, for motors, appliances, and transformers, the OC device that *supplies* such “equipment” may be mounted in an inaccessible location. The rules of **NEC** 240.24, 368.17(C), and 404.8 must be correlated with each other to assure effective Code compliance. And indeed, the customary application of this provision is to the local disconnecting means that is required to be adjacent to the utilization equipment of whatever kind in accordance with an applicable rule in the code, where that disconnecting means is also an overcurrent device in the form of a fused switch or a circuit breaker. This provision does not apply to the more usual application where overcurrent devices are provided to protect branch-circuit or feeder conductors. The revised definition of “readily accessible” in Art. 100, which prohibited the use of tools as a means of reaching readily accessible equipment, created significant mischief in terms of how this section can be applied. The 2017 **NEC** took a small step in the right direction by permitting the use of tools on industrial control panels and similar equipment. However, much more needs to be done. Until that happens, inspectors should be encouraged to take an expansive approach to the words “similar enclosures.” For just one example, NEMA 4X stainless steel panelboards are routinely environmentally protected by stainless steel rim bolts placed around the perimeter of a solid cover. A panelboard is not normally something that would be judged as similar to an industrial control panel, but for now it must be because we clearly are not going to simply stop installing this equipment. Note also, that just because such a panelboard (or other similar equipment) may qualify under this reading, when the doors are open the contents must still be held to traditional provisions, such as the maximum permissible height of an operating handle.

Part **(B)** applies to apartment houses and other multiple-occupancy buildings—such as hotel guest rooms and suites, as described in [Fig. 240-28](#).

In addition, it is important to note that parts **(C)** and **(D)** of 240.24 require that overcurrent devices be located where they will not be exposed to physical damage or in the vicinity of easily ignitable material. Panelboards, fused switches, and circuit breakers may *not* be installed in *clothes closets* in any type of occupancy—residential, commercial, institutional, or industrial. But they may be installed in other closets that do not have easily ignitable materials within them—provided that the working clearances of 110.26 (30-in. [752 mm] wide work space in front of the equipment, 6 ft 6 in. [2.0-m] headroom, illumination, etc.) are observed and the work space is “not used for storage,” as required by 110.26(B).

240.24(E) flatly prohibits what was a somewhat common practice for dwellings, as well as guest

rooms and suites in hotels and motels. In certain areas of the nation, OCPDs were located in areas such as kitchens and bathrooms. Although it is still permissible to locate the OCPDs in the kitchen, the rule of part (E) now forbids location of the overcurrent devices within the bathroom of a dwelling, dormitory, or hotel guest room or suite.

Part (F), new for the 2008 **NEC**, flatly prohibits locating overcurrent devices over the inclined portion of a stairway. The literal text prohibits the location over “steps” which is presumably different from a “landing.” There is no dimension given as to when a step becomes wide enough to be a landing, but that should be relatively obvious and interpreted consistently. Presumably, the required working space width would be a good starting point.

240.33. Vertical Position. Figure 240-29 shows the basic requirements of 240.30, 240.32, and 240.33. The rule in 240.33 is frequently misunderstood as favoring vertical mounting in the sense of having the operator move up and down, as distinguished from moving from side to side. That is the topic of 240.81 but is incorrect here. This section addresses the plane in which the overcurrent device is mounted, and favors a vertical plane as in mounting on a wall, and discourages mounting in a horizontal plane as in face up or face down.

Fig. 240-29. Enclosures for overcurrent protection. (Sec. 240.30.)

This rule has been in the **NEC** for over 90 years, having first appeared in the 1926 edition. The commentary in the 8th edition of this *Handbook*, on the 1953 **NEC**, is instructive as to the intent of this rule:

Installing cabinets or cutout boxes on ceilings is a practice that should be avoided wherever possible. Section 2435 [corresponds to 240.24 in the 2017 **NEC**] calls for cutouts and circuit breakers to be readily accessible, and a box on a ceiling is seldom readily accessible. In a box so installed, one end of a cartridge fuse may fall out of the terminals and make contact with the door of the box, thus grounding the circuit.

In addition to ceiling mounting issues, there have been some occasions for horizontal mounting in other circumstances. Some small panels, with perhaps four to six circuits, have been horizontally mounted, face-up with a door, in the top section of a short but deep wall housing special equipment. The circuit breakers were readily accessible, there was no good alternative, and the inspector agreed

with the result. That said, wall mounting is almost always preferable. The rule also makes allowances for listed busway plug-in units that may have been designed for a horizontal orientation when the busway is in certain positions.

240.40. Disconnecting Means for Fuses. The basic rules are shown in Fig. 240-30. The second sentence covers cable limiters, and as covered in 230.82(1) they can be located ahead of the service disconnect, where no switch is required. The rule presented by the last sentence is illustrated in Fig. 240-31.

Fig. 240-30. Disconnect means for fuses. (Sec. 240.40.)

Fig. 240-31. Single disconnect for one set of fuses is permitted for electric space heating with subdivided resistance-type heating elements. (Sec. 240.40.)

240.50. General (Plug Fuses). Plug fuses must not be used in circuits of more than 125 V between conductors, but they may be used in grounded-neutral systems where the circuits have more than 125 V between ungrounded conductors but not more than 150 V between any ungrounded conductor and ground (Fig. 240-32). And the screw-shell of plug fuseholders must be connected to the load side of the circuit.

Fig. 240-32. Using plug fuses. (Sec. 240.50.)

240.51. Edison-Base Fuses. 240-52. Edison-Base Fuseholders. 240-53. Type S Fuses.

240.54. Type S Fuses, Adapters, and Fuseholders. Rated up to 30 A, plug fuses are Edison-base or Type S. 240.51(B) limits the use of Edison-base fuses to replacements of existing fuses of this type, and even then, they must be replaced if there is evidence of tampering or overfusing. Type S plug fuses are required by 240.53 for all new plug-fuse installations, and 240.52 requires new Edison-base fuseholders to be converted to Type S. These adapters are designed to go in but not come out. Once converted to Type S, an Edison-base fuseholder cannot be unconverted

without the use of a special tool that destroys the adapter in the process. An unqualified person is unlikely to successfully attempt this process. Type S plug fuses must be used in Type S fuseholders or in Edison-base fuseholders with a Type S adapter inserted, so that a Type S fuse of one ampere classification cannot be replaced with a higher-amp rated fuse (Fig. 240-33). Type S fuses, fuseholders, and adapters are rated for three classifications based on amp rating and are noninterchangeable from one classification to another. The classifications are 0 to 15, 16 to 20, and 21 to 30 A. The 0- to 15-A fuseholders or adapters must not be able to take any fuse rated over 15 A, etc. The purpose of this rule is to prevent overfusing of 15- and 20-A circuits.

Fig. 240-33. Type S plug fuse. (Sec. 240.53.)

240.60. General (Cartridge Fuses). The last sentence of part (B) must always be carefully observed. It is concerned with an extremely important matter:

The installation of current-limiting fuses demands extreme care in the selection of the fuse clips to be used. Because current-limiting fuses have an additional protective feature (that of current limitation, that is, extremely fast operation to prevent the flow of the extremely high currents which many modern circuits can produce into a ground fault or short circuit) as compared to noncurrent-limiting fuses, some condition of the mounting arrangement for current-limiting fuses must prevent replacement of the current-limiting fuses by noncurrent-limiting. This is necessary to maintain safety in applications where, for example, the busbars of a switchboard or motor control center are braced in accordance with the maximum let-through current of current-limiting fuses which protect the busbars, but would be exposed to a much higher potential value of fault let-through current if noncurrent-limiting fuses were used to replace the current-limiting fuses. The possibility of higher current flow than that for which the busbars are braced is created by the lack of current limitation in the noncurrent-limiting fuses.

240.60(B) takes the above matter into consideration when it rules that “fuseholders for current-limiting fuses shall not permit insertion of fuses that are not current limiting.” To afford compliance with the Code and to obtain the necessary safety of installation, fuse manufacturers provide current-limiting fuses with special ferrules or knife blades for insertion only in special fuse clips. Such special ferrules and blades do permit the insertion of current-limiting fuses into standard NEC fuse

clips, to cover those cases where current-limiting fuses (with their higher type of protection) might be used to replace noncurrent-limiting fuses. But the special rejection-type fuseholders will not accept noncurrent-limiting fuses—thereby ensuring replacement only with current-limiting fuses.

The very real problem of Code compliance and safety is created by the fact that many fuses with standard ferrules and knife-blade terminals are of the current-limiting type and are made in the same construction and dimensions as corresponding sizes of noncurrent-limiting fuses, for use in standard fuseholders. Such current-limiting fuses are not marked “current limiting” but may be used to obtain limitation of energy let-through. Replacement of them by standard nonlimiting fuses could be hazardous. Note that 240.60(C) covers the required markings on fuses, and in this regard pay close attention to the interrupting rating, which must always be marked if other than the default value of 10,000 A.

Class J and L fuses Both the Class J (0–600 A, 600 V ac) and Class L (601–6000 A, 600 V ac) fuses are current-limiting, high-interrupting-capacity types. The interrupting ratings are 100,000 or 200,000 rms symmetrical amperes, and the designated rating is marked on the label of each Class J or L fuse. Class J and L fuses are also marked “current limiting,” as required in part (C) of 240.60.

Class J fuse dimensions are different from those for standard Class H cartridge fuses of the same voltage rating and ampere classification. As such, they will require special fuseholders that will not accept noncurrent-limiting fuses. This arrangement complies with the last sentence of **NEC** 240.60(B).

Class K fuses These are subdivided into Classes K-1, K-5, and K-9. Class K fuses have the same dimensions as Class H (standard **NEC**) fuses and are interchangeable with them. Classes K-1, K-5, and K-9 fuses have different degrees of current limitation but are not permitted to be labeled “current limiting” because physical characteristics permit these fuses to be interchanged with noncurrent-limiting types. Use of these fuses, for instance, to protect equipment busbars that are braced to withstand 40,000 A of fault current at a point where, say, 60,000 A of current would be available if noncurrent-limiting fuses were used is a clear violation of the last sentence of part (B). As shown in [Fig. 240-34](#), because such fuses can be replaced with nonlimiting fuses, the equipment bus structure would be exposed to dangerous failure. Classes R and T have been developed to provide current limitation and prevent interchangeability with noncurrent-limiting types.

Fuseholders in main switch of motor control center require Class K-1 fuses for current limitation to protect busbars. Fuseholders furnished permit replacement of K-1 fuses with noncurrent-limiting type.

Fig. 240-34. Current-limiting fuseholders must be rejection type. (Sec. 240.60.)

Fuses marked “Class RK1” or “Class RK5” are high-interrupting-capacity types and *are* marked “current limiting.” Although these fuses will fit into standard fuseholders that take Class H and K fuses, special rejection-type fuseholders designed for Class RK1 and RK5 fuses will not accept Class H and K fuses. In that way, circuits and equipment protected in accordance with the characteristics of RK1 or RK5 fuses cannot have that protection reduced by the insertion of other fuses of a lower protective level.

Other UL application data that affect selection of various types of fuses are as follows:

Fuses designated as Class CC (0 to 20 A, 600 V ac) are high-interrupting-capacity types and are marked “current limiting.” They are not interchangeable with fuses of higher voltage or interrupting rating or lower current rating.

Class G fuses (0 to 60 A, 300 V ac) are high-interrupting-capacity types and are marked “current limiting.” They are not interchangeable with other fuses mentioned preceding and following.

Fuses designated as Class T (0 to 600 A, 250 and 600 V ac) are high-interrupting-capacity types and are marked “current limiting.” They are not interchangeable with other fuses mentioned previously.

Part (C) requires use of fuses to conform to the marking on them. Fuses that are intended to be used for current limitation must be marked “current limiting.”

Class K-1, K-5, and K-9 fuses are marked, in addition to their regular voltage and current ratings, with an interrupting rating of 200,000, 100,000, or 50,000 A (rms symmetrical). (See [Fig. 240-35.](#))

Fig. 240-35. Fuses must be applied in accordance with marked ratings. (Sec. 240.60.)

Class CC, RK1, RK5, J, L, and T fuses are marked, in addition to their regular voltage and current ratings, with an interrupting rating of 200,000 A (rms symmetrical).

Although it is not required by the Code, manufacturers are in a position to provide fuses that are advertised and marked indicating they have “time-delay” characteristics. In the case of Class CC, G, H, K, and RK fuses, time-delay characteristics of fuses (minimum blowing time) have been investigated. Class G or CC fuses, which can carry 200 percent of rated current for 12 s or more, and Class H, K, or RK fuses, which can carry 500 percent of rated current for 10 s or more, may be marked with “D,” “time delay,” or some equivalent designation. Class L fuses are permitted to be marked “time delay” but have not been evaluated for such performance. Class J and T fuses are not permitted to be marked “time delay.”

240.61. Classification. This section notes that any fuse may be used at its voltage rating or at any voltage below its voltage rating.

240.67. Arc Energy Reduction. In a major step towards evening the playing field between fuses and circuit breakers, the 2017 **NEC** began applying parallel language taken largely from 240.87 aimed at establishing mandatory requirements to reduce the incident energy of arc flash events, this time in systems relying on fusible switches for overcurrent protection. This section becomes effective at the beginning of 2020. The basic requirement stipulates that a fuse must clear in 0.07 s, which is just over 4 cycles. The value was chosen because typical zone selective interlocking arrangements [240.87(B)(1)] take about the same amount of time to function, so this seemed a fair comparison.

240.80. Method of Operation (Circuit Breakers). This rule requiring trip-free manual operation of circuit breakers ties in with that in 230.76, although this rule requires manual operation

to *both* the closed and the open positions of the CB. According to 230.76, a power-operated circuit breaker used as a service disconnecting means must be capable of being opened by hand but does not have to be capable of being closed by hand. The general rule of 240.80 requires circuit breakers to be “capable of being *closed and opened* by manual operation.” That rule also says that if a CB is electrically or pneumatically operated, it must also provide for manual operation ([Fig. 240-36](#)).

Fig. 240-36. Every CB must be manually operable. (Sec. 240.80.)

240.81. Indicating. This rule requires the up position to be the ON position for any CB. *All* circuit breakers—not just those “on switchboards or in panelboards”—must be ON in the up position and OFF in the down position if their handles operate vertically rather than rotationally or horizontally. This is an expansion of the rule that previously applied only to circuit breakers on switchboards or in panelboards. This brings the rule into agreement with that of the second paragraph of 404.7—which makes the identical requirement for *all* circuit breakers *and* switches in individual enclosures. Switches and circuit breakers in individual enclosures must be marked to clearly show ON and OFF positions and vertically operated switches and CBs must be ON when in the up position ([Fig. 240-37](#)).

V I O L A T I O N !

Fig. 240-37. Handle position of CB in any kind of enclosure must be on in the up position. (Sec. 240.81.)

240.83. Marking. Part (A) requires that the marking of a CB's ampere rating must be durable and visible after installation. That marking is permitted to be made visible by removing the trim or cover of the CB.

In part (B), the Code mandates that the ampere rating be marked on the CB's handle (or escutcheon area) when it is rated 100 A or less. Part (C) presents the same requirement that UL does with regard to the marking of the OC device's ampere interrupting rating (AIR). Where an OC device has more than a 5000 AIR, the AIR must be marked on the CB by the manufacturer.

Part (D) of this section requires that any CB used to switch 120- or 277-V fluorescent lighting be listed for the purpose and be marked "SWD" or "HID." Note that the "HID" rating is somewhat more robust, and therefore such a breaker can be used for fluorescent lighting, but the reverse is not the case and an "SWD" breaker is only good for fluorescent lighting (Fig. 240-38). In commercial and industrial electrical systems, ON-OFF control of lighting is commonly done by the breakers in the lighting panel, eliminating any local wiring-device switches. Be careful to integrate the requirements in 210.4(B) with this process on new installations. If the lighting circuits are configured as multiwire branch circuits, multipole breakers will generally be in order, and a much larger area will go off and on when the breaker operates. However, with the recent focus on energy conservation, large numbers of these lighting zones are being provided with occupancy sensors or other automated methods to run

the lights only where needed, so this is probably not the concern it was years ago.

Fig. 240-38. Circuit breakers used for switching lights must be SWD type. [Sec. 240.83(D).]

The rule of part (E) requires specific voltage markings on circuit breakers.

240.85. Applications. This section repeats UL data regarding interpretation of voltage markings. The wording explains circuit-breaker voltage markings in terms of the device's suitability for grounded and ungrounded systems. Designation of only a phase-to-phase rating—such as "480 V"—indicates suitability for grounded or ungrounded systems. But voltage designations showing a phase-to-neutral voltage by "slash" markings—like 480Y/277V or 120/240V—indicate that such circuit breakers are limited exclusively to use in grounded neutral electrical systems. Specifically, a slash-rated breaker must only be used where all ungrounded conductors to which it will be connected operate at the lower voltage to ground. This makes a real difference in a center-tapped delta system (capable of traditional three-phase 240-V connections and 120/240-V connections across one pair of phases). The other phase, the so-called high leg, will be at 208 V to ground on such systems. Any two-pole circuit breaker connected to the high leg will be (1) operating correctly in terms of line-to-line voltage, but (2) operating beyond its ratings in terms of line-to-ground voltage. A line-to-ground fault will require the breaker to clear a fault that is in progress using only one of its poles at a significantly higher voltage than it was tested.

Breakers without the slash markings are internally braced to withstand and clear full line-to-line voltage faults that can easily flow through only one pole of the breaker, particularly on corner-grounded systems. This requires a far more robust construction than the usual grounded neutral system, where any ground fault that involves only one pole will be at only the line-to-neutral voltage, and for any line-to-line short circuit the interrupting effort will be shared between two poles of the breaker. For this reason track this rule carefully when laying out jobs. Three-pole breakers are generally available without relying on a slash marking, but two-pole breakers without the slash markings are frequently only available by special order and sell at a substantial cost premium.

The last sentence in the first part of Sec. 240.85 calls attention to the marking that identifies a two-pole breaker's suitability for use on corner-grounded systems. Two-pole devices marked 240 or 480 V must be further identified by a marking "1j-3j" to be used on corner-grounded delta systems. These breakers undergo special testing, including some consideration of the "individual pole interrupting capability" discussed in the informational note at the end of the section.

240.86. Series Ratings. This section recognizes the use of the “series-rated” OC devices to ensure adequate fault-current protection. These devices, when operated in series with each other, allow the fault-interrupting capability of the main breaker, under fault conditions, to assist feeder or branch breakers that are applied at a point in the distribution system where the available fault current is greater than the AIR of the feeder or branch breaker. By sharing the arc, and operating in series, the circuit components will be provided the protection required by 110.10, even though a downstream protective device in the series may not have an adequate AIR for the point in the system where it is installed. Application of such OCPDs must satisfy the requirements given here.

When considering the concept of series rated circuit breakers, a key controversy quickly arises, and most of the changes in this part of the **NEC** over the last several code cycles have involved attempts to address this concern. This is the question of how to deal with dynamic impedance. When a circuit breaker trips and begins the process of clearing a fault, its contacts begin to separate and as they do, they draw an arc. Electrical arcs have significant impedance, and that impedance changes rapidly as the internal contacts separate. This is an oversimplification; however, the contacts of a smaller breaker, having less inertia, may open more quickly than those of a larger breaker. In the worst case, the smaller breaker can introduce just enough impedance into the circuit that the larger breaker may not unlatch, and ride out the fault. Assuming that the fault was well beyond the interrupting rating of the smaller breaker, the consequence of the upstream large breaker riding out the fault can easily result in the complete destruction of the downstream breaker.

It turns out that this process is very difficult to accurately predict by engineering modeling, even with second-order differential equations. Therefore, the circuit breaker manufacturers have resigned themselves to bench testing every conceivable combination of breakers in their product lines. The result is the “tested combinations” of 240.86(B), and the mandated marking required in 110.22(C). (See [Fig. 240-39](#) for an example.) Every combination marked on a panelboard label has been bench tested to verify that the combination of this large breaker ahead of that small breaker, ranging from comparatively low fault to the specified maximum available fault current under prescribed test conditions, will clear and both upstream and downstream devices will live to protect again after the interruption is complete. These combinations undergo intermediate testing as well as testing under maximum fault current exposures to ensure that the combination will function in accordance with applicable standards under any overcurrent applied, not just bolted fault conditions. If a combination fails, the manufacturer has two choices: either leave that combination off the label, or make subtle changes in its breakers so the combination will pass reliably.

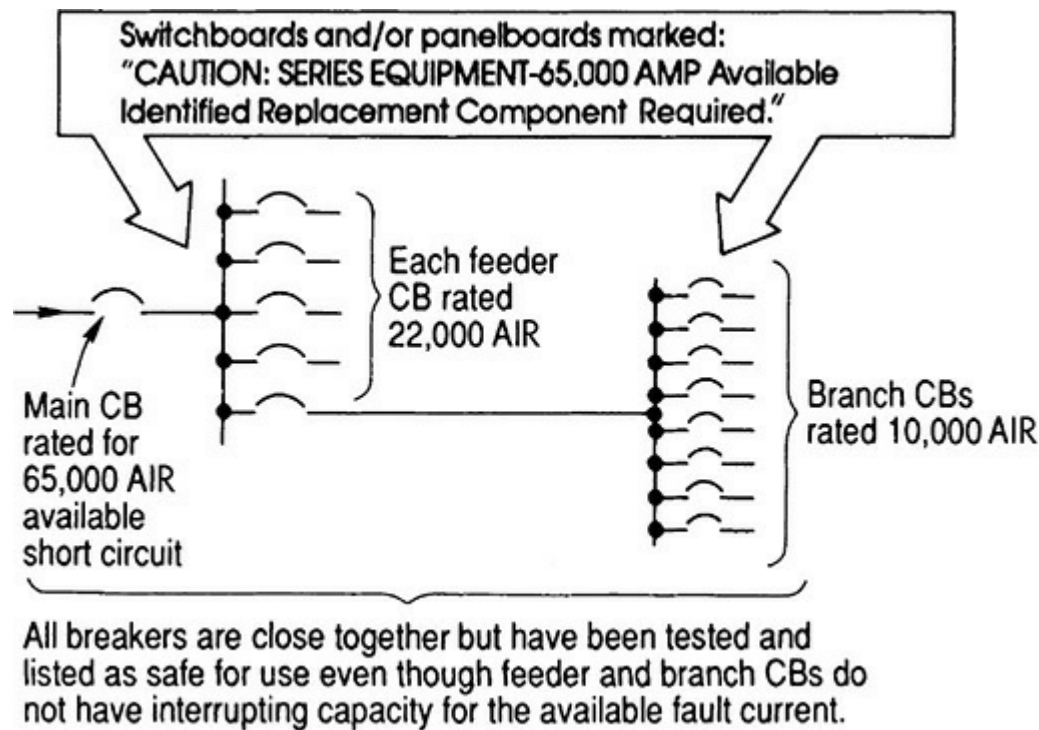

Fig. 240-39. An “additional series combination interrupting rating” must be “marked” on equipment. (Sec. 240.86.)

However, not all combinations, particularly combinations involving obsolete breakers, can be tested, and available fault currents steadily increase as the utility infrastructure stiffens in response to population increases and demands for increased reliability. If that upgrade crosses the previously designed available fault current line at a major industrial facility, the result is that large sections of the facility distribution system may drop dangerously below the interrupting ratings of the existing protective devices. To preserve safety, the facility must now consider buying and installing completely new gear with available fault current ratings that ensure appropriate performance under all overcurrent conditions. This process could involve, quite clearly, an astronomical expense.

That being the case, facilities that have been confronted by this exposure have tried to find a way to address it in some other way, and the fuse industry would love to be part of the solution. For decades the fuse industry has published “let through” calculations and data on its products. The customary approach is what is called an “up-over-and-down” analysis using published current-limiting graphs for the style of fuse considered. Beginning with the available rms fault current on the horizontal axis, read straight up to the diagonal index line for the proposed fuse size, then straight over to a line at a 45° slope, and then read straight down to the horizontal axis once again. The number there is the worst-case let-through rms current for the fuse in question when it is applied in the system being analyzed. If that number is less than interrupting rating of the old circuit breakers, can the problem be solved by adding a fuse?

Not necessarily because the dynamic impedance problem can defeat this design. If, and only if the circuit breaker can be guaranteed to not unlatch for several cycles, then yes, problem solved. And there are some old air-frame power breakers that won’t unlatch for three cycles or so, giving the fuse time to clear the fault. But modern molded case circuit breakers have mechanisms, even those that aren’t officially current limiting, that have internal current paths for which the magnetic forces on large faults tend to oppose each other and blow the contacts apart. The fault is often not a bolted fault but an arcing fault. If that happens and the arc adds enough impedance to take the current below the

current-limiting range of the fuse, then the fuse will delay its response and the breaker will take the hit. It is not always impossible to design for this, but frequently very difficult to impossible. This brings us to current **NEC** requirements.

In addition to bench-tested combinations in 240.86(B), there now exists a procedure to field engineer a series-connected rating, as given in 240.86(A). There are significant restrictions on this approach. First, the procedure can only be used in an existing facility. It must be designed by a licensed professional engineer with appropriate training. He or she must document the selection and stamp the design, which must be made available to the local inspector and all others who will be working with the system. The rating, including the identity of the downstream device, must be field marked on the end use equipment in the manner specified in 110.22(B).

This entire issue continues as one of the most difficult to address in the history of the **NEC** for a particularly compelling reason. Both sides are right. The circuit breaker manufacturers are right to object to oversimplifications by some who market fuses. And the fuse manufacturers are right to point to the astronomical expenses involved in reworking existing plant, and the existence of at least some applications that seem amenable to field engineering. Remember that 90.1(B) doesn't promise electrical installations will be free from hazard, only that they will be essentially free from hazard. So the limited engineering approach has merit, but just when this author was getting comfortable with the 2005 **NEC** provisions that ushered this approach into the **NEC**, along comes documented adverse experience where a facility applied the field engineering process. The methodology appeared to this author to have been competent. Fortunately, the owner was willing to pay to have the engineered combination tested. All five tests failed and the project was redesigned with a separate transformer vault that subdivided the load through smaller gear and avoided the problem. Had the actual bench testing not been done, the engineer would have stamped the plans and this system would be in service today.

To this end, the **NEC** now incorporates an additional paragraph that requires the engineer to *ensure* that the downstream breaker(s) that are part of the series design remain passive while the upstream current-limiting device is interrupting the fault. It remains to be seen how many engineers will put their professional status on the line to offer such assurances. It is significant that both the UL and NEMA representatives on the panel remain opposed to this procedure. Of equal significance is the fact that the allowance remains in the **NEC**, having retained the necessary consensus of the panel. Remember, both sides are right. This controversy will continue.

Part (C) in this section addresses the concern related to applications where motor contribution to downstream faults may render the “lower-rated” device incapable of safely clearing the faulted circuit. Remember that at the instant of an outage a rotating motor is a generator, fully capable of adding current. Any short-circuit current study necessarily considers motor contributions to the fault current available. In any application of “series-rated” OC devices, if the “sum” of motor full-load currents that may be contributed to the lower-rated device—without passing through the higher-rated device—exceeds the lower-rated device's rating by 1 percent (e.g., 100 A of contributed motor current to a 10,000-AIR device), then series-rated devices may *not* be used. This disqualification applies to both bench-tested applications in (B) and to field engineered combinations in (A) because the parent language in the section requires compliance with (A) or (B) as applicable, and (C) in all cases.

240.87. Arc Energy Reduction. Some sophisticated power circuit breakers include features

that allow the breaker's normal instantaneous pickup to be retarded or shut off. For a breaker in an upstream position, this might be desired in order to allow it to selectively coordinate with downstream levels of the distribution, as is now required by 700.32 and a few other articles. There are drawbacks to doing this centering on the increased amount of damage that could be done during an arcing failure, and the increased amount of incident energy capable of injuring a worker if the equipment must be worked hot for any reason.

The 2011 **NEC** recognized these breakers for the first time, and to counteract this drawback mandates the use of additional features in an attempt to counteract them. The 2014 **NEC** added a significant limitation in that this section is now limited to circuit breakers that have a maximum trip setting greater than or equal to 1200 A, and the 2017 **NEC** added more options. One of the six specified strategies (or an approved alternative) must be in place, and there must be documentation available for those who work on or inspect the system showing where such breakers are located.

The first strategy is zone-selective interlocking. This uses a process of communication between an upstream and downstream breaker. When the downstream breaker detects a current rise it signals the upstream breaker not to open and the upstream breaker restrains its operation accordingly. If the fault is between the two breakers, there will be no signal from the downstream breaker and the upstream breaker will exercise its instantaneous function and trip.

The second approach uses relaying to compare the current on the line side of the upstream breaker with the current leaving the downstream breakers collectively. If there is no difference, then the fault cannot be in the intervening feeder and the upstream breaker restrains its operation accordingly. If there is a difference in current, the instantaneous trip function in the upstream breaker activates. Note that this concept and an explanatory note currently reside at 240.92(C)(1)(2).

The third approach involves a manual activation of a control function on the upstream breaker to restore its instantaneous trip capability during a maintenance activity. When the instantaneous function is active, the amount of incident energy possible during a failure is reduced, possibly allowing a reduced hazard risk category exposure for energized work if it is required. If this is done, the status of the control must be clearly indicated. During the maintenance period, selective coordination will have been lost.

The fourth approach was new in the 2014 **NEC** and relies on an "energy-reducing active arc flash mitigation system." This is only somewhat explained in its associated informational note. These systems typically involve the retrofit of some form of rapid-acting interrupting mechanism, perhaps using a vacuum circuit breaker on the medium voltage side of the local unit substation, which has been engineered to act in conjunction with current transformers on the secondary side and a microprocessor supported relay package. The systems are designed to mitigate the amount of energy released in an arc flash event. By way of example, one major manufacturer's literature provides an example of a reduction in arc flash potential from 2-second duration and 62 Cal/sq . cm. incident energy to 0.18-second duration and 5.7 Cal/sq . cm. incident energy.

The fifth and sixth options are new as of the 2017 **NEC** and involve instantaneous trip settings or overrides that are less than the available arcing current. They focus on coordinating the instantaneous trip settings of the breaker such that it is less than the "available arcing current." If this can be arranged, then the amount of fault energy available to an arc will be reduced, which is the focus of this section. Instantaneous trip settings typically run between a half cycle for molded case breakers to three cycles for the older "air-frame" breakers. New Informational Note No. 3 explains the role of instantaneous trip settings, and new Note No. 4 cites an IEEE publication that describes how to

perform arc flash hazard calculations.

All of these approaches are controversial. There is considerable debate in the engineering community about the effectiveness and practicability of these schemes during a high-level fault, when these coordinating functions must successfully proceed in a time interval that is on the order of milliseconds. They also burden a distribution system based on circuit breakers when a comparable fusible distribution, typically based on large Class L fuses, will often have even higher amounts of let-through energy. In fairness, the development of 240.67 in the 2017 cycle does address this question.

Part VIII. Supervised Industrial Installations A supervised industrial installation is limited to the industrial portions of a facility that meet the following three criteria:

- There is qualified maintenance and engineering supervision such that only qualified personnel are running the system.
- The premises electrical system supporting the industrial processes or manufacturing activities or both (and not including any office or other indirect support loads) has a calculated load per Art. 220 that is not less than 2500 kVA.
- The premises electrical system is comprised of not less than one service or feeder that runs over 150 V to ground and over 300 V phase-to-phase.

These installations must comply with all requirements in Art. 240, except as modified in this part. And any such modifications that are applied in the facilities must not extend beyond the manufacturing or process control environment.

240.91. Protection of Conductors. This provision, new as of the 2011 **NEC**, amends 240.4(C) in these supervised environments by allowing limited protection of large conductors above their Table 310.15(B)(16) ampacity. Specifically covering overcurrent devices rated over 800 A, if the conductor ampacity in the proposed application is at least 95 percent of the next higher size overcurrent device [or setting, as covered in 240.6(C)], that next higher rating or setting is allowed.

This allowance only applies in the context of an overcurrent coordination study that establishes short-circuit time/current exposures for the proposed conductors and demonstrates that they would be safely protected. In addition, the overcurrent devices must be listed and marked for the application.

This section is nothing but an elaborate attempt to use 500 kcmil conductors in applications that would otherwise require 600 kcmil conductors. The Table 310.15(B)(16) 75°C ampacity for 500 kcmil wires is 380 A, which just happens to be 95 percent of 400. If you are wiring a large feeder (1200, 1600, 2000 A or higher), this section would allow the use of multiple runs of 500 kcmil instead of the current practice of using 600 kcmil conductors.

The first condition appropriately addresses how the conductor can be expected to perform while it is in use. The second condition implicitly addresses the other side of the equation, namely, how the overcurrent protective device will perform with diminished conductor sizes connected to it.

Remember that the reason for 110.14(C) limits has to do with the ability of connected conductors to function as heat sinks for the devices connected to them. A reduction from 600 to 500 kcmil is very significant in this regard. This is why the equipment *at both ends of the wiring* must be “listed and marked for the application.”

The costs involved in product development, testing, and distribution of this sort of these product lines are enormous and the number of potential applications in these supervised environments is small. It is extremely unlikely that such equipment will come to market. And it bears restating, that *both* the originating overcurrent device *and* the terminating device or other equipment must have been

so evaluated, listed, and marked.

The next section, 240.92, covers the principal impact of Part VIII. This section makes significant modifications to the tap rules in 240.21, as follows:

240.92(B) provides that a short-circuit analysis can be performed based on the short-circuit current rating of the conductors to be protected, using a table that is long familiar to the electrical engineering community but that was new to the **NEC** as of the 2008 cycle. If sensors are arranged to monitor the variables that make up the table formulas, then there will be no adverse outcome. The three eligible taps for this treatment are the 25-ft taps in 240.21(B)(2), the combined primary and secondary 25-ft taps in 240.21(B)(3), and the high-bay manufacturing facility taps in 240.21(B)(4).

240.92(C) allows transformer secondary conductors to be protected using an approach that divorces the short-circuit and ground-fault protection from the overload protection function. The short-circuit and ground-fault protection can be arranged in one of three ways by 240.92(C)(1). The first option liberalizes the winding-ratio limitation of 240.21(C)(1) by allowing secondary conductors, even those extended from a multiwire secondary, to run up to 30 m (100 ft) with primary side protection only, set at not more than 150 percent of tap ampacity after adjusting for the winding ratio. The second option recognizes a differential current relay arranged to operate a shunt-trip mechanism on the upstream overcurrent device. The third option is to verify under engineering supervision that the system as configured will protect the conductors under short-circuit and ground-fault conditions; the new Table 240.92(B) would be one tool in this analysis.

Of course, there is another half of this puzzle, involving overload protection. There are four options per 240.92(C)(2) to provide this protection, the simplest being to terminate in a single overcurrent device sized to the conductor ampacity. Almost as simple is to terminate at a group of protective devices selected so the sum of all their ratings doesn't exceed the conductor ampacity. Although based on 240.21(C)(3), there is no limit on the secondary conductor length. The devices must be grouped, and not exceed six, which also happens to be the limit of the sum-of-the-ratings rule for transformer secondary protection in Notes #2 to the 450.3 protection tables. Remember, nothing in this article can amend the transformer protection rules in Art. 450. If taps to the individual devices are needed, the fact that that limitation also occurs in 240.21 suggests that these smaller taps are also permitted here. The other two approaches, using overcurrent relaying or engineering supervision, directly parallel the comparable provisions for short-circuit and ground-fault protection.

The third issue, covered in 240.92(C)(3) is to provide physical protection for the conductors by enclosing them in a raceway or "by other approved means." This rule directly tracks comparable rules in numerous places in 240.21.

The next major modification involves rules for outside feeder taps as covered in 240.92(D). This rule largely parallels comparable coverage in 240.21(B)(5) and 240.21(C)(4). There is one major departure, that being the normal requirement for a single device at the building termination does not apply. Instead up to six devices can be grouped, with the required protection to comprise the sum of the ratings of the terminating devices.

The final major change, 240.92(E), completely removes 240.21(C)(1) from consideration because in this case the primary protection for the transformer, after being re-proportioned by the winding ratio, is allowed to protect secondary conductors whether or not there is a multiwire secondary.

240.100. Feeders and Branch Circuits (Over 1000 V, Nominal). This section and 240.101 present rules on overcurrent protection for medium-voltage (over 1000 V) feeder conductors. It requires overcurrent protection located at the point of supply, or elsewhere if the

alternate location has been designed under engineering supervision based on fault current analysis, conductor damage curves, and coordination analysis as required. The overcurrent protection can be in the form of fuses or using CTs and relays. Although the rule calls for “short-circuit” protection, it does *not* require that conductors be protected in accordance with their rated ampacities (Fig. 240-40). Remember that the ampacity rules for medium-voltage feeders as given in 215.3(B) and in 210.19(B) for branch circuits pretty much assure that overloads are unlikely. By long history, the overcurrent protection rules here focus on short circuits and ground faults.

TYPE OF DEVICE

REQUIRED MINIMUM RATING

ARTICLE 250. GROUNDING AND BONDING

250.2. Definitions—Bonding Jumper, Supply-Side. This new definition for the 2011 NEC describes a conductor on the supply side of a power source, whether a service or a separately derived system, or within service equipment, whose function is to provide the required low-impedance pathway between metallic elements of the system requiring grounding continuity.

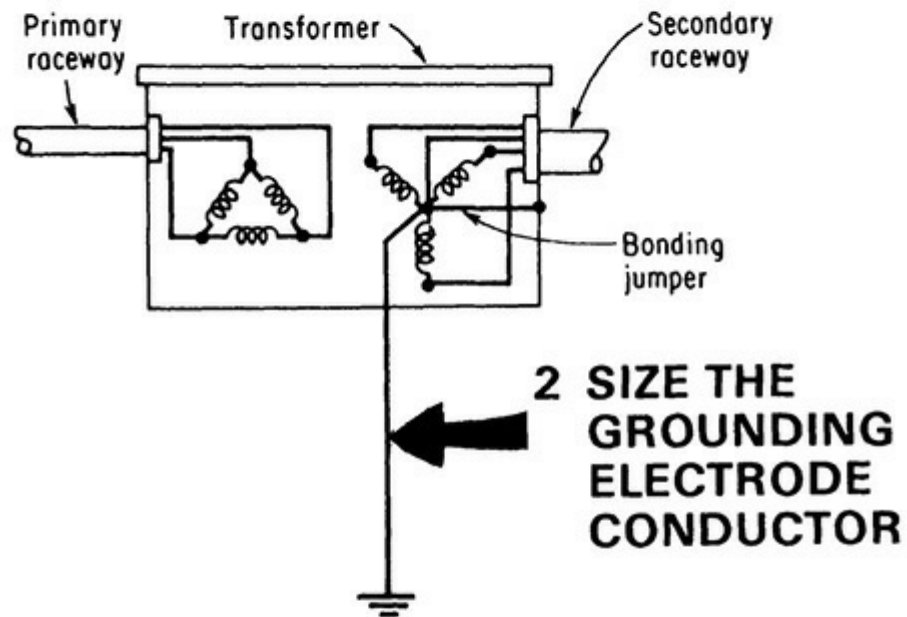

These conductors were previously described as “equipment bonding jumpers” and were covered

in 250.30(A)(2) and 250.102(C). The problem was that when installed on the load side of associated overcurrent devices they were part of the equipment grounding system and sized under 250.122 [see 250.102(D)]. When installed on the supply side of the main overcurrent device (whether for a service or separately derived system) their only function was bonding and they were sized per 250.102(C). To avoid confusion, these separate applications (before and after the main disconnect and overcurrent protection) are now uniquely defined, and the old term “equipment bonding jumper” only applies on the load side of the main. See [Fig. 250-21](#) and the discussion at 250.30(A)(2) for more information.

STEP 1 – BONDING JUMPER

STEP 2 – GROUNDING ELECTRODE CONDUCTOR

STEP 3 – GROUNDING ELECTRODE

Fig. 250-21. Grounding a transformer secondary. (Sec. 250.30.)

250.4. General Requirements for Grounding and Bonding. This section creates an overall context for everything that follows in the article, because it sets the performance requirements for grounding and bonding. That is, it sets out what grounding and bonding are supposed to achieve in an electrical system. The prescriptive requirements that comprise the remainder of the article constitute the methods which, if followed, will result in the electrical system achieving the objectives stated here.

One of the most important, but least understood, considerations in design of electrical systems is that of grounding. The use of the word *grounding* comes from the fact that part of the technique involves making a low-resistance connection to the earth. Remember that “ground” has been redefined to simply mean the earth, as in the planet. The term *grounding* also refers to the “safety ground” that facilitates sensing of faults and provides for automatic operation of the circuit OCPDs by ensuring a low-impedance return path in the event of a fault, but this is only true for grounded systems, and not all systems are grounded. *Bonding* is the process of interconnecting parts such that electrical continuity and conductivity are assured. Specific rules then require bonding noncurrent-carrying metallic components of the distribution system to each other and, in some instances, to noncurrent-carrying components of other systems, such as metal ladders and diving boards at swimming pools, to ensure all noncurrent-carrying metal pieces are at a common potential with respect to ground.

These are examples of an “effective ground-fault current path” which is an intentionally constructed low-impedance path that has been designed to carry ground-fault current safely from the fault location to the electrical supply source. It will facilitate the prompt operation of OCPDs on a grounded system. It will also cause the operation of ground-fault detectors on high-impedance grounded systems and also on ungrounded systems, which, in general, must now be incorporated. It will also provide a safe path for current between two phases of an ungrounded or high-impedance grounded system in the event of two ground faults from different phases in different locations.

For any given piece of equipment or circuit, the connection to earth may be a direct wire connection to the grounding electrode that is buried in the earth; or it may be a connection to some other conductive metallic element (such as conduit or switchboard enclosure) that, through bonding as required in this article, is electrically connected to a grounding electrode.

The combined purpose of grounding and bonding is to provide protection of personnel, equipment, and circuits by largely eliminating the possibility of continuing dangerous or excessive voltages that could pose a shock hazard, and that could damage equipment in the event of overvoltage imposed on the conductors supplying such equipment.

There are two distinct considerations in grounding for grounded electrical systems, covered in Part (A) of this section: grounding of one of the conductors of the wiring system, and grounding of all metal enclosures containing electrical wires or equipment, where an insulation failure in such enclosures might place a potential on the enclosures and constitute a shock or fire hazard. The types of grounding are:

1. *Wiring system ground.* This is covered in (A)(1) and consists of grounding one of the wires of the electrical system, such as the neutral, to limit the voltage upon the circuit that might otherwise occur through exposure to lightning or other voltages higher than that for which the circuit is designed. Another purpose in grounding one of the wires of the system is to limit the maximum voltage to ground under normal operating conditions. Also, a system that operates with one of its conductors intentionally grounded will provide for automatic opening of the

circuit if an accidental or fault ground occurs on one of its ungrounded conductors (Fig. 250-1).

Fig. 250-1. Operating a system with one circuit conductor grounded. (Sec. 250.1.)

A new informational note at this location calls attention to the fact that an important aspect of limiting the voltage to ground includes keeping grounding electrode conductors as short as possible consistent with making the required connection, and in particular avoiding loops and bends as much as possible. This avoids high-frequency reactance issues that are not problems at 60 Hz, but are very significant on lightning transients and the like. Although lightning is inherently a dc event, it is a rapidly interrupted dc event capable of Fourier analysis that approximates a 1000-Hz signal. Loops and long-circuit lengths have progressively higher impact on increasing impedance as the frequency increases. The wording about disturbing the permanent parts of the installation suggests that heroic measures such as drilling partitions and block walls are unnecessary, but the straighter and shorter the path, the better, all things being equal. **NFPA 780**, the *Standard for the Installation of Lightning Protection Systems*, also addresses this topic for the same reason.

2. *Equipment ground or "safety" ground.* This is covered in (A)(2), (A)(3), (A)(4), and (A)(5) on grounded systems. The first topic is the grounding objective, by which noncurrent-carrying metal parts that enclose electrical equipment or conductors, or that comprise such equipment, are connected to earth to limit the voltage to ground on such materials. In conjunction with this process is the bonding objective, which results in the same materials connected together to establish both conductivity and continuity across the entire system, and in the process establishes an effective ground-fault current path that will allow the current to flow such that the operation of the automatic operation of the overcurrent protective device is facilitated (Fig. 250-2). This path must be capable of safely carrying such currents wherever they are imposed and running back to the source of the supply system.

Fig. 250-2. Equipment grounding is interconnection of metal enclosures of equipment and their connection to ground. [Sec. 250.4(A)(3).]

In a grounded electrical system with a ground-fault current path that has excessive impedance due to installation or maintenance issues, if one of the phase conductors of the system (i.e., one of the ungrounded conductors of the wiring system) should accidentally come in contact with one of the metal enclosures in which the wires are run, it might produce a condition where not enough fault current would flow to operate the overcurrent devices. In such a case, the faulted circuit would not automatically open, and a dangerous voltage would be present on the conduit and other metal enclosures. This voltage presents a shock hazard and a fire hazard due to possible arcing or sparking from the energized conduit to some grounded pipe or other piece of grounded metal. Section 250.4(A)(5) places three requirements on these connections so the system will operate as intended.

1. That every effective ground-fault current path be installed by proper mounting, coupling, and terminating of the conductor or raceway intended to serve as the grounding conductor. Also, the condition can be visually checked by the electrical inspector, the design engineer, and/or any other authority concerned.
2. That every grounding conductor be "capable of safely carrying the maximum ground-fault

current likely to be imposed on it” can be established by falling back on those other Code rules [Secs. 250.24(B), 250.28, 250.30, 250.66, 250.122, 250.166, 680.25(A)(D)(E), etc.] that specifically establish a minimum required size of grounding conductor. Although it is reasonable to conclude that adequate sizing of grounding conductors in accordance with those rules provides adequate capacity, such may not always be the case. Where high levels of fault current are available, use of the Code-recommended “minimum” may be inadequate. There are available a number of recognized methods promulgated by such organizations as the International Electrical and Electronic Engineers (IEEE) that can be consulted to determine if the Code-prescribed minimum size of grounding conductor actually is adequate and capable of “safely carrying the maximum fault.” If Code-prescribed minimums cannot safely carry the available fault current, it certainly seems as if it would be a violation of this rule to use a grounding conductor of the Code-prescribed size.

3. When we come to a condition put forth by part **(A)(5)** of Sec. 250.4, “creates a low-impedance circuit facilitating the operation of the overcurrent device” questions arise as to the intent of the rule; and whether specific testing is required to evaluate the result. Here again the answer is in the parent text, namely that if the prescriptive requirements in the article are met, then compliance is usually assumed for enforcement purposes. However, that is not always the case. For example, if the equipment grounding conductor is a wire sized to Table 250.122 limits, and if it could be demonstrated that given the length of run or for any other reason even a solid ground fault would not draw enough current to put the circuit breaker into its instantaneous tripping range, then the note at the bottom of that table would support increasing the size of the equipment grounding conductor or taking other steps to decrease the impedance so the overcurrent device would act promptly. There are a number of software programs that will make these calculations for a variety of grounding conductors including the various steel tubular raceways (Fig. 250-3). To *know* for sure that impedance of any and every grounding conductor is “sufficiently low to limit ... etc.” requires that the actual value of impedance be measured; and such measurement not only involves use of testing equipment but also demands a broad and deep knowledge of the often sophisticated technology of testing in circuits operating on alternating current where inductance and capacitance are operative factors. In short, what is “a low-impedance circuit” and what does “facilitating the operation of the overcurrent device” mean? And if testing *is* done, is it necessary to test every equipment grounding conductor? In the end, comply with the prescriptive rules in Art. 250 unless there is compelling reason to go beyond them, and in the real world the installers and the inspectors will usually be on the same page. However, thinking about these questions is important because it positions you to respond to questions that may arise.

The earth must not be used as a sole equipment grounding conductor.

Fig. 250-3. These are violations of the basic concept of effective grounding. (Sec. 250.4.)

The last sentence in this section prohibits the use of current flow through the earth as the sole

equipment grounding conductor because earth impedance is too high and restricts fault-current flow, as shown at the bottom of Fig. 250-3. Inspectors as well as computer, telecommunications, data systems, and CATV installers have often overlooked this very important Code rule. The one thing to remember with current flow through earth is that it can do no appreciable “work”—it won’t light a 40-W bulb—but, it can and will kill!

4. *Bonding*. This term refers to connecting components together in such a manner as to ensure conductivity and continuity. Once this is done, such components may have other functions as defined subsequently in the article.

Simply stated, grounding of all metal enclosures of electric wires and equipment minimizes any potential above ground on the enclosures. Such bonding together and grounding of all metal enclosures are required for both grounded electrical systems (those systems in which one of the circuit conductors is intentionally grounded) and ungrounded electrical systems (systems with none of the circuit wires intentionally grounded).

Effective equipment grounding is extremely important for grounded electrical systems to provide the automatic fault clearing that is one of the important advantages of grounded electrical systems. A low-impedance path for fault current is necessary to permit enough current to flow to operate the fuses or CB protecting the circuit.

Note that 250.4(A)(4) addresses the “bonding” of other metallic building components and systems that are “likely” to become energized. These connections are not truly ground-return paths because the impedance of such connections is unknown. The return path through building steel or a metal water piping system will be quite high because each item is not necessarily in close proximity to the phase conductors, which of course will result in a higher impedance. However, it is better to make such connections than to leave the steel and piping at a potential above ground should a fault energize them. Depending on the rating of the OC device protecting the faulted circuit, there may be enough current flow to trip the protective device.

Part (B) of this section covers ungrounded systems. These rules omit any counterpart to 250.4(A) (1) because there is no system grounding by definition. However, the bonding and grounding rules are comparable. Although these systems are not set up to facilitate the operation of an overcurrent device in the event of a ground fault, they absolutely must provide a low-impedance path for fault current. If the insulation on one phase conductor fails at one end of the plant, and a similar failure occurs at the other end of the plant on a different phase before the first failure is cleared, the result is a line-to-line short circuit over the intervening equipment grounding system. If a very high standard of workmanship was not adhered to, such an event will produce elevated voltages on metal raceways, etc., and dangerous showers of sparks at every random locknut or other joint not made wrench tight in accordance with 250.120(A).

250.6. Objectionable Current. Although parts (A) and (B) of this section permit “arrangement” and “alterations” of electrical systems to prevent and/or eliminate objectionable flow of currents over “grounding conductors or grounding paths,” part (D) specifically prohibits any exemptions from NEC rules on grounding for “electronic equipment” and states that “currents that introduce noise or data errors” in electronic data-processing and computer equipment are not “objectionable” currents that allow modification of grounding rules.

This paragraph emphasizes the Code's intent that electronic data-processing equipment has its input and output circuits in full compliance with all **NEC** rules on neutral grounding, equipment grounding, and bonding and grounding of neutral and ground terminal buses. 250.6(B) does offer alternative methods for correcting "objectionable current over grounding conductors," but part **(D)** specifically states that such modifications or alternative methods are not applicable to the on-site wiring for electronic or data processing equipment if the only purpose is to eliminate "noise or data errors" in the electronic equipment. This paragraph amplifies the wording of "Premises Wiring" as given in Art. 100.

250.8. Connection of Grounding and Bonding Equipment. This rule has been reformatted and significantly expanded to better cover the topic. There are now eight possibilities for making these attachments, and in a rather obvious 2014 **NEC** clarification, one or more of them can be used. Note that 250.12 still requires clean surfaces unless the attachment means digs through the paint. This is more likely for a locknut than a small screw.

1. *A listed pressure connector.* This includes conventional twist-on-wire connectors, settling a long-standing controversy. One side contended that, with the exception of the green-style connectors with the hole in the end of the connector that are specifically listed for grounding, other such connectors must not be used. The opposite side said that since any fault current passed through conventional connectors on the way to the fault, they should be acceptable for use in the path returning from the fault. Now we know that the second side won the argument.
2. *A terminal bar.* This is common in panels, switchboards, and motor control centers, and also in boxes where other **NEC** rules such as 680.23(F)(2) forbid conventional splicing devices.
3. *A pressure connector listed as grounding and bonding equipment.* These include the green twist-on connectors referred to in item 1 above. Ground-rod clamps and water pipe clamps would also fit in this category.
4. *A connection made by the thermite ("exothermic welding") process.*
5. *A machine screw that engages no fewer than two threads.* For example, conventional steel boxes are 1.59 mm ($\frac{1}{16}$ in.) thick per 314.40(B). A 10-32 screw with 32 threads per inch will have a thread every $\frac{1}{32}$ nd of an inch, and thereby engage two threads in the box. If the metal wall of the enclosure is less than this, as many panels are, there are several options, the best being to only use the screws provided by the manufacturer, who will have anticipated this problem. If that doesn't work, the **NEC** allows you to substitute a nut. If getting behind the enclosure is a problem, try making a small, recessed, steeply angled dimple in the enclosure wall with a prick punch. Then drill the center of the now conical indent with the No. 21 tap drill. When you tap the hole, the tap will engage the bottom sides of the cone as well as the enclosure wall itself. As long as there is at least one good thread in the bottom of the cone formed by the prick punch, a 32-pitch screw will meet this rule, since for sure there will be one more thread in the drilled hole in the enclosure wall making the required total of two.
6. *A thread-forming machine screw under the same requirements as discussed in item 5 above.* Note that this is not a "teck" screw with sheet metal threads. This is a thread forming screw, but with machine threads. They are self-tapping and some (not all) come with drill points that avoid the need for a separate drill bit. Sheet-metal screws must not be allowed and are not recognized. Their thread pitch is far too coarse to produce enough force to reliably hold the connector in place, since any screw is an inclined plane wrapped around a shaft and thus the

mechanical advantage decreases as the pitch coarsens.

7. *A connection that is part of a listed assembly.* Many assemblies come equipped with grounding terminals already part of the equipment. These can be used in accordance with the listing, and the test lab will have evaluated the likely connections at this point as part of the listing process.

8. *Other listed means.* This opens the door for other approaches, provided they are listed.

250.10. Protection of Ground Clamps and Fittings. This rule addresses the need to ensure that grounding connections are protected from physical damage. Obviously, no protection is required where the connection is not subject to damage, such as where it is made within an enclosure. However, where a physical damage potential exists, a fabricated enclosure of wood, metal, or the “equivalent” can be used to protect those connections that may be vulnerable to physical damage. Exactly what constitutes the equivalent will be up to the authority having jurisdiction, usually the local electrical inspector, as will any determination of what is subject to potential damage.

250.20. Alternating-Current Systems to Be Grounded. Part (A) does recognize use of ungrounded circuits or systems when operating at less than 50 V. But system grounding of circuits under 50 V is sometimes required, as shown in Fig. 250-4. Note that if (and only if) system grounding is required, 250.112(I) will then require that equipment grounding be implemented on the low-voltage circuit.

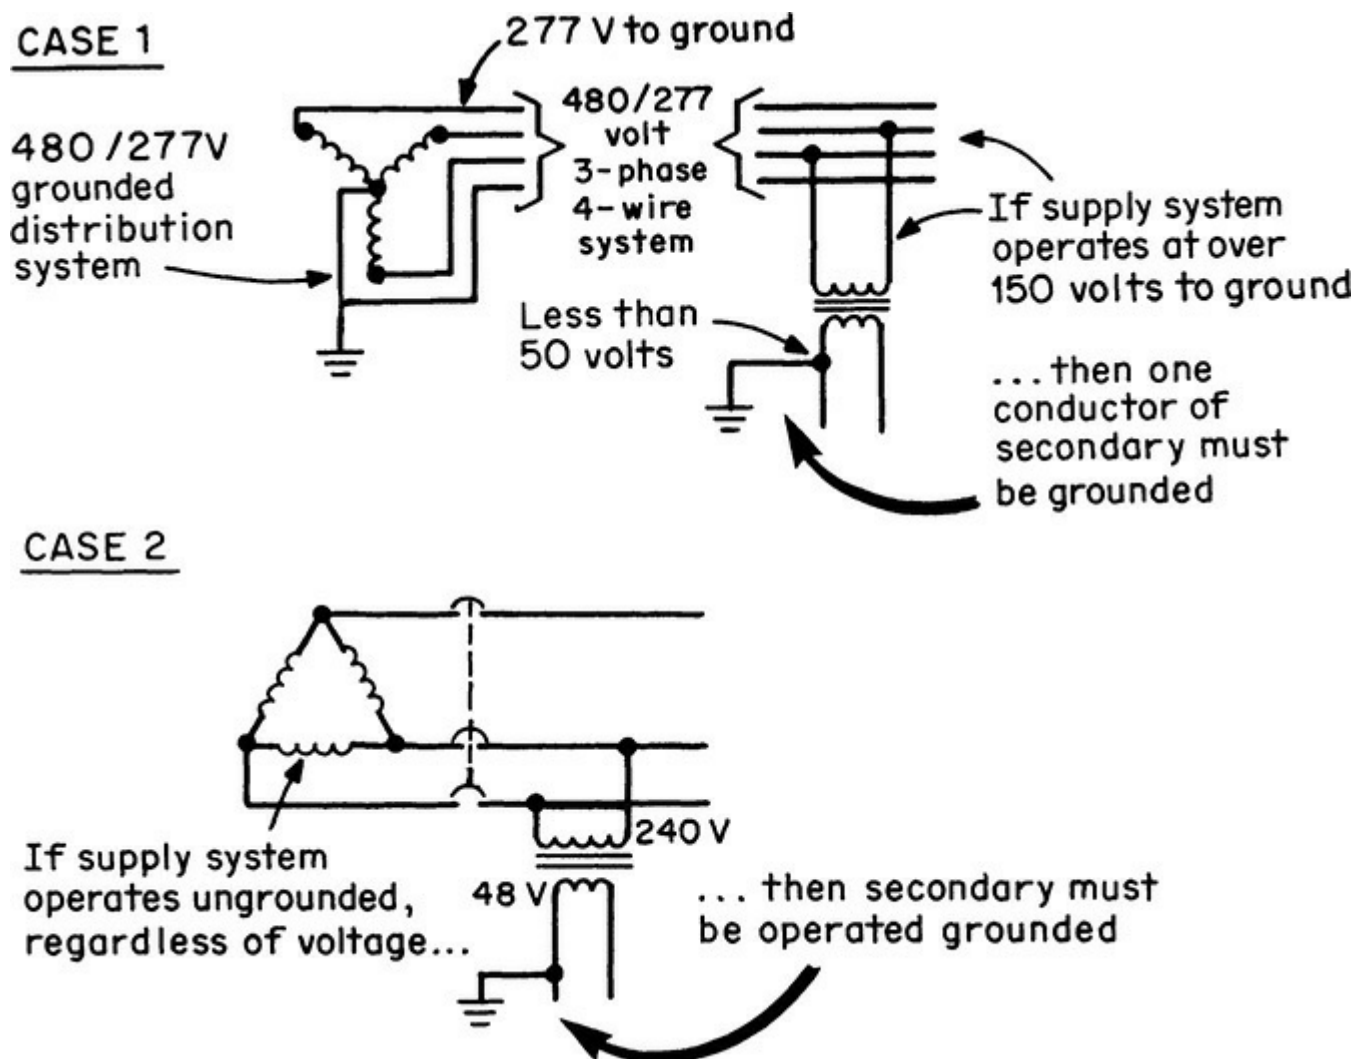

Fig. 250-4. Circuits under 50 V may have to be grounded. (Sec. 250.20.) In addition to the two cases illustrated above, system grounding is also required if the transformer primary conductors came in

from outdoors as overhead conductors.

According to part **(B)(1)** of this rule, all alternating-current wiring systems from 50 to 1000 V *must* be grounded if they can be so grounded that the maximum voltage to ground does not exceed 150 V. This rule makes it *mandatory* that the following systems or circuits operate with one conductor grounded:

1. 120-V, 2-wire systems or circuits must have one of their wires grounded.
2. 120/240-V, 3-wire, single-phase systems or circuits must have their neutral conductor grounded.
3. 208Y/120-V, 3-phase, 4-wire, wye-connected systems or circuits must be operated with the neutral conductor grounded.

In all the foregoing systems or circuits, the neutrals must be grounded because *the maximum voltage to ground does not exceed 150 V* from any other conductor of the system when the neutral conductor is grounded.

In parts **(2)** and **(3)** of this section, all systems of any voltage up to 1000 V must operate with the neutral conductor solidly grounded whenever any loads are connected phase-to-neutral, so that the neutral carries load current. All 3-phase, 4-wire wye-connected systems and all 3-phase, 4-wire delta systems (the so-called *red-leg systems*) must operate with the neutral conductor solidly grounded if they are used as a circuit conductor. That means:

1. The neutral conductor of a 240/120-V, 3-phase, 4-wire system (with the neutral taken from the midpoint of one phase) must be grounded.
2. It is also mandatory that 480Y/277-V, 3-phase, 4-wire interior wiring systems have the neutral grounded if the neutral is to be used as a circuit conductor—such as for 277-V lighting.
3. Also, if 480-V autotransformer-type fluorescent or mercury-vapor ballasts are to be supplied from 480/277-V systems, then the neutral conductor will have to be grounded at the voltage source to conform to 410.138, even though the neutral is not used as a circuit conductor. Of course, it should be noted that 480/277-V systems are usually operated with the neutral grounded to obtain automatic fault clearing of a grounded system ([Fig. 250-5](#)).

Fig. 250-5. Some systems or circuits must be grounded. (Sec. 250.20.)

As covered by the rule of part (C), any ac system of 1000 V or more must be grounded if it supplies portable equipment. Otherwise, such systems do not have to be grounded, although they *may* be grounded. There are several forms of system grounding that can be applied to medium-voltage systems, as covered in Part X of Art. 250. Because of the higher voltages involved, substantial amounts of current will flow into the earth in the event of a failure on a grounded system, whether solidly grounded using either single-point grounded neutrals or multigrounded neutrals, or impedance grounded. Engineers take this into account to design protective designs that address lack of customer tolerance to outages through high-impedance grounding, or lack of tolerance for fault damage through low-impedance grounding. The amount of ground-fault current flow provides enough headroom to design relaying that allows for orderly shutdowns, or shuts down automatically but at current levels that will not cause extensive system damage.

A very important permission is given in 250.20(D). This rule, by recognizing the requirements in 250.36 (or 250.186 for medium voltage), correlates this section with the high-impedance grounding provisions elsewhere in the article.

250.21. AC Systems of 50 Volts to 1000 Volts Not Required to Be Grounded.

Although the NEC does not require grounding of electrical systems in which the voltage to ground would exceed 150 V, it now requires that ground-fault detectors be used with ungrounded systems that operate at more than 150 and less than 1000 V. Such detectors indicate when an accidental

ground fault develops on one of the phase legs of ungrounded systems. Then the indicated ground fault can be removed during downtime of the industrial operation—that is, when the production machinery is not running. Although not required in previous editions of the Code before the 2005 edition—prior to then the use of ground-fault detectors was mentioned in a fine-print note—such equipment is mandated by Part **(B)** of this section. Effective with the 2011 **NEC**, an additional rule mandates that the ground detection equipment be placed as close as practicable to the point of system supply. In addition, 250.21(C) requires ungrounded systems to be marked “ungrounded system” at the system source or first disconnecting means.

Many industrial plants prefer to use an ungrounded system with ground-fault detectors instead of a grounded system. With a grounded system, the occurrence of a ground fault is supposed to draw enough current to operate the overcurrent device protecting the circuit. But such fault clearing opens the circuit—which may be a branch circuit supplying a motor or other power load or may be a feeder that supplies a number of power loads—and many industrial plants object to the loss of production caused by downtime. They would rather use the ungrounded system and have the system kept operative with a single ground fault and clear the fault when the production machinery is not in use. In some plants, the cost of downtime of production machines can run to thousands of dollars per minute. In other plants, interruption of critical processes is extremely costly.

The difference between a grounded and an ungrounded system is that in a grounded system a single ground fault will automatically cause opening of the circuit, which may shut down operations. In an ungrounded system the first ground fault will register at the ground detectors but will not interrupt operations. However, there is the very important negative aspect that the presence of a single ground fault in an ungrounded system exposes the system to the very destructive possibilities of a phase-to-phase short if another ground fault should simultaneously develop on a different phase leg of the system (Fig. 250-6).

UNGROUNDED SYSTEMS

Single accidental ground on any phase leg does not interrupt service

Simultaneous accidental grounds on two phases constitute a short circuit and open one or two protective devices

Ground detector device may be used to signal presence of accidental ground on any phase

Fig. 250-6. Characteristics of ungrounded systems. (Sec. 250.21.) Ground detectors are now mandatory for most ungrounded system applications.

Grounded neutral systems are generally recommended for high-voltage (over 600 V) distribution. Although ungrounded systems do not undergo a power outage with only one-phase ground faults, the time and money spent in tracing faults indicated by ground detectors and other disadvantages of ungrounded systems have favored use of grounded neutral systems. Another design issue is that transient overvoltages have no way out of an ungrounded system, but they can be removed easily on a grounded system. This has encouraged many engineers to look into high-impedance grounded systems. These systems have a way to bleed out transients, but as in the case of ungrounded systems the first fault will not disrupt power. Grounded systems are more economical in operation and maintenance if a process outage can be tolerated. In such a system, if a fault occurs, it is isolated immediately and automatically.

Grounded neutral systems have many other advantages. The elimination of multiple faults caused by undetected restriking grounds greatly increases service reliability. The lower voltage to ground that results from grounding the neutral offers greater safety for personnel and requires lower equipment voltage ratings. And on high-voltage (above 600 V) systems, residual relays can be used to detect ground faults before they become phase-to-phase faults that have substantial destructive ability.

Part **(3)** of the basic rule recognizes use of ungrounded control circuits derived from transformers. According to the rules of 250.20(B), any 120-V, 2-wire circuit must normally have one of its conductors grounded; the neutral conductor of any 240/120-V, 3-wire, single-phase circuit must be grounded; and the neutral of a 208/120-V, 3-phase, 4-wire circuit must be grounded. Those requirements have often caused difficulty when applied to control circuits derived from the secondary of a control transformer that supplies power to the operating coils of motor starters, contactors, and relays. For instance, there are cases where a ground fault on the hot leg of a grounded control circuit can cause a hazard to personnel by actuating the control circuit fuse or CB and shutting down an industrial process in a sudden, unexpected, nonorderly way. A metal-casting facility is an example of an installation where sudden shutdown due to a ground fault in the hot leg of a grounded control circuit could be objectionable. Because designers often wish to operate such 120-V control circuits ungrounded, 250.21(3) permits ungrounded control circuits under certain specified conditions.

A 120-V control circuit may be operated ungrounded when all the following exist:

1. The circuit is derived from a transformer that has a primary rating less than 1000 V.
2. Whether in a commercial, institutional, or industrial facility, supervision will assure that only persons qualified in electrical work will maintain and service the control circuits.
3. There is a need for preventing circuit opening on a ground fault—that is, continuity of power is required for safety or for operating reliability.
4. Some type of ground detector is used on the ungrounded system to alert personnel to the presence of any ground fault, enabling them to clear the ground fault in normal downtime of the system (Fig. 250-7).

FOR SEPARATE OR BUILT-IN TRANSFORMER—

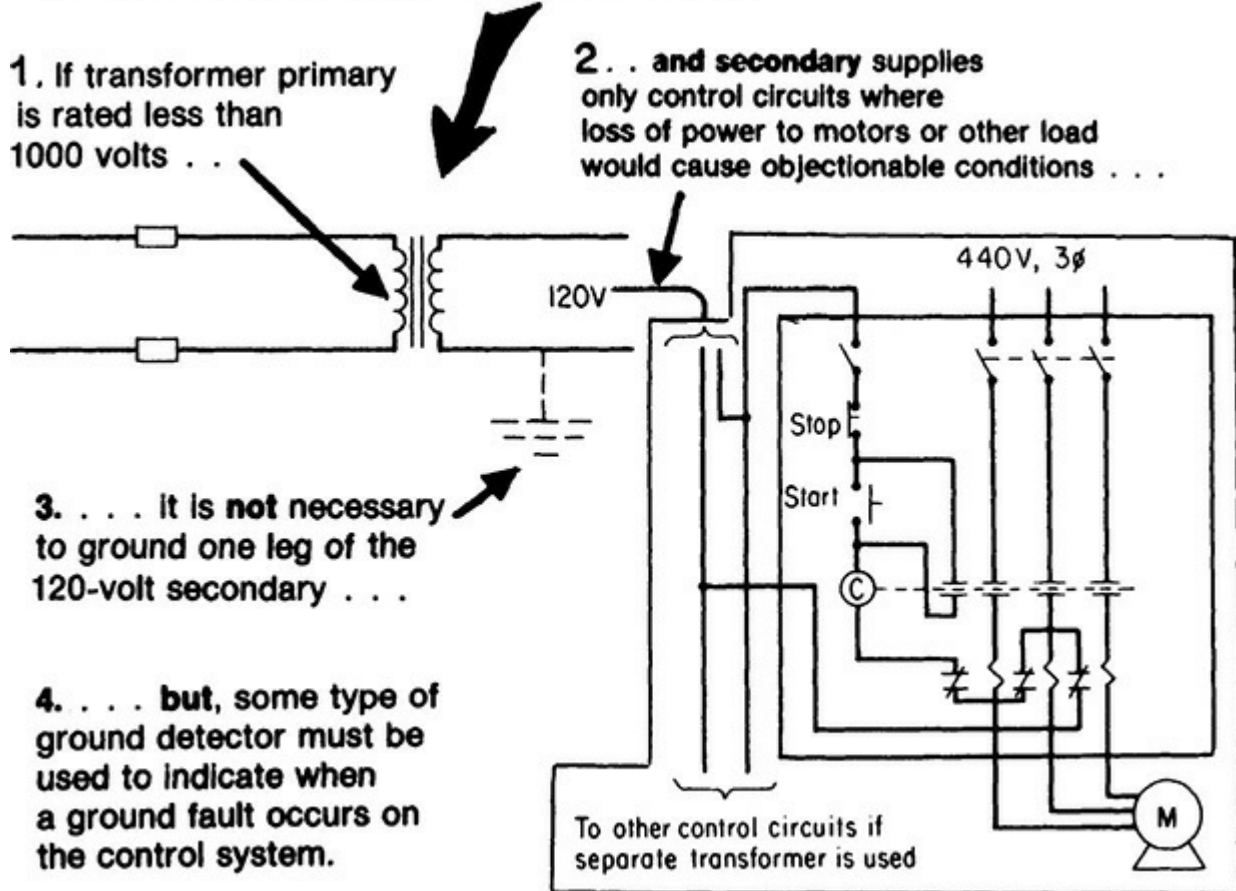

Fig. 250-7. Ungrounded 120-V circuits may be used for controls. (Sec. 250.21.)

Although no mention is made of secondary voltage in this Code rule, this rule permitting ungrounded control circuits is primarily significant only for 120-V control circuits. The **NEC** has long permitted 240- and 480- and even 600-V control circuits to be operated ungrounded. Application of this rule can be made for any 120-V control circuit derived from a control transformer in an individual motor starter or for a separate control transformer that supplies control power for a number of motor starters or magnetic contactors. Of course, the rule could also be used to permit ungrounded 277-V control circuits under the same conditions.

250.24. Grounding Service-Supplied Alternating-Current Systems. As noted in parts (A) and (A)(1), when a premises is supplied by an electrical system that has to be operated with one conductor grounded—either because it is required by the Code (e.g., 240/120-V, single phase) or because it is desired by the system designer (e.g., 240-V, 3-phase, corner grounded)—a connection to the grounding electrode must be made at the service entrance (Fig. 250-8). That is, the neutral conductor or other conductor to be grounded must be connected at the service equipment to a conductor that runs to a grounding electrode. The conductor that runs to the grounding electrode is called the “grounding electrode conductor”—an official definition in the **NEC**.

Fig. 250-8. Grounded interior systems must have *two* grounding points. (Sec. 250.24.)

The Code rule of 250.24(A)(1) says that the connection of the grounding electrode conductor to the system conductor that is to be grounded must be made “at any accessible point from the *load end* of the overhead service conductors, service drop, underground service conductors, or service lateral” to the service disconnecting means. This means that the grounding electrode conductor (which runs to building steel and/or water pipe or driven ground rod) must be connected to the system neutral or other system wire to be grounded either in the enclosure for the service disconnect or in some enclosure on the supply side of the service disconnect. Such connection may be made, for instance, in the main service switch or CB or in a service panelboard or switchboard. Or, the grounding electrode conductor may be connected to the system grounded conductor in a gutter, CT cabinet, or meter housing on the supply side of the service disconnect (Fig. 250-9). The utility company should be checked on grounding connections in meter sockets or other metering equipment. In some areas, the connection really is literally at the load end of the service drop (or lateral), in the form of connections made right below the weatherhead in the case of a service drop.

THIS IS THE BASIC RULE

THIS IS PART (A)(4)

Fig. 250-9. Grounding connection must be made in SE equipment or on its line side. (Sec. 250.24.)

As a result of this requirement, if a service is fed to a building from a meter enclosure on a pole or other structure some distance away, as is commonly done on farm properties, and an overhead or underground run of service conductors is made to the service disconnect in the building, the grounding electrode conductor will not satisfy the Code if it is connected to the neutral in the meter enclosure but must be connected at the load end of the underground or overhead service conductors. The connection should preferably be made within the service-disconnect enclosure.

This rule on grounding connections is shown in Fig. 250-10. If, instead of an underground lateral, an overhead run were made to the building from the pole, the overhead line would be a “service drop.” The rule of 250.24(A)(1) would likewise require the grounding connection at the load end of

the service drop. If a fused switch or CB is installed as service disconnect and protection at the load side of the meter on the pole, then that would establish the service at that point, and the grounding electrode connection to the bonded neutral terminal would be required at that point. The circuit from that point to the building would be a feeder and not service conductors. But electrical safety and effective operation would require that an equipment grounding conductor be run with the feeder circuit conductors for grounding the interconnected system of conduits and metal equipment enclosures along with metal piping systems and building steel within the building. Or, if an equipment grounding conductor is not in the circuit from the pole to the building, the neutral could be bonded to the main disconnect enclosure in the building and a grounding electrode connection made at that point also. However, that alternative is now restricted to existing applications only.

Fig. 250-10. Connection to grounded conductor at load end of lateral or drop. (Sec. 250.24.)

In addition to the grounding connection for the grounded system conductor at the point of service entrance to the premises, according to 250.24(A)(2), it is further required that another grounding connection be made to the same grounded conductor at the transformer that supplies the system. This means, for example, that a grounded service to a building must have the grounded neutral connected to another grounding electrode at the utility transformer on the pole, away from the building, as well as having the neutral grounded to a water pipe and/or other suitable electrode at the building, as shown in Fig. 250-8. And in the case of a building served from an outdoor transformer pad or mat

installation, the conductor that is grounded in the building must also be grounded at the transformer pad or mat, per 250.24(A)(2). However, this connection must not be made if the facility will be using a high-impedance grounded neutral system. On these systems, the second electrode at the transformer would allow return current to leave the building system through the earth, bypassing the monitoring equipment.

250.24(A)(4) permits the grounding electrode conductor to be connected to the equipment grounding bus in the service-disconnect enclosure—instead of the neutral block or bus—for instance, where such connection is considered necessary to prevent desensitizing of a service GFPE hookup that senses fault current by a CT-type sensor on the ground strap between the neutral bus and the ground bus. (See Fig. 250-9.) However, in any particular installation, the choice between connecting to the neutral bus or to the ground bus will depend on the number and types of grounding electrodes, the presence or absence of grounded building structural steel, bonding between electrical raceways and other metal piping on the load side of the service equipment, and the number and locations of bonding connections. The grounding electrode conductor may be connected to either the neutral bus or terminal lug or the ground bus or block in any system that has a conductor or a busbar bonding the neutral bus or terminal to the equipment grounding block or bus. Where the neutral is bonded to the enclosure simply by a bonding screw, the grounding electrode conductor must be connected to the neutral in all cases, because screw bonding is not suited to passing high lightning currents to earth.

One of the most important and widely discussed regulations of the entire Code revolves around this matter of making a grounding connection to the system grounded neutral or grounded phase wire. The Code says in part (A)(5), “A grounded conductor shall not be connected to normally noncurrent-carrying metal parts of equipment, to equipment-grounding conductor(s), or be reconnected to ground on the load side of the service disconnecting means.” Once a neutral or other circuit conductor is connected to a grounding electrode at the service equipment, the general rule is that the neutral or other grounded leg must be insulated from all equipment enclosures or any other grounded parts on the load side of the service. That is, bonding of equipment-grounding and neutral buses within subpanels (or any other connection between the neutral or other grounded conductor and equipment enclosures) is prohibited by the **NEC**.

There are some situations that are essentially “exceptions” to that rule, but they are few and are very specific:

1. In a system, even though it is on the load side of the service, when voltage is stepped down by a transformer, a grounding connection must be made to the secondary neutral to satisfy Secs: 250.20(B) and 250.30. Since this is a separately derived system, it isn't really an exception, because separately derived systems have no conductor that is common to the service-supplied system, and therefore the service neutral is not being regrounded in this case. Further, 250.30(A) now expressly forbids regrounding any grounded conductor of a separately derived system without specific code authorization.
2. When a circuit is run from one building to another, it may be necessary or prohibited to connect the system “grounded” conductor to a grounding electrode at the other building—as covered by 250.32. This is now generally prohibited in new installations as well, although it remains an option for “installations made in compliance with previous editions of this Code that permitted such connection” only.
3. In grounding of ranges and dryers, where supplied by an existing circuit as covered by 250.140, and Exception No. 1 to 250.142(B).

The Code makes it a violation to bond the neutral block in a panelboard to the panel enclosure in other than a service panel, or in a comparable location at the beginning of a separately derived system where no such connection has been placed at the energy source for that system. In a panelboard used as service equipment, the neutral block (terminal block) is bonded to the panel cabinet by the bonding screw provided. And such bonding is required to tie the grounded conductor to the interconnected system of metal enclosures for the system (e.g., service-equipment enclosures, conduits, busway, boxes, panel cabinets). It is this connection that provides for flow of fault current and operation of the overcurrent device (fuse or breaker) when a ground fault occurs. However, there must not be any connection between the grounded system conductor and the grounded metal enclosure system at any point on the load side of the service equipment, because such connection would constitute connection of the grounded system conductor to a grounding electrode (through the enclosure and raceway system to the water pipe or driven ground rod). Such connections, like bonding of subpanels, can be dangerous, as shown in [Fig. 250-11](#).

1. THIS CONDITION WILL EXIST....AND...

2. THIS HAZARD COULD DEVELOP

PANEL ENCLOSURE AND OTHER METAL RACEWAY AND ENCLOSURES CONNECTED TO PANEL ARE HOT.

Fig. 250-11. NEC prohibits bonding of subpanels because of these reasons. (Sec. 250.24.)

This rule on not connecting the grounded system wire to a grounding electrode on the load side of the service disconnect must not be confused with the rule of 250.140, which permits the grounded system conductor to be used for grounding the frames of electric ranges, wall ovens, counter-mounted cooking units, and electric clothes dryers, but only from existing branch circuits. The connection referred to in 250.140 is that of an ungrounded metal enclosure to the grounded conductor for the purpose of grounding the enclosure. If a new circuit is run, it must be provided with an equipment grounding conductor and a 4-wire plug and receptacle must be used.

There is an important “exception” to the rule that each and every service for a grounded ac system have a grounding electrode conductor connected to the grounded system conductor anywhere on the supply side of the service-disconnecting means (preferably within the service-equipment enclosure) and that the grounding electrode conductor be run to a grounding electrode at the service. Because controversy has arisen in the past about how many grounding electrode conductors have to be run for a dual-feed (double-ended) service with a secondary tie, part **(A)(3)** recognizes the use of a single grounding electrode conductor connection for such dual services. It says that the single grounding electrode connection may be made to the “tie point of the grounded circuit conductors from each power source.” The explanation on this Code permission was made by NEMA, the sponsor of the rule, as follows:

Unless center neutral point grounding and the omission of all other secondary grounding is permitted, the selective ground-fault protection schemes now available for dual power source systems with secondary ties will not work. Dual power source systems are utilized for maximum service continuity. Without selectivity, both sources would be shut down by any ground fault. This proposal permits selectivity so that one source can remain operative for half the load, after a ground fault on the other half of the system.

Figure 250-12 shows two cases involving the concept of single grounding point on a dual-fed service:

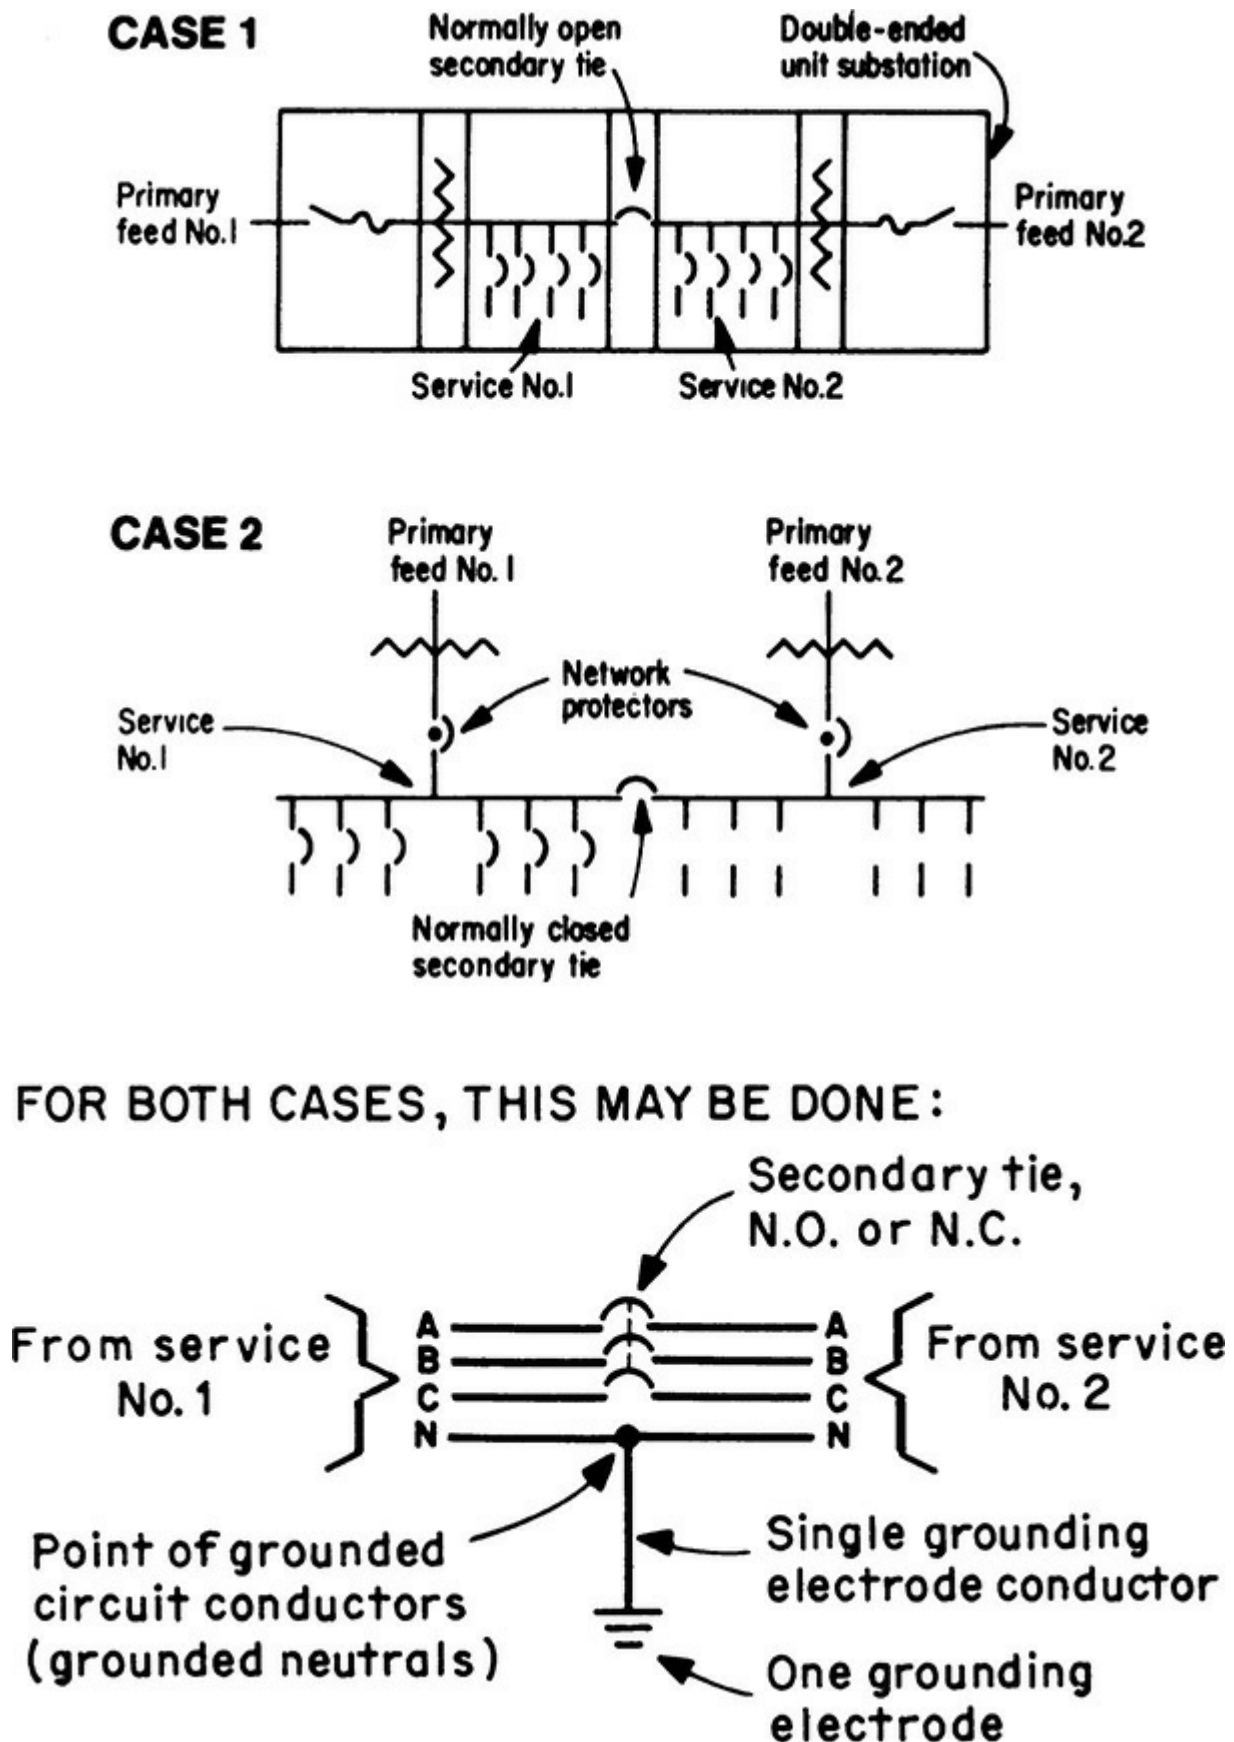

Fig. 250-12. One grounding connection permitted for a double-end service. (Sec. 250.24.)

- In case 1, if the double-ended unit substation is in a locked room in a building it serves or consists of metal-enclosed gear or a locked enclosure for each transformer, the secondary circuit from each transformer is a “service” to the building. The question then arises, “Does there have to be a separate grounding electrode conductor run from each secondary service to a grounding electrode?”

- In case 2, if each of the two transformers is located outdoors, in a separate building from the one they serve, in a transformer vault in the building they serve, or in a locked room or enclosure and accessible to qualified persons only or in metal-enclosed gear, then the secondary circuit from each transformer constitutes a service to the building. Again, is a separate grounding connection required for each service?
- In both cases, a single grounding electrode connection may serve both services, as shown at the bottom of [Fig. 250-12](#).

The Code rule in part **(A)(3)** refers to “services that are dual fed (double ended) in a common enclosure or grouped together.” The phrase *common enclosure* can readily cover use of a double-ended loadcenter unit substation in a single, common enclosure. But the phrase *grouped together* can lend itself to many interpretations and has caused difficulties. For instance, if each of two separate services is a single-ended unit substation, do both the unit substations have to be in the same room or within the same fenced area outdoors? How far apart may they be and still be considered grouped together? As shown in case 2 of [Fig. 250-12](#), if separate transformers and switchboards are used instead of unit substations, may one of the transformers and its switchboard be installed at the opposite end of the building from the other one? The Code does not answer those questions, but it seems clear that the wording does suggest that both the services must be physically close and at least in the same room or vault or fenced area. That understanding has always been applied to other Code rules calling for grouping—such as for switches and CBs in 404.8 and for service disconnects in 230.72(A).

Part **(B)** of 250.24 mandates a connection between the grounded conductor—usually a neutral conductor—and the equipment grounding conductor for all systems required or desired to be grounded. Such installation must satisfy the requirements of 250.28. This connection uses the *main bonding jumper* and it is the most important single connection in the entire electrical system because without it overcurrent devices will not clear ground faults.

Part **(C)** requires that whenever a service is derived from a grounded neutral system, the grounded neutral conductor must be brought into the service entrance equipment, even if the grounded conductor is not needed for the load supplied by the service. A service of less than 1000 V that is grounded outdoors at the service transformer (pad mount, mat, or unit substation) must have the grounded conductor routed with the ungrounded service conductors and run to “each service disconnecting means” and bonded to the separate enclosure for “each” service disconnect. If two to six normal service disconnects [as permitted by 230.71(A)] are installed in separate enclosures (or even additional disconnect switches or circuit breakers for emergency, fire pump, etc.), the grounded circuit conductor must be run to a bonded neutral terminal in each of the separate disconnect enclosures fed from the service conductors. The exception to this rule clarifies that if multiple service disconnect switches or circuit breakers are installed within “an assembly listed for use as service equipment”—such as in a service panelboard, switchboard, or multimeter distribution assembly—only a single grounded (neutral) conductor has to be run to the single, common assembly enclosure and bonded to it.

Running the grounded conductor to each individual service disconnect enclosure is required to provide a low-impedance ground-fault current return path to the neutral to ensure operation of the overcurrent device for safety to personnel and property. (See [Fig. 250-13](#).) In such cases, the neutral functions strictly as an equipment grounding conductor, to provide a closed circuit back to the transformer for automatic circuit opening in the event of a phase-to-ground fault anywhere on the load

side of the service equipment. Only one phase leg is shown in these diagrams to simplify the concept. The other two phase legs have the same relation to the neutral.

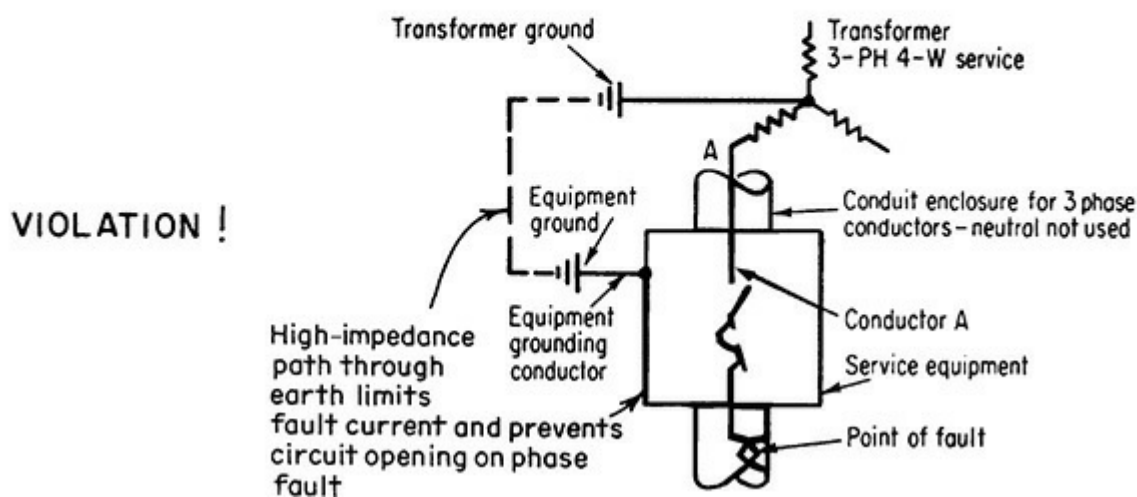

Fig. 250-13. Clearing of ground faults on the load side of any service disconnect depends on fault-current return over a grounded circuit conductor (usually a neutral) brought into each and every enclosure for service disconnect switch or CB. (Sec. 250.24.)

The same requirements apply to installation of separate power and light services derived from a common 3-phase, 4-wire, grounded “red-leg” delta system. The neutral from the center-tapped transformer winding must be brought into the 3-phase power service equipment as well as into the lighting service, even though the neutral will not be used for power loads. This is shown in [Fig. 250-14](#) and is also required by 250.24(C)(1). This grounded conductor must be sized as covered in Table 250.102(C)(1). If the installation is large enough to use paralleled conductors in two or more raceways, then the grounded conductors are to be no smaller than 1/0 AWG and run in each of the paralleled raceways, sized by bringing the size of the largest ungrounded resulting phase connection

into the new Table 250.102(C)(1). Remember, for example, that a four-conductor paralleled hookup might consist of two raceways containing two sets of conductors each, and in such a case the area used in Table 250.102(C)(1) would be twice the area of the largest phase conductor.

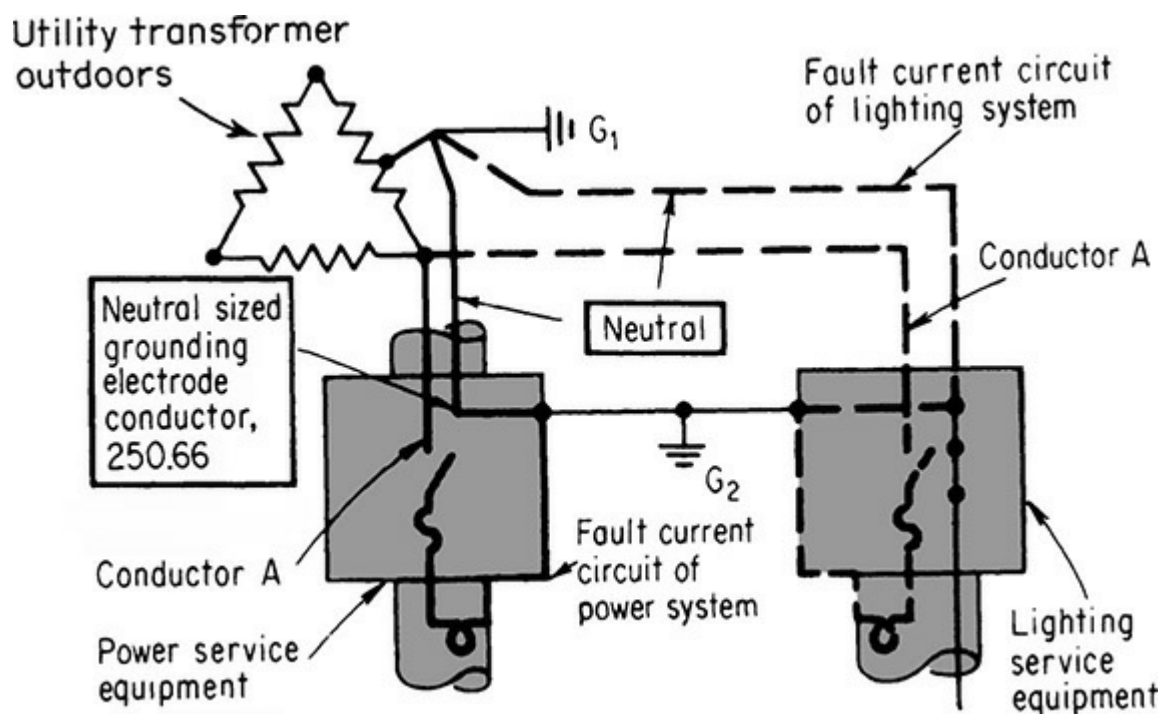

Fig. 250-14. Neutral must be brought in to each service equipment and bonded to enclosure. (Sec. 250.24.)

In any system where the neutral is required on the load side of the service—such as where 208Y/120-V or 480Y/277-V, 3-phase, 4-wire distribution is to be made on the premises—the neutral from the supply transformer to the service equipment is needed to provide for neutral current flow under conditions of load unbalance on the phase legs of the premises distribution system. But, even in a premises where all distribution on the load side of the service is to be solely 3-phase, 3-wire (such as 480-V, 3-phase, 3-wire distribution) and the neutral conductor is not required in the premises system, this Code rule says that the neutral must still run from the supply transformer to the service equipment.

It should be noted that 250.24(C)(3) calls for the grounded conductor to be no smaller than the ungrounded conductors where the supply is a corner-grounded delta system. That makes sense because the grounded conductor, in such an application, is a phase conductor. Given that the load to be supplied will be carried by all three supply conductors—including the grounded phase conductor—the grounded conductor must be sized as an ungrounded conductor to satisfy this rule.

Part (C)(2) of the rule covers cases where the service phase conductors are paralleled, with two or more conductors in parallel per phase leg and neutral, and requires that the size of the grounded neutral be calculated on the equivalent area for parallel conductors. If the calculated size of the neutral (at least 12½ percent of the phase leg cross section) is to be divided among two or more conduits, and if dividing the calculated size by the number of conduits being used calls for a neutral conductor smaller than 1/0 in each conduit, the informational note calls attention to 310.10(H), which gives No. 1/0 as the minimum size of conductor that may be used in parallel in multiple conduits. For that reason, each neutral would have to be at least a No. 1/0, even though the calculated size might be,

say, No. 1 or No. 2 or some other size smaller than No. 1/0. But the Code rule does permit subdividing the required minimum 12½ percent grounded (neutral) conductor size by the total number of conduits used in a parallel run, thereby permitting a multiple makeup using a smaller neutral in each pipe.

As shown in Fig. 250-15, the minimum required size for the grounded neutral conductor run from the supply transformer to the service is based on the size of the service phase conductors. In this case, the overall size of the service phase conductors is 4×500 kcmil per phase leg, or 2000 kcmil. Because that is larger than 1100 kcmil, it is not permitted to simply use Table 250.66 in sizing the neutral. Instead, 2000 kcmil must be multiplied by 12½ percent. Then $2000 \text{ kcmil} \times 0.125$ equals 250 kcmil—the minimum permitted size of the neutral conductor run from the transformer to the service equipment. It is the Code's intent to permit the required 250-kcmil-sized neutral to be divided by the number of conduits. From NEC Table 8 in Chap. 9, it can be seen that four No. 2 conductors, each with a cross-sectional area of 66,360 circular mils, would approximate the area of one 250 kcmil (250,000 circular mils divided by 4 = 62,500 circular mils). But, because No. 1/0 is the smallest conductor that is permitted by 310.4 to be used in parallel for a circuit of this type, it would be necessary to use a No. 1/0 copper conductor in each of the four conduits, along with the phase legs. Remember, however, that corner-grounded delta services must not have the grounded conductor reduced in size from that of the other 2-phase legs.

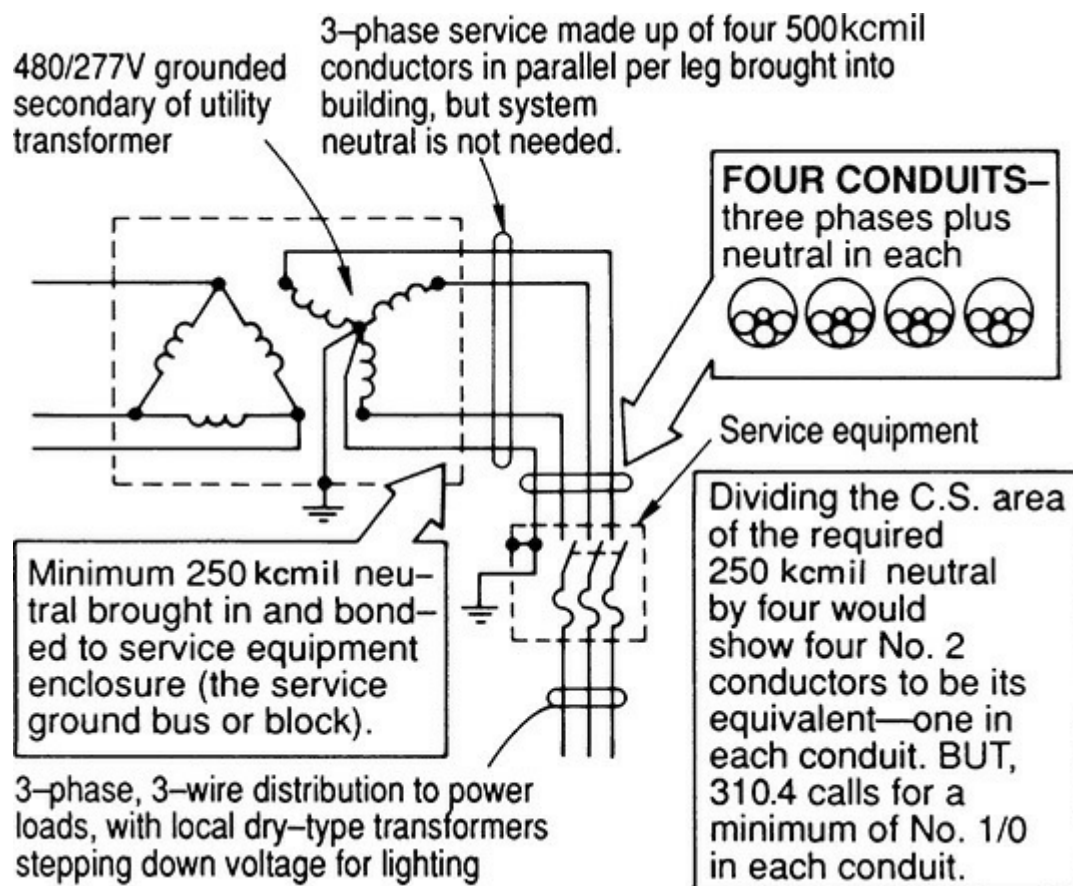

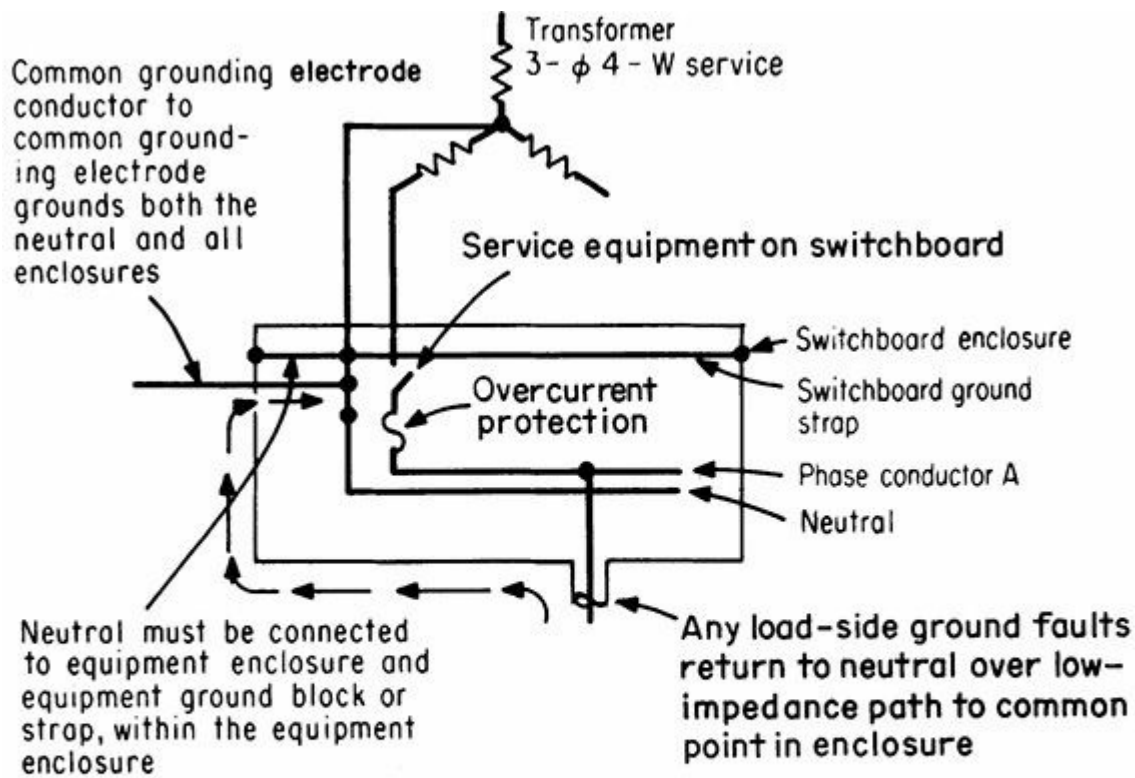

Fig. 250-15. Grounded service conductor must *always* be brought in. (Sec. 250.24.)

250.24(D) requires all the bonded components—the service-equipment enclosure, the grounded neutral or grounded phase leg, and any equipment grounding conductors that come into the service enclosure—to be connected to a common grounding electrode (250.58) by the single grounding electrode conductor. A common grounding electrode conductor shall be run from the common point so

obtained to the grounding electrode as required by Codes 250.24 and 250.58 ([Fig. 250-16](#)). Connection of the system neutral to the switchboard frame or ground bus within the switchboard provides the lowest impedance for the equipment ground return to the neutral.

PROPER CONNECTIONS:

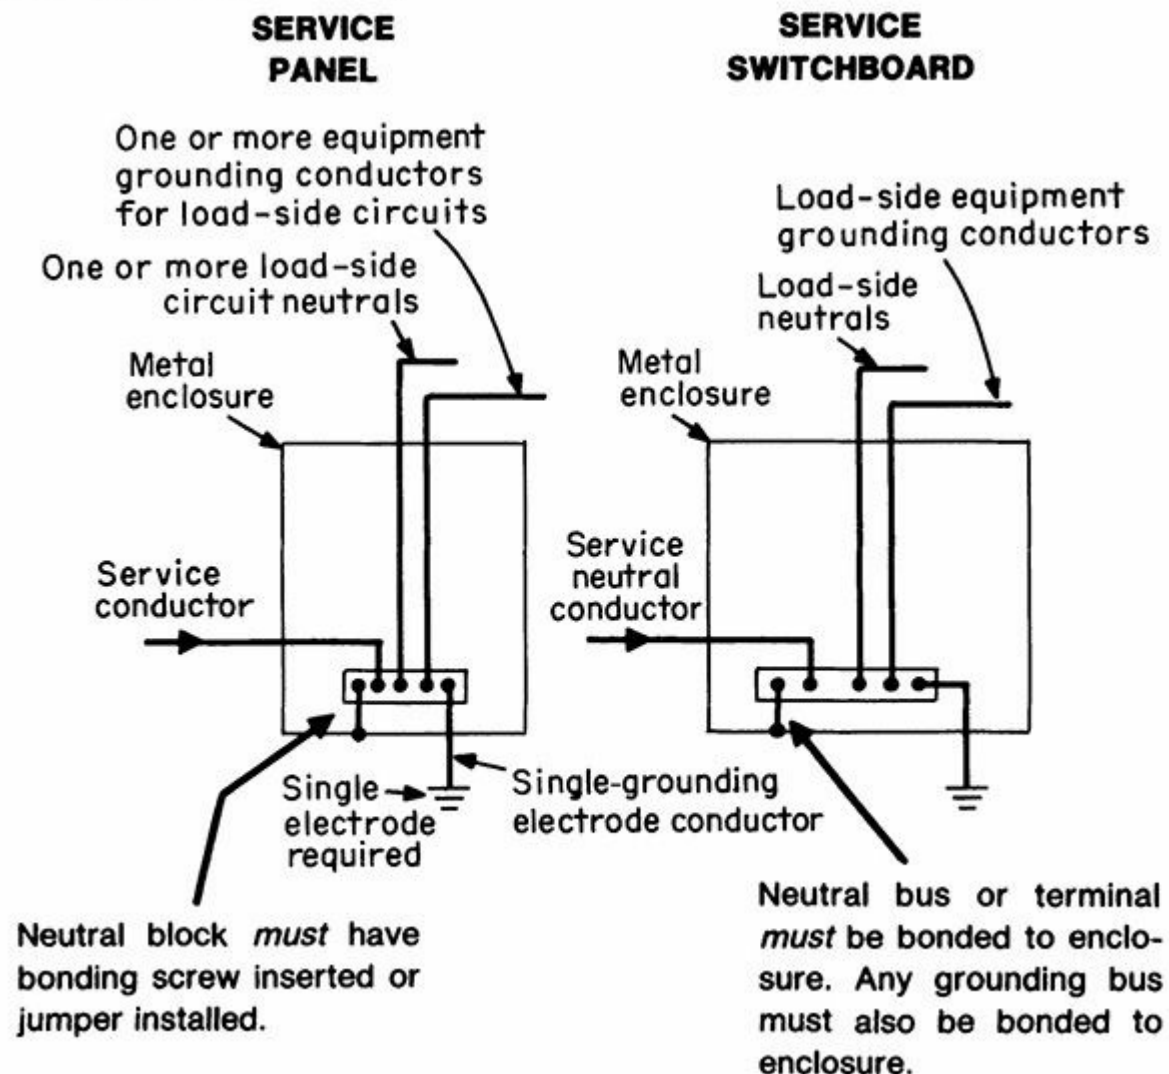

Fig. 250-16. Common grounding electrode conductor for service and equipment ground. [Sec. 250.24(D).]

250.24(E) covers ungrounded systems. They too require grounding electrode conductors, also connected at any accessible point from the load end of the service lateral or drop to the enclosure for the disconnecting means. This connection accomplishes the ground reference objective as set forth in 250.4(B)(1). The system equipment grounding conductors and the service enclosure are connected here, but there is, of course, no connection to a phase conductor.

250.26. Conductor to Be Grounded—Alternating-Current Systems. Selection of the wiring system conductor to be grounded depends upon the type of system. In 3-wire, single-phase systems, the midpoint of the transformer winding—the point from which the system neutral is derived—is grounded. For grounded 3-phase wiring systems, the neutral point of the wye-connected transformer(s) or generator is the point connected to ground. In delta-connected transformer hookups, grounding of the system can be effected by grounding one of the three phase legs, by grounding a center tap point on one of the transformer windings (as in the 3-phase, 4-wire “red-leg” delta system), or by using a special grounding transformer that establishes a neutral point of a wye connection that is grounded.

250.28. Main and System Bonding Jumpers. The NEC now makes a semantic distinction between two conductors with identical functions and essentially identical installation requirements. For any grounded system, the arguably single most important connection is the (usually) single-point connection between the equipment grounding system and the grounded circuit conductor. If this connection is compromised, no meaningful fault current can complete a connection to the system source, and in that process thereby remove voltage from enclosures and create the high-current return that will cause OCPDs to open immediately. In the case of a system supplied by a service, this conductor is the “main bonding jumper.” In the case of a separately derived system, this conductor is the “system bonding jumper.”

As required by the wording of 250.24(B), a “main bonding jumper” must be installed between the grounded and grounding conductors at or before the service disconnect. The main bonding jumper that bonds the service enclosure and equipment grounding conductors (which may be either conductors or conduit, EMT, etc., as permitted by 250.118) to the grounded conductor of the system is required to be installed within the service equipment or within a service conductor enclosure on the line side of the service. This is the bonding connection required by 250.130(A) (Fig. 250-17). It should be noted that in a service panel, equipment grounding conductors for load-side circuits may be connected to the neutral block, and there is no need for an equipment grounding terminal bar or block. For grounded separately derived systems, 250.30(A)(1) imposes the same requirement for system bonding jumpers.

**Conduits are also
equipment grounding
conductors**

**Main bonding jumper (wire, bus, screw or similar conductor)
must be *within* service equipment or service conductor enclosure**

Fig. 250-17. Main bonding jumper must be within SE enclosure. (Sec. 250.28.)

If a grounding conductor were used to ground the neutral to the water pipe or other grounding electrode and a separate grounding conductor were used to ground the switchboard frame and housing to the water pipe or other electrode, without the neutral and the frame being connected in the switchboard, the length and impedance of the ground path would be increased. The proven hazard is that the impedance of the fault-current path can limit fault current to a level too low to operate the overcurrent devices “protecting” the faulted circuit.

Note that a number of grounding electrodes that are bonded together, as required by 250.50, are considered to be one grounding electrode.

Part (A) calls for use of copper or other “corrosion-resistant” conductor material—which does include aluminum and copper-clad aluminum. Part (B) notes that if the bonding jumper is in the form of a screw, the screw head must be finished with a green coloring. This allows the inspector to zero in on the required connection, and not confuse the bonding screw with other screws that may not be making the required connections. Part (C) demands use of connectors, lugs, and other fittings that have been designed, tested, and listed for the particular application, as covered in 250.8.

Part (D) covers sizing of any bonding jumper within the service equipment enclosure or on the line or supply side of that enclosure. Refer to the definitions of “Bonding Jumper, Main” and “Bonding Jumper, System” in Art. 100.

The minimum required size of this jumper for this installation is determined by calculating the size of one service phase leg. For example, with three 500 kcmil per phase, that works out to 1500-kcmil copper per phase. Because that value is in excess of 1100-kcmil copper, as noted in Table 250.102(C)(1), the minimum size of the main bonding jumper must equal at least 12½ percent of the phase leg cross-sectional area. Then,

$$12\frac{1}{2}\% \times 1500 \text{ kcmil} = 0.125 \times 1500 = 187.5 \text{ kcmil}$$

Referring to Table 8 in [Chap. 9](#) in the back of the Code book, the smallest conductor with at least

that cross-sectional area (csa) is No. 4/0, with a csa of 211,600 cmil or 211.6 kcmil. Note that No. 3/0 has a csa of only 167.8 kcmil. Thus No. 4/0 copper with any type of insulation would satisfy the Code.

If there are multiple service enclosures, the main bonding jumper in each is sized on the basis of the size of the largest ungrounded service-entrance line or phase conductor supplying that enclosure. If the multiple enclosures are fed from a common wireway with large service conductors tapped with smaller conductors feeding each actual service disconnect enclosure, the grounding in the parent wireway requires additional consideration. Any bonding connections necessarily take place on the supply side of the service disconnects, and therefore the bonding conductors within the wireway will be “supply-side bonding jumpers” (refer to the discussion at the definition in 250.2). These jumpers will be sized like grounding electrode conductors, increased if necessary in the event the ungrounded conductors exceed the tabulated values in Table 250.102(C)(1), as covered in the example in the previous paragraphs. If the grounding electrode conductor departs from this common wireway, it is sized in accordance with the normal rules based on the size of the entering common service conductors, as covered in 250.64(D)(3).

For separately derived systems with multiple enclosures, the same procedure can be used, or a system bonding jumper can be located at the derived system source. In this case, the bonding jumper will be sized on the basis of the largest ungrounded phase or line conductor cross-section area figured collectively across comparable conductors as represented in all the feeders supplied by the system.

250.30. Grounding Separately Derived Alternating-Current Systems. A separately derived ac wiring system is a source derived from an on-site generator (emergency or standby), a battery-inverter, or the secondary winding(s) of a transformer, or from any of the many other sources that do not share a direct connection with other sources, including PV systems. The 2014 **NEC** also inserted language at this point covering large separately derived systems connected in parallel, such as with multiple transformers supplying double-ended switchgear. These systems must comply with 250.20, 250.21, 250.22, and 250.26. Therefore:

1. Any system that operates at over 50 V but not more than 150 V to ground must be grounded [250.20(B)].
2. This requires the grounding of generator windings and secondaries of transformers serving 208/120-V, 3-phase or 240/120-V, single-phase circuits for lighting and appliance outlets and receptacles, at loadcenters throughout a building, as shown for the very common application of dry-type transformers in [Fig. 250-18](#).

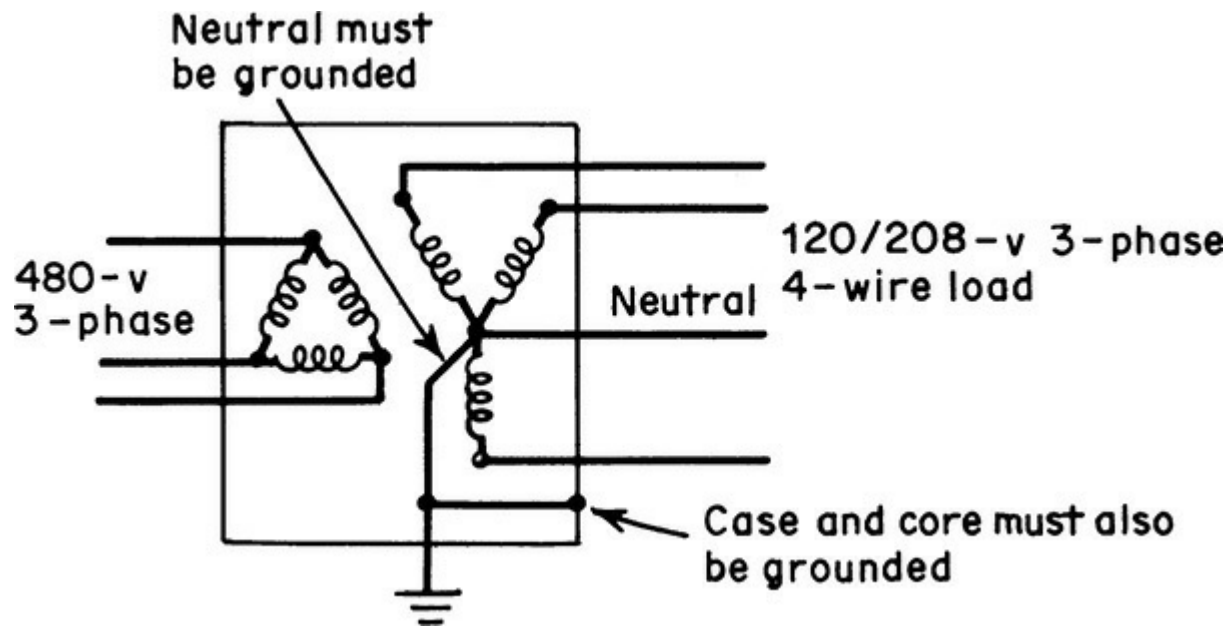

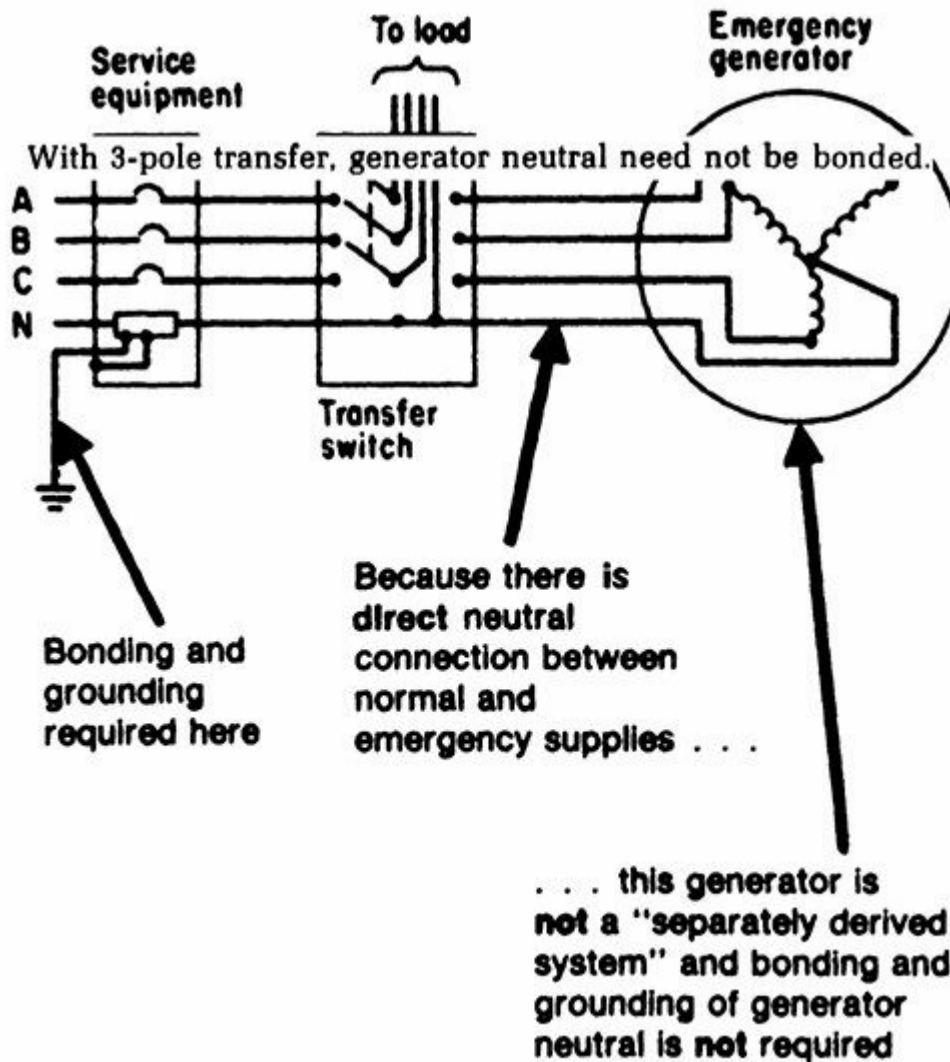

Fig. 250-18. Grounding is required for “separately derived” systems. (Sec. 250.30.)

3. All Code rules applying to both system and equipment grounding must be satisfied in such installations.

The first informational note in this section specifically identifies an on-site generator (emergency or standby) as “not a separately derived system” if the neutral conductor from the generator is connected solidly through a terminal lug in a transfer switch to the neutral conductor from the normal (usually, the power company) service to the premises (Fig. 250-19). Therefore, the generator neutral point does not have to be bonded to the frame and connected to a grounding electrode. In fact, such a bonding point is prohibited in this case. It squarely violates 250.24(A)(5) because the downstream (from the service) connection from neutral to equipment ground in the generator remains active regardless of the position of the transfer switch. But, a grounding conductor selected from Table 250.122, based on the size of the generator’s OC protection, must be connected to the generator frame/enclosure and the equipment ground bus within the transfer switch.

Generator neutral *must* be bonded when neutral is opened.

With 3-pole transfer, generator neutral need not be bonded.

Fig. 250-19. Not all generators are wired in a way that creates a separately derived system.

The second informational note essentially cautions that the neutral conductor from a generator to a transfer switch must be sized at least equal to 12½ percent of the cross-sectional area of the largest associated phase conductor (445.13) to ensure adequate conductivity (low impedance) for fault current that might return over that neutral when the generator is supplying the premises load, the neutral of both the generator and the normal service are connected solidly through the transfer switch (making the generator not a separately derived system), and the generator neutral is not bonded to the generator case and grounded at the generator. Under such a set of conditions, fault current from a ground fault in the premises wiring system would have to return to the point at the normal service equipment where the equipment grounding conductor (service equipment enclosure, metal conduits, etc.) is bonded to the service neutral. Only from that point can the fault current return over the neutral conductors, through the transfer switch to the neutral point of the generator winding. 445.13 effectively requires that such a generator neutral must satisfy 250.30(A)(3), which says that a neutral that might function as an equipment grounding conductor must have a cross-sectional area at least equal to 12½ percent of the cross-sectional area of the largest phase conductor of the generator circuit to the transfer switch (Fig. 250-20). The actual reference is to 250.30(A), which in turn now references Table 250.102(C)(1) for sizing, and is over two pages long; as a service to readers the relevant provisions have been identified here.

Fig. 250-20. Neutral conductor from service equipment to generator neutral point must be sized at least equal to 12½ percent of the cross-sectional area of the generator phase leg. (Sec. 445.13).

The effect of the rules on transfer switches is as follows:

- *3-pole transfer switch.* If a solid neutral connection is made from the service neutral, through

the transfer switch, to the generator neutral, then bonding and grounding of the neutral at the generator are not required because the neutral is already bonded and grounded at the service equipment. And if bonding and grounding were done at the generator, it could be considered a violation of 250.6(A) and would have to be corrected by 250.6(B) (Fig. 250-6). It also squarely violates 250.24(A)(5) because the downstream (from the service) connection in the generator remains active regardless of the position of the transfer switch.

- *4-pole transfer switch.* Because there is no direct electrical connection of either the hot legs or the neutral between the service and the generator, the generator in such a hookup is a separately derived system and must be grounded and bonded to the generator case at the generator (Fig. 250-19).

It should be noted that the 4-pole transfer switch and other neutral-switching techniques came into use to eliminate problems of GFPE desensitizing that were caused by use of a 3-pole transfer switch when the neutral of the generator was bonded to the generator housing. As a result, the use of a 4-pole transfer switch or some other technique that opens the neutral is the only effective way to avoid GFPE desensitizing. Ground-fault protection is not compatible with a solid neutral tie between the service and an emergency generator—with or without its neutral bonded. However, for smaller systems that are not using GFPE, 3-pole transfer switches with a solid neutral are still very common.

Refer to the discussion under 250.24(A)(4) on the relationship between GFPE desensitizing and the point of connection of the grounding electrode conductor.

Referring to Fig. 250-21, the steps involved in satisfying the Code rules are as follows:

Step 1—250.30(A)(1)

A system bonding jumper must be installed between the transformer secondary neutral terminal and the metal case of the transformer. The size of this system bonding conductor is based on 250.28(D) and is selected from Table 250.102(C)(1) of the Code, based on the size of the transformer secondary phase conductors. For cases where the transformer secondary circuit is larger than 1100-kcmil copper or 1750-kcmil aluminum per phase leg, the bonding jumper must be not less than 12½ percent of the cross-sectional area of the secondary phase leg as described in Note 1 to that table.

example Assume this is a 75-kVA transformer with a 120/208-V, 3-phase, 4-wire secondary. Such a unit would have a full-load secondary current of

$$75,000 \div (208 \times 1.732) \text{ or } 209 \text{ A}$$

If we use No. 4/0 THW copper conductors for the secondary phase legs (with a 230-A rating), we would then select the size of the required bonding jumper from Table 250.102(C)(1) accordingly. The table shows that 4/0 copper service conductors require a minimum of No. 2 copper or No. 1/0 aluminum for a grounding electrode conductor. The bonding jumper would have to be either of those two sizes.

If the transformer were a 500-kVA unit with a 120/208-V secondary, its rated secondary current would be

$$\frac{500 \times 1000}{1.732 \times 208} = 1388 \text{ A}$$

Using, say, THW aluminum conductors, the size of each secondary phase leg would be four 700-kcmil aluminum conductors in parallel (each 700-kcmil THW aluminum is rated at 375 A; four are 4×375 or 1500 A, which suits the 1388-A load).

Then, because 4×700 kcmil equals 2800 kcmil per phase leg and is in excess of 1750 kcmil, Note 1 to Table 250.102(C)(1) requires

the bonding jumper from the case to the neutral terminal to be at least equal to $12\frac{1}{2}$ percent \times 2800 kcmil (0.125×2800) or 350-kcmil aluminum.

The system bonding jumper must remain within the enclosure. [Figure 250-22](#) shows the connection made at the source and dashed lines showing the alternate possibility of connections made at the system disconnecting means. However, the location of the system bonding jumper and the connection to the grounding electrode conductor must occur at the same point.

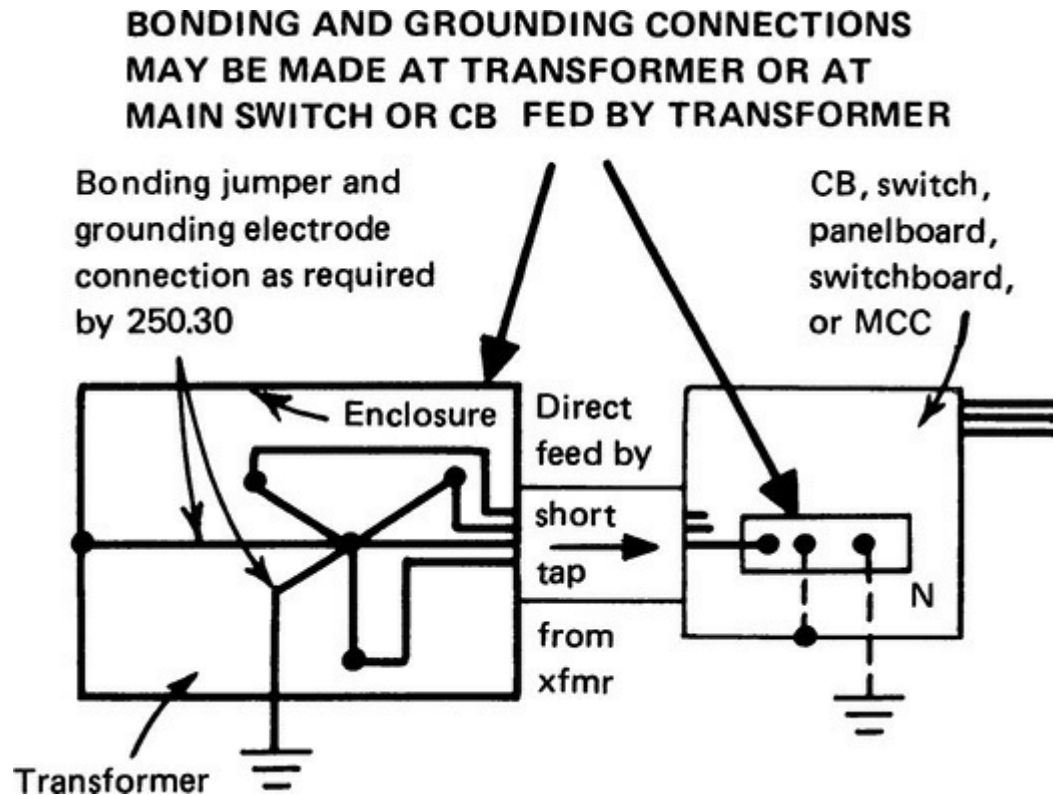

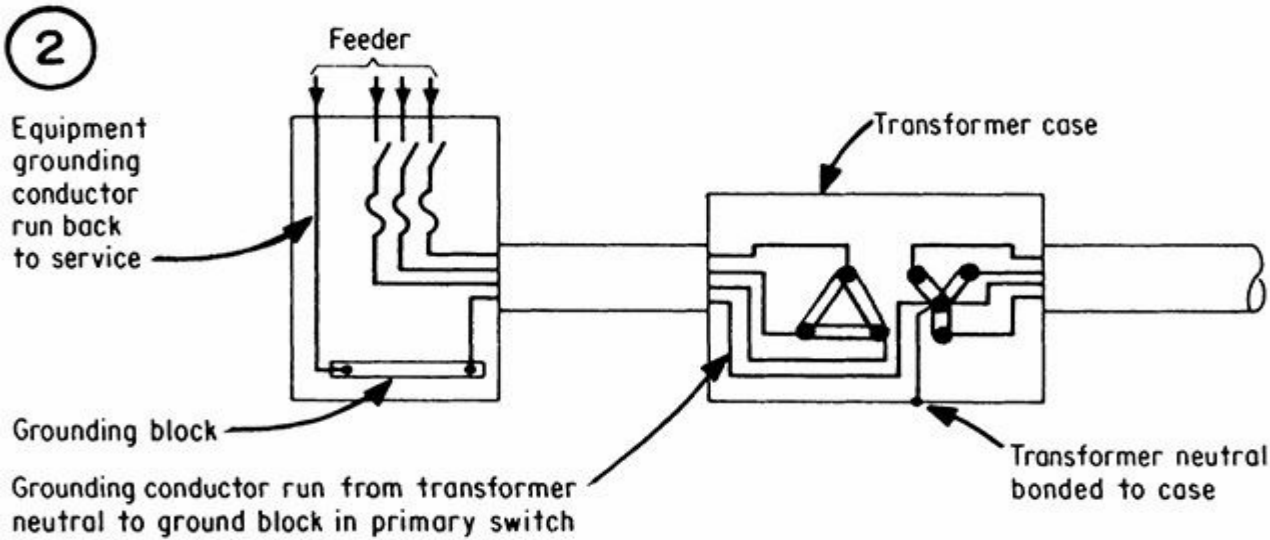

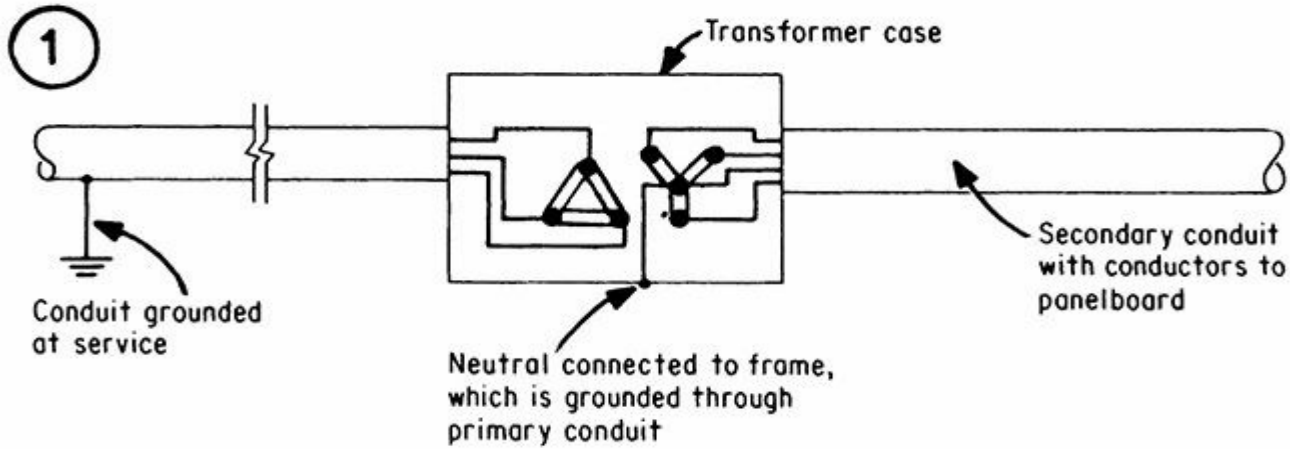

Fig. 250-22. Transformer secondary bonding and grounding must be “at the source” or at a secondary disconnect or protective device. Either the connections at the left, or the ones at the right are permitted, but never both. And in either case, the transformer enclosure and the disconnect enclosure must be bonded by a supply-side bonding conductor in accordance with 250.30(A)(2), unless the transformer is outside the building in accordance with 250.30(A)(1) Exception No. 2. (Sec. 250.30.)

In the event the transformer is outside the building, with no likelihood of a parallel path being established for neutral load current, then (A)(1) Exception No. 2 together with (A)(2) exception team up to allow system bonding connections at both locations. In such applications, the system neutral functions as the fault current return path back to the source. As such, in accordance with (A)(3) it must be able to carry the fault current, and therefore must have a minimum size as set in Table 250.102(C) (1) (but need not be larger than the largest ungrounded conductor). The inevitable earth connections at each end are not considered to establish a parallel fault current return path in such cases.

Figure 250-23 shows techniques of transformer grounding that have been used in the past but are no longer acceptable, along with an example of “case grounding,” which is specifically recognized by the exceptions to 250.30(A)(1), (A)(5), and (A)(6).

NOT PERMITTED FOR POWER TRANSFORMERS

THIS IS PERMITTED

TRANSFORMER NOT OVER 1000 VA -- FOR Class 1, Class 2, or Class 3 circuits

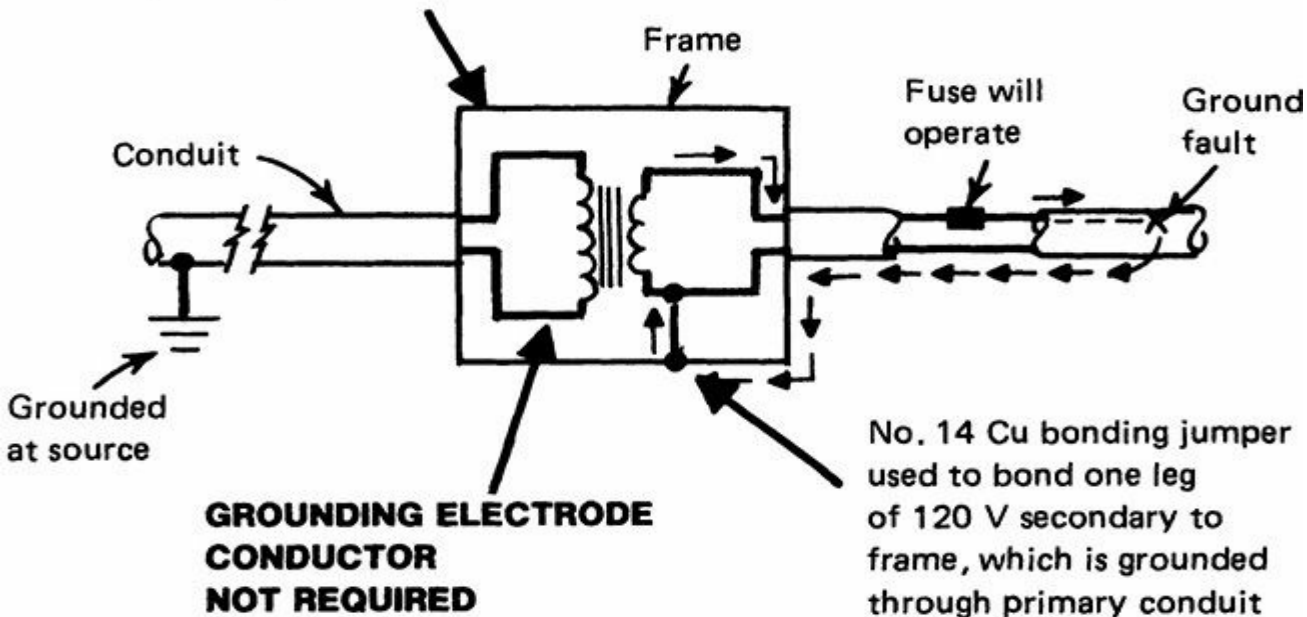

Fig. 250-23. Code rules regulate specific hookups for grounding transformer secondaries. (Sec. 250.30.)

Exception No. 3 to Sec. 250.30(A)(1) exempts small transformers for control, signal, or power-limited circuits from the basic requirement for a grounding electrode conductor run from the bonded secondary grounded conductor (such as a neutral) to an extension of a grounding electrode (nearby building steel or a water pipe). This exception, along with Exception No. 3 to 250.30(A)(5) and Exception No. 2 to (A)(6), applies to transformers used to derive control circuits, signal circuits, or power-limited circuits, such as circuits to damper motors in air conditioning systems. A Class 1, Class 2, or Class 3 remote-control or signaling transformer that is rated not over 1000 VA simply has to have a grounded secondary conductor bonded to the metal case of the transformer. No grounding electrode conductor is needed, provided that the metal transformer case itself is properly grounded by grounded metal raceway that supplies its primary or by means of a suitable (Sec. 250.118) equipment grounding conductor that ties the case back to the grounding electrode for the primary system, as indicated at the bottom of [Fig. 250-24](#). Exception No. 3 to 250.30(A)(1) permits use of a No. 14 copper conductor to bond the grounded leg of the transformer secondary to the transformer frame, leaving the supply conduit to the transformer to provide the path to ground back to the main service ground, but depending on the connection between neutral and frame to provide effective return for clearing faults, as shown. Grounding of transformer housings must be made by connection to grounded cable armor or metal raceway or by use of a grounding conductor run with circuit conductor (either a bare conductor or a conductor with green covering).

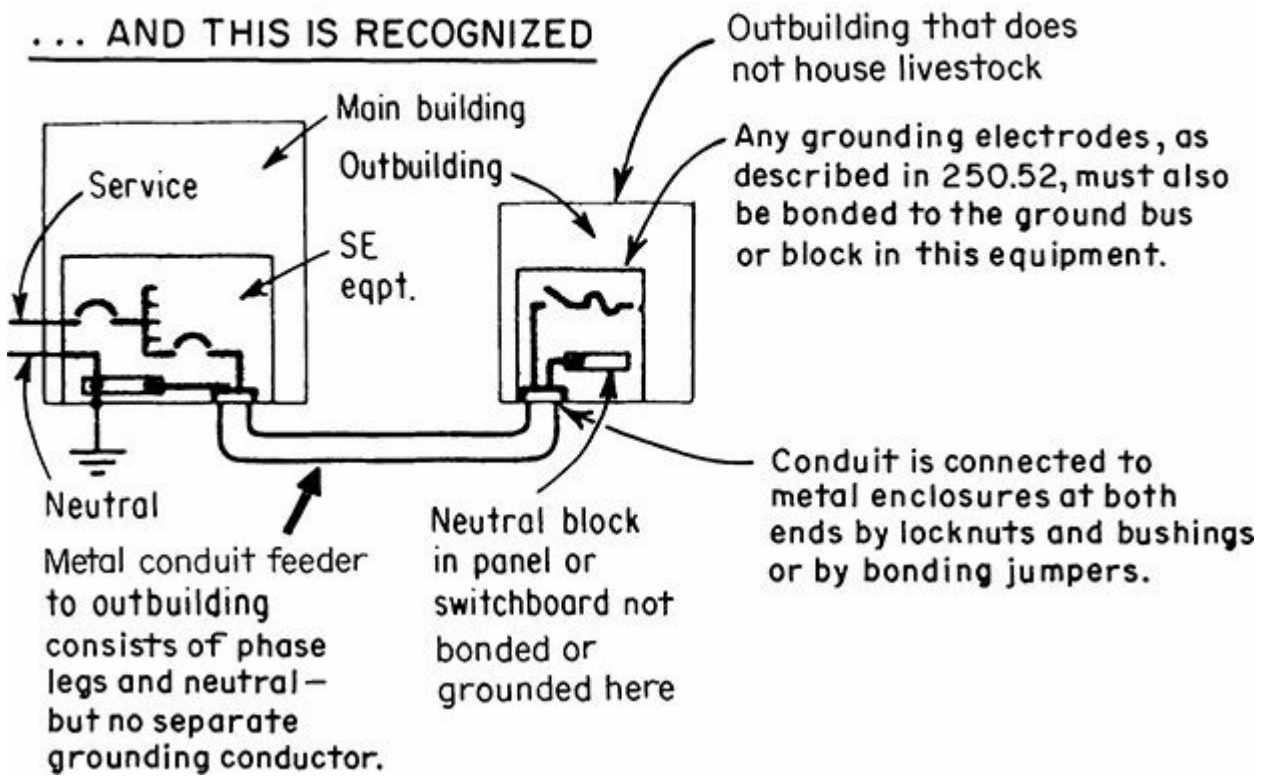

Fig. 250-24. Equipment grounding rules for outbuildings now parallel comparable rules for wiring within a building. (Sec. 250.32.)

Because the rule on bonding jumpers for the secondary neutral point of a transformer refers to

250.28, and therefore ties into Table 250.102(C)(1), the smallest size that may be used is No. 8 copper, as shown in that table. But for small transformers—such as those used for Class 1, Class 2, or Class 3 remote-control or signaling circuits—that large a bonding jumper is not necessary and is not suited to termination provisions. For that reason, Exceptions No. 3 to 250.30(A)(1) and 250.30(A)(5), and also Exception No. 2 to 250.30(A)(6), permit the bonding jumper for such transformers rated not over 1000 VA to be smaller than No. 8. The jumper simply has to be at least the same size as the secondary phase legs of the transformer and in no case smaller than No. 14 copper or No. 12 aluminum.

Step 2—250.30(A)(5) and (6)

A grounding electrode conductor must be installed from the transformer secondary neutral terminal to a suitable grounding electrode. This grounding conductor is sized the same as the required bonding jumper in Step 1. That is, this grounding electrode conductor is sized from Table 250.66 as if it is a grounding electrode conductor for a service with service-entrance conductors equal in size to the phase conductors used on the transformer secondary side. But this grounding electrode conductor does not have to be larger than 3/0 copper or 250-kcmil aluminum when the transformer secondary circuit is over 1100-kcmil copper or 1750-kcmil aluminum.

example For the 75-kVA transformer in Step 1, the grounding electrode conductor must be not smaller than the required minimum size shown in Table 250.102(C)(1) for 4/0 phase legs, which makes it the same size as the bonding jumper—that is, No. 2 copper or No. 1/0 aluminum. But, for the 500-kVA transformer, the grounding electrode conductor is sized directly from Table 250.66—which requires 3/0 copper or 250-kcmil aluminum where the phase legs are over 1100-kcmil copper or 1750-kcmil aluminum.

The rule of 250.30(A)(1) permits the bonding and grounding connections to be made either right at the transformer or generator or at the first disconnect or overcurrent device fed from the transformer or generator, as in [Fig. 250-22](#), but wherever the bonding jumper is connected, the grounding electrode conductor must be attached at the same point.

Part **(A)(6)(a)** recognizes the use of a “common grounding electrode conductor” as the electrode for a separately derived system. This represents relief from the requirement for connection of a separate grounding electrode conductor from each separately derived system to the water piping system within 5 ft from its point of entry to the building when building steel is not available. In high-rise construction where no building steel is available, a single grounding electrode conductor, connected to, say, the service enclosure, could be run in a shaft and be used as the “grounding electrode” for the separately derived systems.

Basically stated, this rule permits what amounts to a “grounding electrode” bus. First, as would be expected, all connections must be made at accessible locations. Next, there must be a positive means of connection employing irreversible pressure connectors, exothermic welding, or listed connectors to copper busbars not less than 1/4 in. × 2 in. In addition, the minimum acceptable size for this continuous grounding electrode conductor is 3/0 copper, and 250 kcmil for aluminum, and the installation must also satisfy the requirements given in 250.64, which covers the installation requirements for grounding electrode conductors.

It should be noted that although high-rise construction without structural steel is perhaps the most obvious use for this permission, the wording used seems to permit horizontal distribution as well. If a situation presents itself where a continuous grounding electrode conductor run horizontally would be a benefit, then such application would seem to be acceptable.

In addition to a 3/0 conductor, the 2017 **NEC** added two more possibilities for the common

grounding electrode conductor. First, a metal water pipe can be used if it complies with 250.68(C)(1). Normally this is trivial, since the total length permitted is 5 ft from where the water pipe electrode emerges from ground and changes function into a sort of grounding electrode conductor. However, the nonresidential exception is anything but trivial. Unchanged from prior editions, it allows a water pipe extension of indefinite length as long as it is not concealed. This may be a very plausible possibility in many occupancies to accomplish this function.

The other addition is the metal structural framework of a building as covered in 250.68(C)(2). The rules in Sec. 250.68 underwent considerable refinement in the 2017 **NEC**; refer to the additional discussion in this book at that location for the details. Obviously a metal building frame offers extensive opportunities for remote connection, so this will be a very practical alternative in many situations.

The exception following part (A) of 250.30 exempts high-impedance grounded transformer secondaries or generator outputs from the need to provide direct (solid) bonding and grounding electrode connections of the neutral, as required in parts (A)(1), (A)(3), and (A)(4). This simply states an exception to each part that is necessary to operate a high-impedance grounded system.

Step 3—250.30(A)(4)

The 2017 **NEC** drastically simplified the rules for the grounding electrode system on separately derived systems. Make the connection to the building or structure grounding electrode system. Simple, end of story, and in the same vein if the separately derived system originates in listed equipment suitable for use as service equipment, the grounding electrode for that equipment can be used for the separately derived system. This latter provision was Exception No. 2 in prior Code and now is the only exception here. If the separately derived system is outdoors, then the rules in 250.30(C), specifically developed for this condition, are the ones to follow.

Step 4—250.30(A)(2) and (A)(3)

A supply-side bonding jumper must connect the source and the separately derived system disconnecting means. In the case of the systems illustrated in [Figs. 250-21](#) and [250-22](#), that is simply the steel conduit, as recognized in 250.30(A)(2). However, in cases where there is no “nonflexible metal raceway,” a wire or busbar will need to be installed. Because this occurs on the supply side of the first overcurrent protective device, it cannot be sized as an equipment grounding conductor in accordance with 250.122. Instead, 250.102(C) sets the size, which is the same calculation as in 250.28(D) for the main and system bonding jumpers: Use Table 250.102(C)(1) and for large systems where the ungrounded conductors exceed the range of the table, use a wire no smaller than $\frac{1}{8}$ (12½%) the cross-sectional area as the phase legs. If a busbar is to be used, its cross-sectional area must be calculated (or obtained from the manufacturer) and it must be no smaller than a wire used for the same purpose.

A closely related case concerns the grounded circuit conductor, covered in 250.30(A)(3). If the system bonding jumper is installed at the main disconnect, then the grounded circuit conductor becomes the low-impedance path between the separately derived system loads and the source. As such, just as in the case of 250.24(C), the grounded circuit conductor is sized for fault return duty using the same procedures. Review the discussion on that topic and also [Fig. 250-15](#) for complete information. Corner grounded delta systems also follow the same procedures for services because the

provisions of 250.30(A)(3)(c) and 250.24(C)(3) are the same.

250.30(B). Ungrounded Systems. These systems must also have a grounding electrode conductor connected to a grounding electrode. The conductor is sized in accordance with Table 250.66 just as in the case of grounded systems, and the electrode must match up with the one specified in 250.30(A)(4). In addition, a supply-side bonding conductor must connect the source and the disconnecting means, and it must comply with 250.30(A)(2) just as in the case of grounded systems.

250.30(C). Outdoor Sources. Just as additional grounding rules apply to service sources originating off site [See 250.24(A)(2)], separately derived systems must have a local grounding electrode conductor connected between the source and a qualified grounding electrode.

The exception following this part of 250.30 exempts high-impedance grounded transformer secondaries or generator outputs from the need to provide direct (solid) bonding and grounding electrode connections of the neutral, as normally required in parts (A)(1), (A)(3), and (A)(4). This simply states an exception to each part that is necessary to operate a high-impedance grounded system. The repetition of this exception allows this procedure to be used when the transformer source is, for example, in an outdoor unit substation and it is desired to make all connections at that point.

250.32. Buildings or Structures Supplied by a Feeder(s) or Branch Circuit(s). In 250.24(A), bonding of a panel neutral block (or the neutral bus or terminal in a switchboard, switch, or circuit breaker) to the enclosure is required in service equipment. The informational note following part (A)(5) in that section calls attention to the fact that 250.32 covers grounding connections in those cases where a panelboard (or switchboard, switch, etc.) is used to supply circuits in a building and the panel is fed from another building. Where two or more buildings are supplied from a common service to a main building, and therefore by feeders or branch circuits or both, and not by a service, a grounding electrode at each other building shall be connected to the ac system equipment grounding conductor. There shall be no such connection to a grounded conductor under the normal rules. In other words, the wiring in the second building is now treated exactly the same as any wiring within the originating building that originates in a subpanel. The previous allowance for bonding equipment grounding and grounded circuit conductors at the building disconnect for the second building has been largely revoked. It now lives on, but only as an exception covered later. That is, there will be a system grounding electrode system that must satisfy the basic rules covered in parts (B) or (C) of this section, but the only connection will be to the local equipment grounding system at the building disconnect. (See [Fig. 250-24](#).)

There is an exception to part (A) that provides that for a separate building supplied by only one branch circuit where the branch circuit has an equipment grounding conductor run with it, a grounding electrode is not required. A multiwire branch circuit qualifies a single circuit under the wording of the exception. An example would be a small residential garage with a single lighting outlet and a receptacle. As long as an equipment grounding conductor is run with the circuit conductors, then no grounding electrode system need be provided.

Note that if two or more two-wire or multiwire branch circuits supply the outbuilding, then the grounding electrode must be provided and connected. This may not be straightforward. A grounding electrode conductor cannot be smaller than 8 AWG, and then only if run in raceway; 6 AWG is required otherwise. Terminating a 6 AWG conductor in a small device box, or daisy-chaining it through in multiple device boxes for the several circuits involved all of which require disconnecting means in accordance with 225.31, may be a challenge. If a feeder supplies the second building at a small panel the task is, of course, a simple one.

It follows that the supply to any outbuilding, whether a large feeder or a single branch circuit, must be run with an equipment grounding conductor of any type recognized by 250.118 along with the circuit conductors. (See [Fig. 250-24](#).) As shown at the bottom of that illustration, a grounding electrode connection to the grounded neutral conductor at the outbuilding is prohibited. If the separate building has an approved grounding electrode and/or interior metallic piping system, the equipment grounding conductor shall be bonded to the electrode and/or piping system and the neutral conductor is connected to the neutral bus without a bonding jumper between the neutral and ground busses. However, if the separate building does not have a grounding electrode—that is, does not have 10 ft (3.0 m) or more of underground metal water pipe, does not have grounded structural steel, and does not have any of the other electrodes recognized by 250.52(A)(1) through (4)—then at least one of the other recognized grounding electrodes given in 250.52(A)(5) through (7) [or (8) if desired and available] must be installed unless the supply is a single two-wire or multiwire branch circuit as just covered above. That would most likely be a rod, pipe, or plate electrode—such as a driven ground rod—and it must be bonded to the equipment ground terminal or equipment grounding bus in the enclosure of the panel, switchboard, circuit breaker, or switch in which the feeder terminates ([Fig. 250-24](#)).

For “installations made in compliance with previous editions of this Code that permitted such connection,” a special exception does allow a system grounding connection to the local grounding electrode conductor and the equipment grounding conductors, just as if the building were supplied by a service. The qualifying wording for this exception is a significant improvement over prior wording (existing premises wiring systems) because it settles whether the wiring system had to have been in existence for the premises generally (which would include all wiring on the parcel), or whether the second building had to have been previously wired. For example, if building No. 1 was wired in 1965, there was an existing premises wiring system that predated the code change. The new wording clarifies that building No. 2 actually had to have been wired prior to the 2008 edition of the **NEC** (when this grounding method was very severely limited) in order to have the wiring scheme legitimized. This practice was (and still is) used in uncounted millions of locations because it was the default procedure for the first 100 years of **NEC** editions. It is now headed down the road to extinction. There are additional conditions on its use. There must be no parallel metallic return paths that would allow current that should flow over the grounded circuit conductor to instead return to the service through other paths. Examples include an equipment grounding conductor, including a wiring method to the second building that is itself an equipment grounding conductor, such as rigid metal conduit. In such a case, a system grounding connection in the second building would send normal circuit current through the conduit in parallel with the enclosed grounded circuit conductor (usually a neutral). Another example would be a metallic water piping system common to both buildings; since such systems must be bonded to the grounding systems in each building the water pipes would become parallel conductors for the same reason.

In addition, as covered in 230.95, there must be no GFPE installed in any parent location because any line-to-ground fault in the second building will return over the neutral and look like ordinary load to the GFPE sensor. Finally, the neutral must have sufficient ampacity to perform both as a neutral (220.61) and as an equipment grounding conductor (250.122). New as of the 2014 **NEC** is a second exception to correlate with the fact that under the conditions governing 250.30(A)(1) Exception No. 2 (outdoor transformer supply) a bonded neutral condition will exist. This exception is essentially trivial because no load beyond the feeder it supplies will be connected at this remote location. It is

also questionable because it is neither a building nor a structure and seemingly out of the scope of 250.32.

Part (2) is new as of the 2011 edition and covers instances where the remote building or structure is supplied by a separately derived system. For example, a large facility might distribute power at 480 V and set pad-mount transformers outside detached process buildings. If there is overcurrent protection where these feeders originate, the wiring doesn't differ from conventional feeder (or branch circuit) wiring as covered in 250.32(B)(1). If, however, the conductors arrive with no overcurrent protection, as could be done under the outdoor transformer secondary tap rule in 240.21(C)(4), then the wiring reverts to that for separately derived systems and must comply with 250.30(A). In the usual case where a supply-side bonding jumper would be necessary, it must be connected to the building disconnect and to the local grounding electrode conductor. Refer to the discussion at 250.30(A)(2) for more information.

Figure 250-25 shows another condition in which a grounding electrode connection must be made at the other building, as specified in the basic rule of 250.32(C).

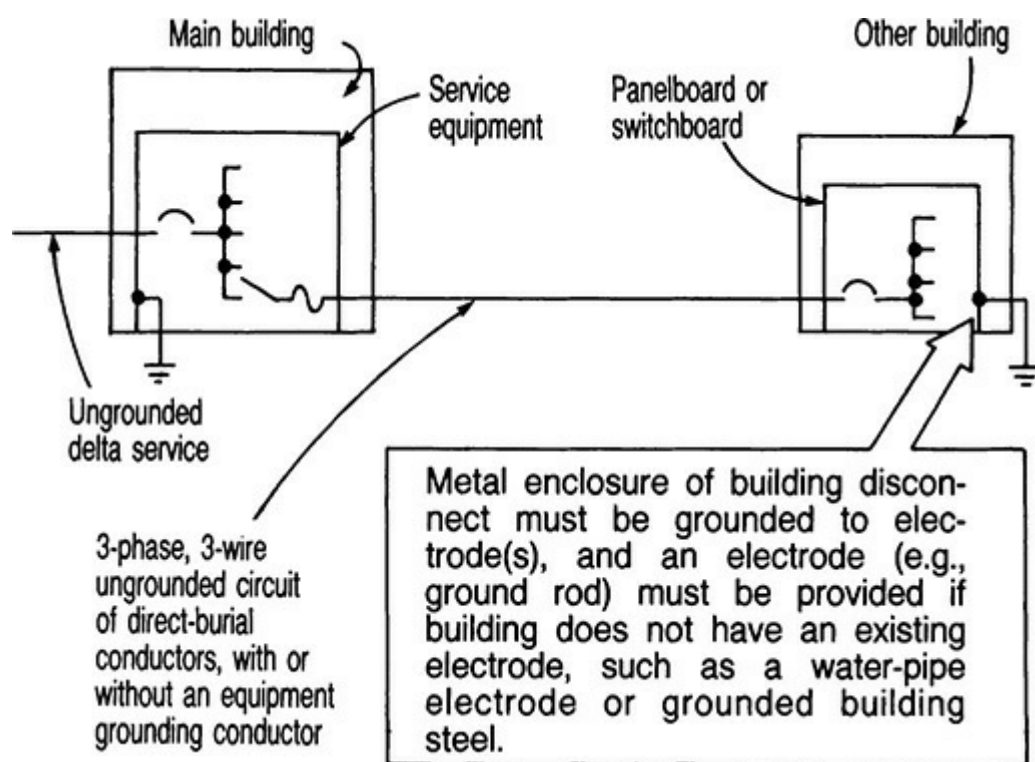

Fig. 250-25. Grounding connection for an ungrounded supply to outbuilding. (Sec. 250.32.) Under current requirements, the equipment grounding conductor must be provided with the supply conductors. [Sec. 250.32(C)(1)].

If the 3-phase, 3-wire, ungrounded feeder circuit to the outbuilding had been run with a separate equipment grounding conductor that effectively connected the metal enclosure of the disconnect in the outbuilding to the grounding electrode conductor in the SE equipment of the main building, a connection to a grounding electrode would still be required. There is no distinction regarding the presence of an equipment grounding conductor or ground path. Under all situations where an ungrounded system supplies another building, a grounding electrode connection would be required at the outbuilding, and then the equipment grounding conductor run to the outbuilding would have to be bonded to any grounding electrodes that were “existing” at that building—such as an underground metal water service pipe and/or a grounded metal frame of the building. All grounding electrodes that

exist at the outbuilding must be bonded to the ground bus or terminal in the disconnect at the outbuilding, whether or not an equipment grounding conductor is run with the circuit conductors from the main building.

Just as in the case of grounded systems, this topic now has two subheadings, one for a conventional supply and one for a supply through a separately derived system. For a conventional supply, or a separately derived supply with overcurrent protection established at the source, an equipment grounding conductor must be provided and be connected to the building disconnect and to the local grounding electrode. If the overcurrent protection is at the building, then the arrangement follows 250.30(B) and any separate supply-side bonding jumper must make the same connections.

Part **(D)** covers design of the grounding arrangement for a feeder from one building to another building when the main disconnect for the feeder is at a remote location from the building being supplied—such as in the other building where the feeder originates. The rule prohibits grounding and bonding of a feeder to a building from another building if the disconnect for the building being fed is located in the building where the feeder originates. Part **(D)** correlates the grounding concepts of 250.32 with the disconnect requirements of 225.32, Exceptions Nos. 1 and 2. The rule also incorporates consideration of a standby generator as a source of supply where the generator is located remote from the building supplied, as covered in 700.12(B)(6), 701.12(B)(5), and 702.12. The exceptions in 225.32 address industrial situations where buildings may have no local disconnects, and instead rely on “documented safe switching procedures” and the behavior and knowledge of highly trained staff to accomplish the discontinuation of electric power in an emergency.

In all of these cases, there must still be a grounding electrode conductor, but special provisions must be made to address how the associated grounding electrode conductor will be connected to the local electrical system. There are three requirements. First, regrounding the neutral at the building supplied is prohibited. Second, the feeder must include an equipment grounding conductor, which must connect to the on-premises equipment grounding system and to an on-site grounding electrode unless only one branch circuit is supplied. Third, the equipment grounding and grounding electrode interconnection must occur in a junction box to be located immediately inside or outside the building supplied.

250.32(E) clarifies that the sizing rules for grounding electrode conductors located in buildings supplied by branch circuits or feeders or both follow the sizing rules for such conductors generally. They are based on the size of the ungrounded conductors that are the source of supply, with the usual Table 250.66 upper limit of 3/0 AWG as the maximum required size.

250.34. Portable and Vehicle-Mounted Generators. Part **(A)**, which covers portable generators, rules that the frame of a portable generator does not have to be grounded if the generator supplies only equipment mounted on the generator and/or plug-connected equipment through receptacles mounted on the generator, provided that the noncurrent-carrying metal parts of equipment and the equipment grounding conductor terminals are bonded to the generator frame. (See [Fig. 250-26.](#))

1. . . . the generator supplies equipment mounted on generator and/or cord-and-plug-connected equipment through receptacles on the generator, and

2. metal parts of equipment and equipment grounding terminals of receptacles are bonded to generator frame.

When frame of portable generator is left ungrounded as permitted in 250.34 . . .

... the generator frame is a suitable (and required) bonding point for the equipment grounding terminals of receptacles and noncurrent-carrying metal parts of equipment.

Fig. 250-26. Grounding details for a portable generator.

A clarification in part (A) points out that, where a portable generator is used with its frame *not*

grounded, the frame is permitted to act as the grounding point for any cord-connected tools or appliances plugged into the generator's receptacles. This ensures that tools and appliances that are required by 250.114 to be grounded do satisfy the Code when plugged into a receptacle on the ungrounded frame of a portable generator.

Part **(B)** notes that the frame of a vehicle-mounted generator may be bonded to the vehicle frame, which then serves as a grounding point—it is not a grounding electrode, and since “ground” is defined as the earth, actually both the portable and vehicle-mounted generators covered here are operating ungrounded. This is only permitted when the generator supplies only equipment mounted on the vehicle and/or cord- and plug-connected equipment through receptacles on the vehicle or generator. When the frame of a vehicle is used as the grounding point for a generator mounted on the vehicle, grounding terminals of receptacles on the generator must be bonded to the generator frame, which must be bonded to the vehicle frame.

If either a portable or vehicle-mounted generator supplies a fixed wiring system external to the generator assembly, it must then be grounded as required for any separately derived system (as, for instance, a transformer secondary), as covered in 250.30.

The wording of part **(C)** brings application of portable and vehicle-mounted generators into compliance with the concept previously described in 250.30 on grounding and bonding of the generator neutral conductor. A generator neutral *must be* bonded to the generator frame when the generator is a truly separately derived source, such as the sole source of power to the loads it feeds. If the neutral is solidly connected to the building's utility service neutral, then such a supply would not be considered separately derived, and would not be subject to the bonding and grounding requirements given in 250.30. And if the generator neutral is *not* tied into the neutral conductor of the building's normal supply, such as where connected through a 4-pole transfer switch as part of a *normal/emergency* hookup—for feeding the load normally from the utility service and from the generator on an emergency or standby basis—then the generator would have to comply with the rule of 250.30, which covers grounding of separately derived systems ([Fig. 250-27](#)). A note to this section refers to 250.30, and that rule is applicable to grounding and bonding of portable generators that supply a fixed wiring system on a premises. In such a case, bonding of the neutral to the generator frame is not required if there is a solid neutral connection from the utility service, through a transfer switch to the generator, as shown in the bottom sketch of [Fig. 250-27](#).

Portable or vehicle generator as sole source or separately derived

Portable generator supplying premises wiring

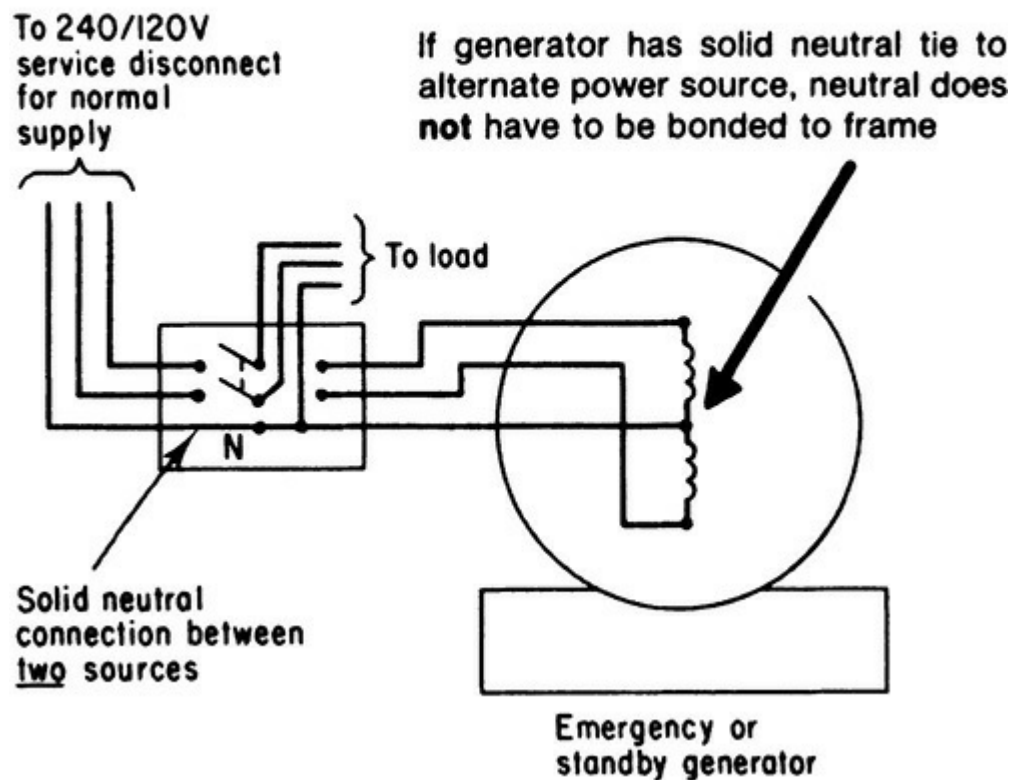

Fig. 250-27. Generator neutral may be required to be grounded. (Sec. 250.34.)

Watch Out! The recently released UL standard on Portable Engine Generator Assemblies (UL

2201) requires all 15-kW or smaller portable generators to have bonded neutral connections. However, the bonded neutral also means that their output wiring must be wired as a separately derived system if it is used to power a premises wiring system. This, in turn, makes them only suitable for transfer switches that transfer the grounded circuit conductor along with the ungrounded conductors. This is incompatible with the overwhelming majority of transfer arrangements now in place and available in the market for residential and light commercial applications. This outcome is proving to be very controversial; many generators are not listed and do not have bonded neutrals. Many generator companies believe that operating a small generator with a floating neutral is actually safer, and a perfectly valid alternative to a bonded neutral. One company now has its small generators with a bonding connection that is easily reconfigured in the field, so they can be run either way.

However, although UL released the new generator standard in March of 2009, not a single portable generator has ever been listed to its provisions. The generator industry adamantly opposes its provisions, and as of the 2014 **NEC** 445.20 creates an opening for a generator with an on-board twist-lock receptacle that, when in use, disables any on-board 15- and 20-A receptacles. The concept is that powering a building and utilizing its main bonding jumper is harmless in such cases. Refer to the discussion at 445.20 for more information.

250.35. Permanently Installed Generators. This is a new section as of the 2008 **NEC** covering permanently installed generators. There must be an appropriately designed fault current path so wiring faults will be cleared properly. If the generator neutral is not connected to any other neutral source in the supplied building, in consequence of the generator qualifying as a separately derived system and having its neutral controlled in the transfer switch, then the grounded circuit conductor of the transfer switch simply complies with all the rules in 250.30. In other words, if the generator is the energy source for a separately derived system, then it is wired like any other separately derived system.

On the other hand, if the generator neutral is permanently connected to the premises neutral through a transfer switch with a solid neutral, there are two possibilities for sizing that neutral depending on where the overcurrent device for the generator output is located. If it is on the generator, then the fault-current path will be over an *equipment grounding conductor* sized in accordance with Table 250.122 [technically, 250.102(D) but that section immediately points to 250.122] based on the size of the OCPD. Example: A standby generator rated 50 kVA, 208Y/120-V has a 150-A circuit breaker mounted on the unit. An equipment grounding conductor must be run with the supply conductors, not smaller than 6 AWG.

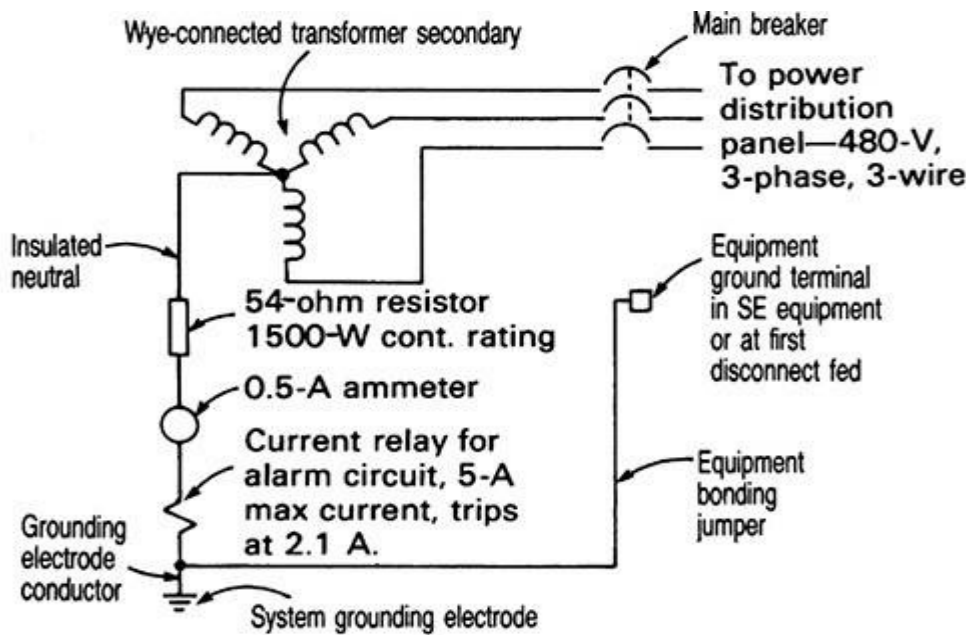

If the OCPD is at the transfer switch, then the fault current path will be over a *supply-side bonding conductor* sized in accordance with 250.102(C), which means it will follow Table 250.102(C) with upward sizing, if necessary, in instances where the associated current-carrying load conductors exceed 1100 kcmil. Example: Same generator as before, output conductors sized per 445.13 at 115 percent of FLC. Therefore, $1.15(50,000 \text{ VA} \div 360 \text{ V}) = 160 \text{ A}$; 2/0 AWG conductors selected for the supply. From Table 250.102(C), the associated supply-side bonding jumper is 4 AWG copper.

250.36. High-Impedance Grounded Neutral Systems. (Adapted from Practical Electrical Wiring, 22nd ed., © Park Publishing, 2014, all rights reserved.) These systems combine the best features of the ungrounded systems in terms of reliability, and the best features of the grounded systems in terms of their ability to dissipate energy surges due to their grounding connection. They are permitted for 3-phase ac systems running from 480 to 1000 V, provided no line-to-neutral loads are connected, there is qualified maintenance and supervision, and ground detectors

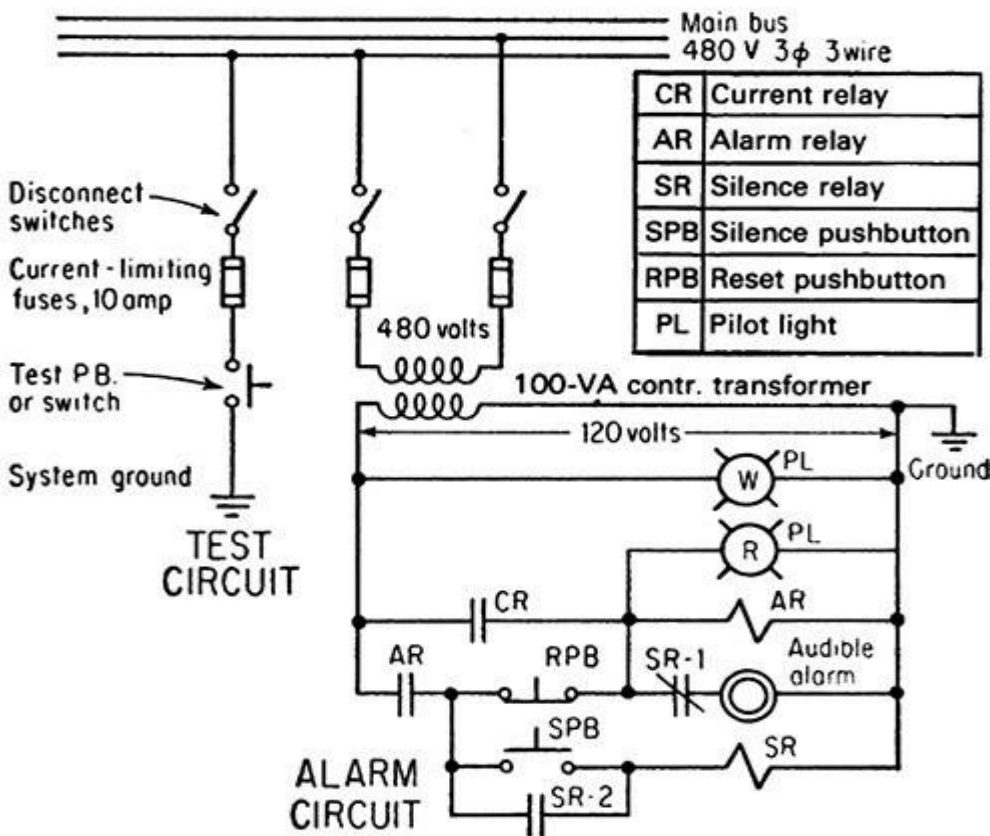

are installed.

These systems behave like ungrounded systems in that the first ground fault will not cause an overcurrent device to operate. Instead, detectors required by **NEC 250.36(2)** will alert qualified supervisory personnel. Remember, a capacitor is two conductive plates separated by a dielectric. A plant wiring system consists of miles and miles of wires, all of which are separated by their insulation. This means that a plant wiring system is a giant though very inefficient capacitor, and it will charge and discharge 120 times each second. The resistance is set such that the current under fault conditions is only slightly higher than the capacitive charging current of the system. Since a fault will often continue until an orderly shutdown can be arranged, the resistor must be continuously rated to handle this duty safely.

As shown in [Fig. 250-28](#), the grounding impedance must be installed between the system neutral [250.36(A)] and the grounding electrode conductor. Where a system neutral is not available, the grounding impedance must be installed between the neutral derived from a grounding transformer [see 450.5(B)] and the grounding electrode conductor, as shown in [Fig. 250-29](#). The neutral conductor between the neutral point and the grounding impedance must be fully insulated. Size it at 8 AWG minimum. This size is for mechanical concerns; the actual current is on the order of 10 A or less [250.36(B)].

1—Diagram of resistance-grounded system shows how neutral of main transformer(s) is grounded through a resistor, ammeter and current relay. Ground fault on any phase causes current to flow from fault through ground at transformer, through current relay, ammeter and resistor back to transformer neutral. Resistor limits fault current; current relay, which trips at any current level above 2.1 amps, initiates alarm.

2—Test circuit (on left of diagram) allows application of temporary ground to system to test alarm function. In alarm circuit, contacts CR close when current relay, which is connected in neutral-conductor ground-circuit at main transformer, senses a ground fault (see Fig. 1). Operation of contacts CR initiates audible and visual alarm.

Fig. 250-28. This is a typical application of resistance-grounded system operation on a wye-connected supply secondary. (Sec. 250.36.)

Contrary to the normal procedure of terminating a neutral at a service disconnecting means enclosure, when the system is high-impedance grounded, the grounded conductor is prohibited from being connected to ground except through the grounding impedance [250.36(C)]. In addition, the neutral conductor connecting the transformer neutral point to the grounding impedance is not required to be installed with the phase conductors. It can be installed in a separate raceway to the grounding impedance [250.36(D)]. The normal procedure (usually performed by the utility) of adding a grounding electrode outside the building at the source of a grounded system (should one be used as the energy source for an impedance-grounded system) must *not* be observed [250.24(A)(2) Exception], because any grounding currents returning through the earth to the outdoor electrode will bypass and therefore desensitize the monitor.

An equipment bonding jumper [250.36(E)] must be installed unspliced from the first system disconnecting means or overcurrent device to the grounded side of the grounding impedance. The grounding electrode conductor can be attached at any point from the grounded side of the grounding impedance to the equipment grounding connection at the service equipment of the first system disconnecting means [250.36(F)]. Note that the size of the equipment bonding jumper depends on the end to which the grounding electrode conductor is connected, as shown in [Fig. 250-29](#) [250.36(G)]. A connection at the impedance makes the bonding jumper a functional extension of the grounding electrode conductor, and it must be sized accordingly. A connection at the load end of the equipment grounding bus makes the bonding jumper a functional extension of the neutral, normally sized at 8 AWG [250.36(B)].

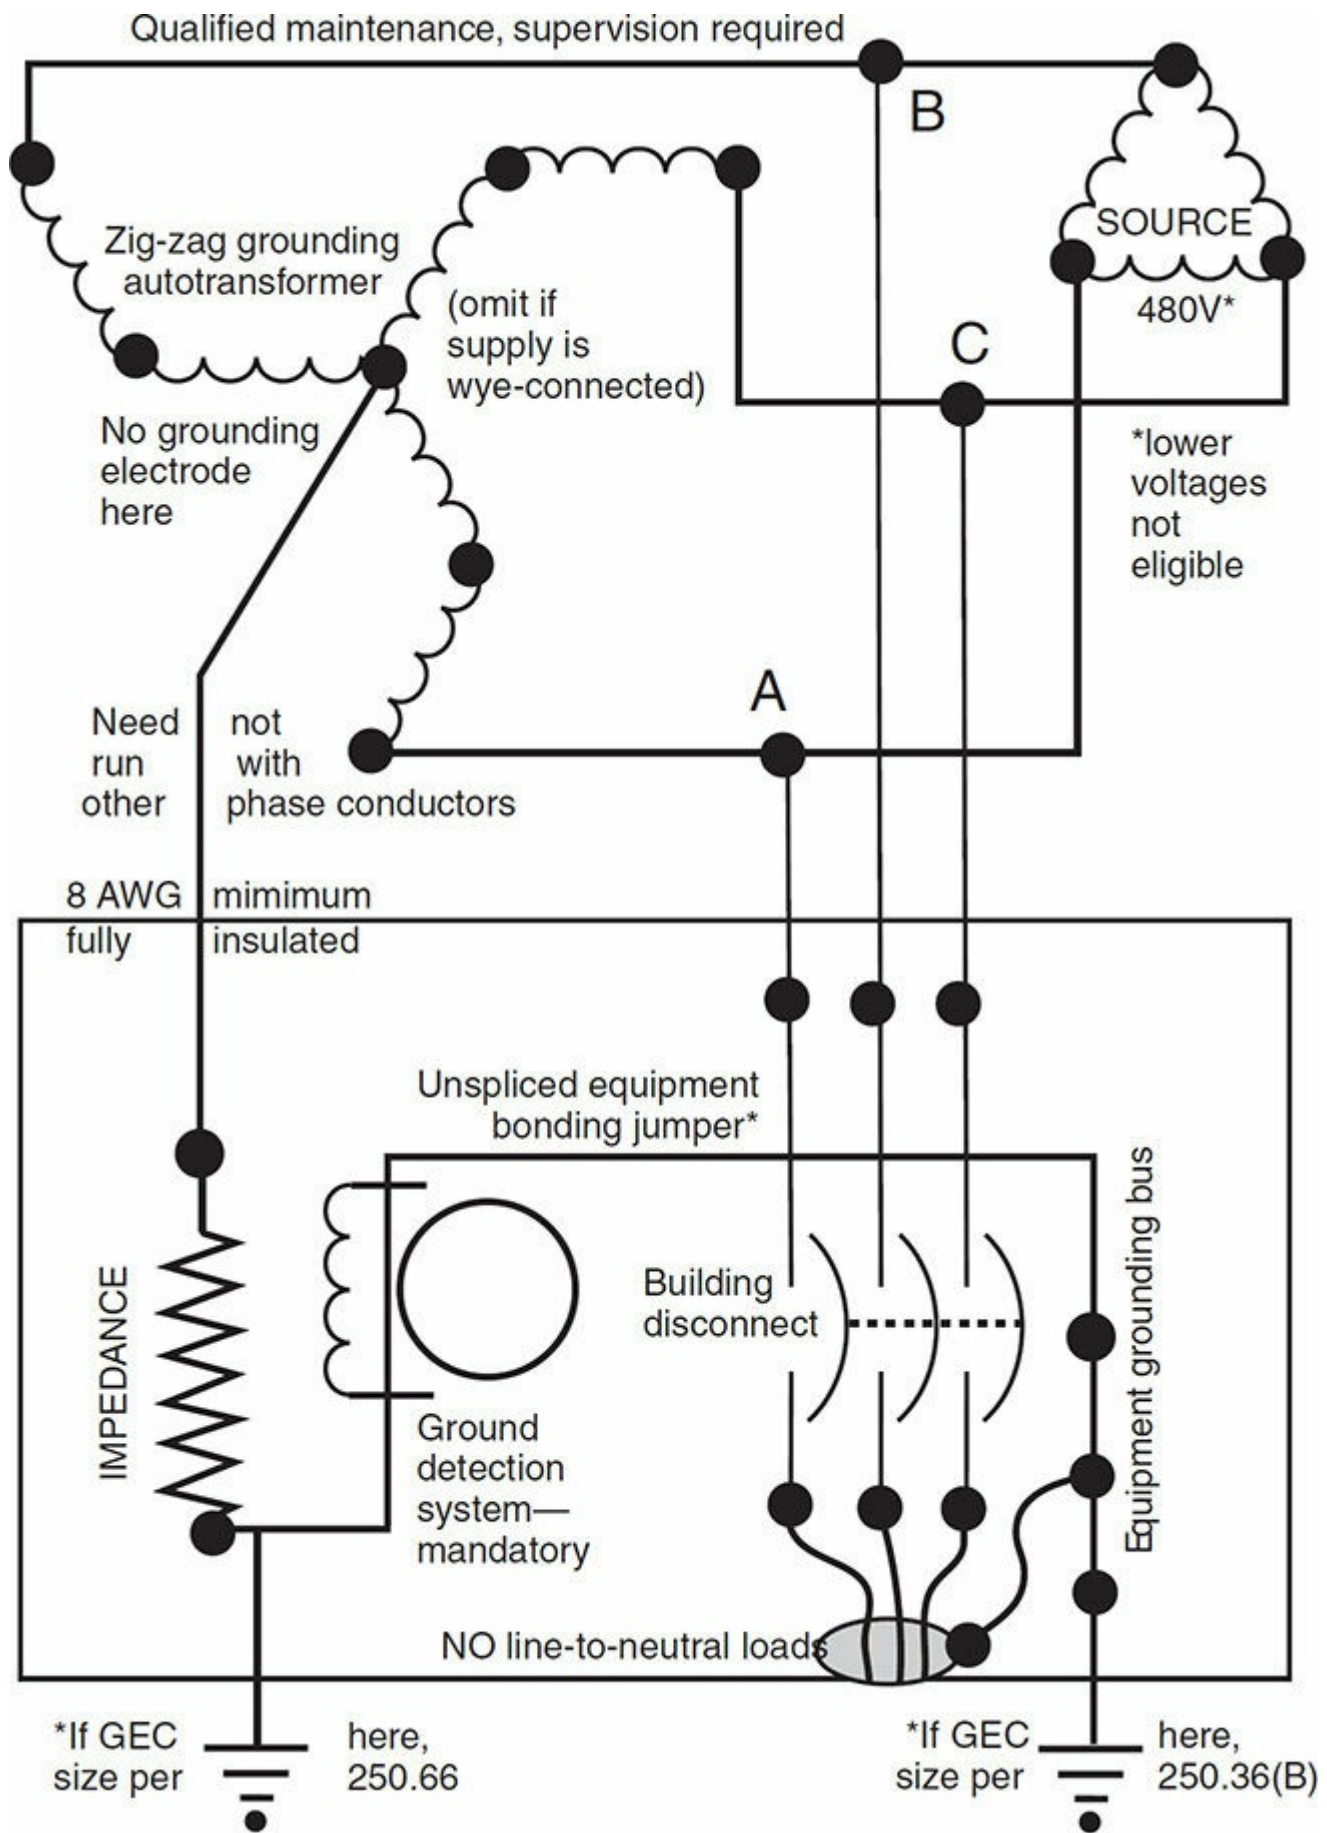

Fig. 250-29. High-impedance grounded neutral systems can be retrofitted on systems supplied by ungrounded delta distributions. This drawing illustrates most of the rules in 250.36.

250.50. Grounding Electrode System. The rule in this section covers the grounding

electrode arrangement required at the service entrance of a premise or in a building or other structure fed from a service in another building or other structure, as covered in 250.32. This section mandates interconnection of the grounding electrodes specified in 250.52(A)(1) through (A)(7), which describe certain building components and other recognized electrodes that must be hooked together to form a “grounding electrode system.” [Figure 250-30](#) shows a number of potential elements in a grounding electrode system as envisioned by the NEC. Where the grounding electrodes described in 250.52(A)(1) through (A)(4) are not *present* at the building or structure served—either by its own service or supplied from another building—then at least one of the grounding electrodes identified in parts (A)(4) through (A)(8) must be installed to form a grounding electrode system.

**GROUNDING ELECTRODE SYSTEM:
BONDING JUMPERS, SIZED FROM TABLE
250.66, TIE WATER PIPE, BUILDING STEEL,
AND 1/2-in.-DIA STEEL REINFORCING
BARS TOGETHER.**

NOTE: At point “A”, a bonding jumper **must** be used around the water meter and must be not smaller than the grounding-electrode conductor.

Fig. 250-30. Metal in-ground supporting structures and reinforcing bars must be used as an electrode if present. (Sec. 250.50.)

The use of the word “present,” which in the 2005 edition replaced “available” in the 2002 and many previous **NEC** editions, was probably the most far-reaching change in the **NEC** achieved by changing a single word. The effect of the change was to bring qualifying concrete-encased electrodes (illustrated in Fig. 250-31) into grounding electrode system if they are present, not just if they are available. Therefore, the order of construction on building projects frequently had to change because as soon as the building steel in the footings was set and tied, an electrical connection had to be made and an electrical inspection performed. Another approach involves bringing a segment of reinforcing steel out of the pour that is tightly tied to the segment(s) making up the qualified electrode; however, most electrical inspectors will want to know that some disinterested and qualified third party witnessed the other end of such steel before the concrete truck arrived. And if that inspection does not take place, the general contractor risks having to dismantle a foundation and start over.

Fig. 250-31. Concrete-encased electrode, connections to reinforcing steel. This rule can have a significant impact on trade sequencing. It is a superior electrode, and can be easily created in any foundation with 20 ft of bare copper arranged to be encased in the pour. The **NEC** also recognizes placements in other portions of the foundation as long as the concrete is in direct contact with the soil. (Sec. 250.50.) As of the 2011 **NEC**, the wording changed and now allows a horizontal run above the footing provided it is below the grade line. However, the deeper the better, because there is more permanent moisture, and a placement below frost counteracts the enormous increases in resistance that occur when the ground freezes.

The problem of connecting to these electrodes after the concrete has dried is an obvious one, which is why there is an exception to 250.50 that waives the rule for concrete-encased electrodes in existing buildings when the concrete would have to be disturbed in order to complete a connection.

The overlapping of this rule—mentioning part **(A)(4)** twice—is a little strange, but the wording of

the rule here would recognize a ground ring, if present, as the grounding electrode system. And where a water pipe, building steel, or rebars in the footing or foundation—as covered in 250.52(A)(1) through (A)(3)—*and* a ground ring [250.52(A)(4)] are *not* available at the building or structure, then the Code would accept a ground ring, as described in 250.52(A)(4), that is installed specifically to serve as the grounding electrode system for the building or structure. The concept here is that (A)(1) through (A)(3) electrodes are extremely unlikely to be capable of being added in the field, but the others, including ground rings, are capable of field installation after the building is in place.

The electrodes identified in 250.52(A)(8) are never required to be connected, unless one desires to do so. That is, by excluding part **(A)(8)** from the first sentence, it is never mandatory to hook up such equipment wherever it exists. Rather, the way this rule is worded, such underground metal piping systems or metal structures *may be* used as a grounding electrode, but are *not required* to always be connected to the grounding electrode system.

It should be noted that the requirements for service or building grounding electrode systems given here now apply to the grounding of a separately derived system, such as a local step-down transformer, which is covered by part **(A)(4)** of 250.30 ([Fig. 250-32](#)). The simplification of electrode choices in that section means that any qualified building electrode can be used for such systems.

Fig. 250-32. Grounding electrode conductor from the bonded secondary neutral of this local transformer was connected to grounded building steel before concrete floor was poured. This installation is not covered by the rules of 250.50, but is covered by 250.30 and complies with those rules. (Sec. 250.50.)

250.50 calls for a “grounding electrode system” instead of simply a “grounding electrode” as required at one time. Up to the 1978 **NEC**, the “water-pipe” electrode was the premier electrode for service grounding, and “other electrodes” or “made electrodes” were acceptable *only* “where a

water system (electrode) ... is not available.” If a metal water pipe to a building had at least 10 ft (3.0 m) of its length buried in the ground, that *had* to be used as the grounding electrode and no other electrode was required. The underground water pipe was the preferred electrode, the *best* electrode.

For many years now, and in the present **NEC**, of all the electrodes previously and still recognized by the **NEC**, the water pipe is the least acceptable electrode and is the only one that may never be used by itself as the *sole* electrode. It must always be supplemented by at least one “additional” grounding electrode (Fig. 250-33). Any one of the other grounding electrodes recognized by the **NEC** is acceptable as the *sole* grounding electrode, by itself.

Fig. 250-33. Connection to an underground metal water-supply pipe is never adequate grounding for electric service equipment. (Sec. 250.53.)

Take a typical water supply of 12-in. (305-mm)-diameter metal pipe running, say, 400 ft (122 m) underground to a building with a 4000-A service. In 250.53 the Code requires that the water pipe, connected by a 3/0 copper conductor to the bonded service-equipment neutral may *not* serve as the only grounding electrode. It must be supplemented by one of the other electrodes from 250.52. So the installation can be made acceptable by, say, running a No. 6 copper grounding electrode conductor from the bonded service neutral to an 8-ft (2.44-m), 5/8-in. (15.87-mm)-diameter ground rod. Although that seems like using a mouse to help an elephant pull a load, it is the literal requirement of 250.53. And if the same building did not have 10 ft (3.0 m) of metal water pipe in the ground, the 8-ft (2.44-m) ground rod would be entirely acceptable as the *only* electrode, provided it has a “ground-

resistance measurement” of 25 Ω or less, as required by 250.53(A)(2) Exception. And even if that resistance can’t be met, then one more such electrode cures the code compliance problem regardless of resistance.

In fairness, the panel certainly recognizes the mouse/elephant issue. The problem has never been the suitability of a water pipe, which will always be a good electrode. The problem is that the **NEC** cannot predict when water supply companies will, often without warning, remove metal water pipes and substitute polyethylene or some other plastic in its place. This is an ongoing and very prevalent problem. Think of the ground rod therefore not as a “supplemental” electrode, but as a reserve electrode instead. This is why 250.53(D)(2) requires these supplemental electrodes to meet the same 25- Ω rule as where the electrodes are the sole electrodes present. A water pipe does not actually need supplementation in terms of its electrode function, as long as it is in the ground. But if it is removed, something has to remain in its place.

250.52. Grounding Electrodes. This section identifies those building components and other equipment that are recognized as “grounding electrodes.” The basic rule of 250.50 requires that all or any of the electrodes specified in 250.52(A)(1) through (A)(7), if they are present on the premises, must be bonded together to form a “grounding electrode system.” It should be understood and remembered that the grounding electrodes described in parts (A)(1) through (A)(4) are not required to be provided. But, if such building components or a ground ring are present at the building or structure, then it is required that they be interconnected. The electrodes described in parts (A)(5), rod and pipe electrodes, or (A)(6), plate electrodes, or (A)(7), other listed electrodes such as chemically enhanced designs, would also be required to be interconnected, if they already existed, and at least one would have to be installed if none of the grounding electrodes given in (A)(1) through (A)(4) were available. Alternately, the grounding electrode—“Other Local Metal Underground Systems and Structures”—recognized by part (A)(8) would be acceptable as the sole grounding electrode, where available, and its presence would eliminate the need to drive a rod, pipe, or plate electrode, or install a ground ring.

Note: The other underground metal systems and structures are not mandated to always be interconnected; rather, such systems and structures *may be* used as, or interconnected with the “grounding electrode system.”

If present at the building or premises supplied, the following shall be interconnected:

- (A)(1) If there is at least a 10-ft (3.0-m) length of underground metal water pipe, connection of a grounding electrode conductor must, generally, be made to the water pipe at a point less than 5 ft (1.52 m) from where the water piping enters the building. As a general principle, grounding electrodes are conductive objects in actual contact with earth; even if an unbroken length of water pipe extends out of the earth, only the portion in the earth is the electrode, and the portion extending out of the ground is a conductive object that may or may not be permitted to be utilized to extend the electrode for the purposes of making a connection.
- (A)(2) The 2017 **NEC** no longer describes this as a metal building frame. It is now a “metal in-ground support structure.” This represents an additional step in an ongoing effort to confine the term “grounding electrode” to conductive objects that can actually transfer electric current into the earth (see [Fig. 250-34.](#)) A new informational note drives that home by listing typical examples. The paragraph also contains the permission in the prior **NEC** to

only bond one of multiple in-ground structures into the grounding electrode system in the event there are multiple instances. The former rules in this location about the hold-down bolts and their connection to concrete-encased electrodes have been moved to 250.68(C) as part of the larger editorial plan.

250.52(A)(2) recognizes the metal in-ground support structure as a suitable grounding electrode by itself, connected to bonded service neutral by conductor sized from Table 250.66.

250.104(A) requires interior metal water piping to be bonded to service grounding, such as by bonding to the grounding electrode (the building frame in this case), with jumper sized from Table 250.66.

NOTE: Rebars in foundation could also serve as the only electrode if building did not have metal frame.

ONE METHOD of grounding building structural members to ground cable system.

Fig. 250-34. Metal in-ground support structures may be the sole grounding electrode. (Sec. 250.52.)

- (A)(3) If there is at least a total of 20 ft (6.0 m) of one or more 1/2-in. (13-mm)-diameter (No. 4 or larger) steel reinforcing bars or rods embedded in the concrete footing or foundation low enough so the enclosing concrete is in direct contact with earth, or at least 6.0 m (20 ft) of 4 AWG copper wire likewise embedded in concrete, a bonding connection must be made to the bare wire or to one of the rebars—and obviously that has to be done before concrete is poured for the footing or foundation. The electrode length, in whole or in part, can also be measured vertically as long as the concrete surrounding the portion encased is in direct contact with earth. Second, if the reinforcing steel is discontinuous so that multiple qualified concrete-encased electrodes exist on any given building, it is sufficient (although not required or even advisable) to bond just one of them into the grounding electrode system. In fact, since the rule simply refers to multiple concrete-encased electrodes, if 6.0 m (20 ft) of 4 AWG bare copper, which independently qualifies, were added, the

requirement would be met without making a connection to the steel. Refer to the beginning of coverage on 250.53 for a more extensive discussion of how these electrodes must be installed.

(A)(4) If present, a “ground ring” consisting of a buried, bare copper conductor, 2 AWG or larger, that is at least 6.0 m (20 ft) long and in direct contact with the earth is supplied, a bonding connection to it must be made. No minimum depth is given because the installation of ground rings is covered by part **(E)** of 250.53, which calls for a minimum cover of 750 mm (2½ ft).

If a building has all or some of the electrodes described, the preceding applications are mandatory to the extent they are present. If it has none, then any one of the electrodes described in 250.52(A)(4) through (A)(8) must be installed and/or used as the grounding electrode system for service grounding or outbuilding grounding.

An electrode by definition is an object in physical, conductive contact with earth. However, under some circumstances the **NEC** has allowed them to extend out of the earth for connection purposes. The 2011 **NEC** placed the rules for such electrode extensions together in one location, 250.68(C). Paragraph (1) at that location addresses water pipes, covered in (A)(1) above, and Paragraph (2) at that location addresses metal building frames, described in (A)(2) above. The 2014 **NEC** added concrete-encased electrodes, covered in (A)(3) above, as Paragraph (3). The principle is that when an electrode extends beyond its contact with earth, it has become a grounding electrode conductor of some form and the exposed portion is no longer an electrode. To correlate with this principle, 250.62 as of the 2014 **NEC** now effectively describes these extensions as covered in 250.68(C) under a heading “grounding electrode conductor material.” Please refer to coverage at 250.68(C) for more information on this important topic.

(A)(5) describes rods and pipes that would be recognized as grounding electrodes. Whether a pipe or a rod, the minimum is 2.44 m (8 ft). Pipe not smaller than metric designator 21 (trade size ¾) is permitted, but generally requires corrosion protection where made of iron or steel. Rods must not be smaller than 15.87 mm (5⁄8 in.) where made of iron or steel. Stainless-steel rods that are less than 15.87 mm (5⁄8 in.) and nonferrous rods, such as brass, copper, or “their equivalent,” must be listed for use as a grounding electrode and be not smaller than 12.70 mm (½ in.).

(A)(6) covers “other listed grounding electrodes” and includes specially designed and listed products such as those made of punched copper pipe prefilled with chemical additives to enhance effectiveness.

(A)(7) covers plate electrodes, which must have a surface area such that not less than 0.186 m² (2 ft²) is exposed to the soil when buried. Note that as worded, a plate with soil exposure on two sides need only have a footprint of 0.093 m² (1 ft²). The minimum thickness for steel or iron plate electrodes is 6.4 mm (¼ in.), but where nonferrous plate electrodes are used, the minimum thickness required is 1.5 mm (0.06 in.). Clearly, use of listed electrodes, exclusively, will go a long way toward ensuring a safe and acceptable installation.

These last three electrodes are listed in the UL *Electrical Construction Materials Directory* under the heading “Grounding and Bonding Equipment”—which also covers bonding devices, ground clamps, grounding and bonding bushings, ground rods, armored grounding wire, protector grounding wire, grounding wedges, ground clips for securing the ground wire to an outlet box, water-meter shunts, and similar equipment. Only listed devices are acceptable for use. And listed equipment is

suitable only for use with copper, unless it is marked “AL” and “CU.”

The last grounding electrode recognized by 250.52(A) is **(A)(8)**, which covers “Other Metal Underground Systems and Structures.” The basic thrust of the rule in 250.50 is that these underground piping systems or tanks, if metallic, may be used as the grounding electrode in lieu of the other electrodes described in parts **(A)(4)** through **(A)(6)**. It is never *required* that a connection be made to such underground systems or structures; but, if desired, such a connection would constitute compliance with the rule in 250.50 calling for a grounding electrode system. Note that underground metal well casings have been specifically added to the list of examples of such electrodes. One reason for making these electrodes optional is that they may be at some distance from the system connection. As discussed in the informational note to 250.4(A)(1), grounding electrode conductors should be as short as practicable. This is due to the effects of distance on increasing the impedance of high-frequency transients.

In this context, it is necessary to revisit the language in 250.52(A)(1) (the water pipe electrode description) about bonding to a metal well casing. This is not a requirement to use metal well casings as electrodes generally. However, if the metal portion of a water pipe goes all the way out to the side of a well casing, and then continues down into the depths of the well, the casing has to be bonded to the pipe at the upper end. This arrangement is uncommon but not unknown, particularly for large or deep wells for which a steel riser is considered necessary. The bonding requirement in this case is no different from, and serves the same function as, the familiar requirement to bond both ends of a steel conduit to an enclosed grounding electrode conductor. In this case, the metal water pipe is the conductor, the well casing is the ferrous enclosure, and the bond at the upper end in conjunction with both pipes being in contact with a common destination at the bottom addresses the impedance problem.

Part **(B)(1)** warns that a metal underground gas piping system must *never* be used as a grounding electrode. A metal underground gas piping system has been flatly disallowed as an acceptable grounding electrode because gas utility companies reject such practice and such use is in conflict with other industry standards.

As a general rule, if a water piping system or other approved electrode is not available, a driven rod or pipe is used as the grounding electrode system ([Fig. 250-35](#)). A rod or pipe driven into the ground does not always provide as low a ground resistance as is desirable, particularly where the soil becomes very dry, or where soil chemistry reduces conductivity. In the granitic soils of the Northeast, for example, the resistance on a conventional 8-ft copper-plated ground frequently approaches 1000 Ω in moist soil, significantly higher than test results demonstrated for comparable electrodes in the desert outside Las Vegas. A famous demonstration carried out by a ground resistance tester vendor in moist soil in central Massachusetts in the 1980s forever settled this point in the minds of the many inspectors from around New England who witnessed it. Ten fully driven ground rods, widely spaced so as to not have their cones of influence overlap, were connected in parallel. The resistance tester was connected to the field and the reference electrode for the tester was spaced out a great distance so as to get a reliable test result from so large a field. The overall result was 320 Ω ! A ground rod is certainly better than no electrode, but not always by very much. Part **(B)(2)** of 250.52 prohibits use of an aluminum grounding electrode. The requirement to use concrete-encased electrodes wherever present in new construction is providing a welcome improvement in this area.

Fig. 250-35. A driven ground rod must have at least 8 ft (2.44 m) of its length buried in the ground, and if the end of the rod is above ground (arrow), both the rod and its grounding-electrode-conductor attachment must be protected against physical damage.

Part **(B)(3)**, new in the 2017 **NEC**, forbids the use of swimming pool bonding structures as grounding electrodes. The intent of Art. 680 is that these structures must retain their focus on equipotential bonding to mitigate voltage gradients in the pool area. Directly connecting them (through a main or system bonding jumper) to a system neutral is asking for the injection of voltage gradients they are intended to eliminate.

250.53. Grounding Electrode System Installation. When two or more grounding electrodes of the types described in 250.52 are to be combined into a “grounding electrode system,” as required by 250.50, the rules of this section govern such installation and provide additional conditions, restrictions, and requirements.

Although not called out for special installation rules in this section, the greatly increased importance of concrete-encased electrodes has raised some areas of discussion regarding installation details. These electrodes are known as the “Ufer system,” and they have particular merit in new construction where the bare copper conductor can be readily installed in a foundation or footing form before concrete is poured, even if no reinforcing steel is scheduled to be installed and thereby become a mandatory electrode. Installations of this type using a bare copper conductor have been installed as far back as 1940, and tests have proved this system to be highly effective.

These electrodes must be completely encased within the concrete, which means simply laying the electrode on the dirt at the bottom of a form does not comply. The electrode must be elevated at least

50 mm (2 in.) into the pour either by positioning on supports or by lifting after the pour and while the concrete is still wet. The latter approach is effective, but creates the logistical problem of needing the inspector present at that exact moment to witness the encasement. The footing itself must be in direct contact with the earth, which means that dry gravel or polyethylene sheets between the footing and the earth are not permitted (Fig. 250-36).

BARE COPPER CONDUCTOR ... OR

... 1/2 IN. DIAMETER REBARS OR RODS

Fig. 250-36. The “Ufer” grounding electrode is concrete-encased, and the grounding electrode conductor does not have to be larger than 4 AWG copper in either case. [Sec. 250.52(A)(3).]

The **NEC** requires these electrodes to be “continuous” and also says that the encased electrode can be made of “multiple pieces connected together.” The panel intends that where multiple segments are used, they still extend in the same sort of line the 20-ft long solid bar would make. And yes, this would mean for a vertical application the pier or other concrete structure would need to extend at least 20 ft down, or perhaps somewhat less if the electrode were oriented on a slant. However, the segment allowance is not intended to vary from the geometrical concept of a 20-ft long solid reinforcing bar. The reason for this is that Herbert Ufer’s original testing used a horizontal, straight-line configuration. There apparently is no subsequent testing that has been done on other geometries, such as four 5-ft lengths bonded together and installed in four piers with at least 5 ft of concrete below grade. It is true that four 5-ft rods in the same area will have their areas of influence overlap and their paralleling efficiency diminished in comparison to a continuous run, hence the long-standing spacing limitation in 250.53(B) for paralleled ground rods. This subject was not revisited in either the 2014 **NEC** or the 2017 **NEC**.

It is generally advisable, depending on the additives that may be in the concrete, to provide additional corrosion protection in the form of plastic tubing or sheath at the point where the grounding electrode leaves the concrete foundation. Do not use ferrous raceways for this, however, or the result will be a magnetic choke unless bonding at both ends has been arranged to the enclosed conductor, which is seldom practical.

For concrete-encased steel reinforcing bar or rod systems used as a grounding electrode in underground footings or foundations, welded-type connections (metal-fusing methods) may be used for connections that are encased in concrete. Compression or other types of mechanical connectors may also be used. *Conventional “acorn” ground rod clamps are not suitable for this purpose.* The connectors listed for use on rebar are made of a special alloy formulated to break through the oxide coating on the reinforcing steel, and they are marked with the size of bar for which they have been designed, along with a “DB” designation (direct burial) that is required for any grounding or bonding product that will be used below grade or embedded in concrete. These instructions, along with any torque specifications, must be followed exactly per 110.3(B).

In 250.53(A) the Code calls for the upper end of the rod to be buried below “permanent moisture level,” where “practicable.” That wording clearly shows that the Code intends the ground rod or plate to be completely buried, unless something prevents such installation. However, the rule of part (G) in this section does provide remedies for problem installations, and includes a requirement for “protection” of the ground rod and clamp where the rod is not “flush with or below ground.” Suffice it to say that to the maximum extent possible, always ensure that rod, pipe, and plate be buried below the permanent moisture level. [See 250.53(G).]

The second part of 250.53(A) includes the specific concepts in former 250.56 on ground rod (or pipe or plate) resistances, which was deleted. Because of marginal resistance readings in so many cases for these electrodes, the default instruction is now to supplement any one of these electrodes with another, even another of the same type (and thereby resulting in the usual two ground rods in such cases). If a single electrode does qualify for the 25 Ω criterion, then it may continue to be used without supplementation, but now that is found in a new exception to the general rule. (See. [Fig. 250-37.](#))

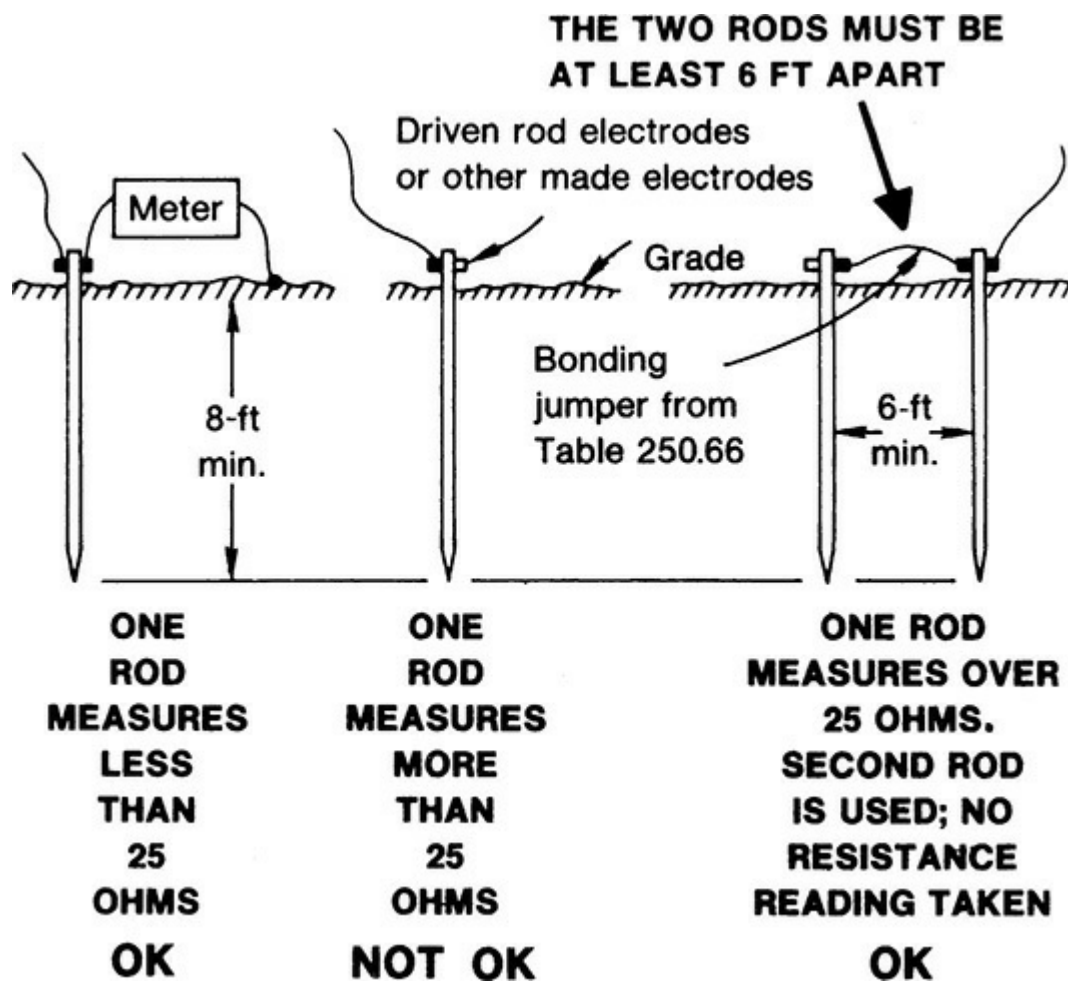

Fig. 250-37. Earth resistance of ground rod must be considered. [Sec. 250.53(A)(2) and exception.]

Insofar as rod, pipe, or plate electrodes are concerned, there is a wide variation of resistance to be expected, and the present requirements of the National Electrical Code concerning the use of such electrodes do not provide for a system that is in any way comparable to that which can be expected where a good underground metallic piping can be utilized.

It is recognized that some types of soil may create a high rate of corrosion and will result in a need for periodic replacement of grounding electrodes. It should also be noted that the intimate contact of two dissimilar metals, such as iron and copper, when subjected to wet conditions can result in electrolytic corrosion.

Under abnormal conditions, when a cross occurs between a high-tension conductor and one of the conductors of the low-tension secondaries, the electrode may be called upon to conduct a heavy current into the earth. The voltage drop in the ground connection, including the conductor leading to the electrode and the earth immediately around the electrode, will be equal to the current multiplied by the resistance. This results in a difference of potential between the grounded conductor of the wiring system and the ground. It is therefore important that the resistance be as low as practicable.

Where rod, pipe, or plate electrodes are used for grounding interior wiring systems, resistance tests should be conducted on a sufficient number of electrodes to determine the conditions prevailing in each locality. The tests should be repeated several times a year to determine whether the conditions have changed because of corrosion of the electrodes or drying out of the soil.

Figure 250-38 shows a ground tester being used for measuring the ground resistance of a driven electrode. Two auxiliary rod or pipe electrodes are driven to a depth of 1 or 2 ft (300 to 600 mm), the distances A and B in the figure being 50 ft (15 m) or more. Connections are made as shown

between the tester and the electrodes; then the crank is turned to generate the necessary current, and the pointer on the instrument indicates the resistance to earth of the electrode being tested. In place of the two driven electrodes, a water piping system, if available, may be used as the reference ground, in which case terminals P and C are to be connected to the water pipe.

Fig. 250-38. Ground-resistance testing must be done with the proper instrument and in strict accordance with the manufacturer's instructions. [Sec. 250.53(A)(2) and exception.]

But, as previously noted, where two rods, pipes, or plate electrodes are used, it is not necessary to take a resistance reading, which is required in the case of fulfilling the requirement of $25\ \Omega$ to ground for one such electrode.

The $25\text{-}\Omega$ rule has a very long history in the **NEC**, beginning with the 1918 edition. In what was then Class C (Inside Work), Rule 15A (Method of Grounding, when Protective Grounding is

Required), subheading (t), the following text appeared: “*The combined resistances of the ground wires and connections of any grounded circuit, equipment, or lightning arrester should not exceed 3 ohms for water pipe connections nor 25 ohms for artificial grounds where these must be used. Where, because of dry or other high resistance soils it is impracticable to obtain artificial ground resistance as low as 25 ohms, two such grounds six feet apart if practicable must be installed, and no requirement will be made as to resistance.*”

The water pipe specification was changed to a fine print note in the 1933 **NEC**, which stated that in general the resistance to ground of water pipes didn't exceed 3 Ω . The note was quite extensive, with commentary and recommendations on other electrodes. This arrangement continued until the 1975 **NEC** removed the note entirely, as unnecessary. However, the 25- Ω parameter for rod, pipe, and plate electrodes still survives.

250.53(B) says that where it is necessary to bury more than one pipe or rod or plate in order to lower the resistance to ground, they should be placed at least 6 ft (1.8 m) apart. If they were placed closer together, there would be little improvement.

Where two driven or buried electrodes are used for grounding two different systems that should be kept entirely separate from one another, such as a grounding electrode of a wiring system for light and power and a grounding electrode for a lightning rod, care must be taken to guard against the conditions of low resistance between the two electrodes and high resistance from each electrode to ground. If two driven rods or pipes are located 6 ft (1.83 m) apart, the resistance between the two is sufficiently high and cannot be greatly increased by increasing the spacing. The rule of this section requires at least 6 ft (1.83 m) of spacing between electrodes serving different systems.

As covered by 250.53(C), the size of the bonding jumper between pairs of electrodes must not be smaller than the size of grounding electrode conductor indicated in 250.66, both the table of sizes based on the largest associated ungrounded conductor(s) and the individual provisions that are based on particular electrodes. The installation must satisfy the indicated rules of 250.64, and must be connected as required by 250.64 and 250.70.

Part (D) of 250.53 presents additional criteria for the hookup of the grounding electrode system.

A very important sentence of 250.53(D)(1) says that “continuity of the grounding path or the bonding connection to interior piping shall not rely on water meters or filtering devices and similar equipment.” The intent of that rule is that a bonding jumper always *must be used* around a water meter. This rule is included because of the chance of loss of grounding if the water meter is removed or replaced with a nonmetallic water meter. The bonding jumper around a meter must be sized in accordance with Table 250.66. Although the Code rule does not specify that the bonding jumper around a meter be sized from that table, the reference to “bonding jumper ... sized in accordance with 250.66,” as stated in 250.53(C), would logically apply to the water-meter bond. The reference to filters and the like is even more crucial, because they are commonly nonmetallic, and therefore continuity would be lost permanently and not just when the equipment is out for servicing.

It usually saves both material costs and labor expense to integrate compliance with 250.104(A)(1) at the same time as making any required grounding electrode connection to a water pipe electrode. The other rule requires an interior metal water piping system to be bonded to the service or to the grounding electrode conductor using the same size bonding jumper as is required for the grounding electrode conductor run to a water pipe. Since a water meter or filter raises continuity issues, a connection on the street side does not satisfy 250.104(A)(1). The very simple solution is to leave the grounding electrode conductor long enough to attach to both sides of a meter or filter as necessary.

For example, the installation in [Fig. 250-34](#) almost certainly will have a water meter installed subsequently, and the electrician would have saved money and time if he had connected to both sides with a slightly longer ground wire.

In the last sentence of 250.53(D)(2), an electrode (such as a driven ground rod) that supplements an underground water-pipe electrode must be “bonded” to any one of several points in the service arrangement. It may be “bonded” to (1) the grounding electrode conductor or (2) the grounded service conductor (grounded neutral), such as by connection to the neutral block or bus in the service panel or switchboard or in a CT cabinet, meter socket, or other enclosure on the supply side of the service disconnect or (3) grounded metal service raceway or (4) any grounded metal enclosure that is part of the service. (See [Fig. 250-39](#).) It may also be bonded to an interior part of a metal water system in those occupancies where the interior part of the water pipe is allowable for grounding electrode connections. Item (5) is new as of 2011 and reminds users that if they are working with an electrode in a second building fed from another, 250.32(B)(1) Exception No. 1 will limit the permissibility of connecting a grounding electrode conductor to the grounded circuit conductor in those cases. This item is somewhat incongruous in a list of permitted supplemental electrodes.

Grounding electrode conductor sized from Table 250.66 must connect bonded service neutral to clamp on water-pipe electrode, on either side of water meter, with same size bonding jumper around water meter.

Because building does not have grounded metal frame or either of the electrodes described in 250.52 (A) (2) through (A) (4), the rule of 250.53 (D) (2) requires that one of the other electrodes of 250.52 be used to supplement the water-pipe electrode—such as a driven ground rod.

Fig. 250-39. Supplementing water-pipe electrode in building without metal frame. The 25 Ω requirement applies to rods used as supplemental electrodes to the same extent as where they are the only electrodes. As in those cases, a second rod or plate is always a cure for the resistance problem in terms of meeting the minimum requirement. (Sec. 250.53.)

The rule of 250.53(E) makes very clear that a ground rod, pipe, or plate electrode that is used to supplement a water-pipe electrode does not require any larger than a No. 6 copper (or No. 4 aluminum) conductor for a bonding jumper that is the only connection from the ground rod to the grounding-electrode conductor, to the bonded neutral block or bus in the service equipment, to any grounded service enclosure or raceway, or to interior metal water piping.

The basic rule of 250.53(G) calls for a ground rod to be driven straight down into the earth, with at least 8 ft (2.44 m) of its length in the ground (in contact with soil). *This means that if you can see the end of a 2.44-m (8-ft) rod above the ground surface, even a little bit, it cannot possibly have been driven far enough to meet the requirement.* If rock bottom is hit before the rod is 8 ft (2.44 m)

into the earth, it is permissible to drive it into the ground at an angle—not over 45° from the vertical—to have at least 8 ft (2.44 m) of its length in the ground. However, if rock bottom is so shallow that it is not possible to get 8 ft (2.44 m) of the rod in the earth at a 45° angle, then it is necessary to dig a $2\frac{1}{2}$ -ft (750-mm)-deep trench and lay the rod horizontally in the trench. [Figure 250-40](#) shows these techniques. Note that for any of these installations the ground rod clamp must be suitable for direct burial, and that means there will be a marking to that effect.

Fig. 250-40. In all cases, a ground rod must have at least 8 ft (2.44 m) of its length in contact with the soil.

A second requirement calls for the upper end of the rod to be flush with or below ground level—*unless* the aboveground end and the conductor clamp are protected either by locating it in a place where damage is unlikely or by using some kind of metal, wood, or plastic box or enclosure over the end (Sec. 250.10). In the case of an 8-ft rod this is not an issue because as noted, if you can see the end, the installation does not meet the **NEC**. However, there are 3.0-m (10-ft) ground rods, and if

they are not fully driven this provision may come into play.

This two-part rule was added to the Code because it had become a common practice to use an 8-ft (2.44-m) ground rod driven, say, 6½ ft (1.98 m) into the ground with the grounding electrode conductor clamped to the top of the rod and run over to the building. Not only is the connection subject to damage or disconnection by lawnmowers or vehicles, but also the length of unprotected, unsupported conductor from the rod to the building is a tripping hazard. The rule says—bury everything or protect it! Of course, the buried conductor-clamp assembly that is flush with or below grade must be resistant to rusting or corrosion that might affect its integrity, as required by 250.70.

250.54. Auxiliary Grounding Electrodes. This is an extremely important rule that has particular impact on the use of electrical equipment outdoors. The first part of the rule accepts the use of “auxiliary grounding electrodes”—such as a ground rod—to “augment” the equipment grounding conductor; BUT an equipment grounding conductor must always be used where needed and the connection of outdoor metal electrical enclosures to a ground rod is never a satisfactory alternative to the use of an equipment grounding conductor. The use of just ground-rod grounding would have the earth as “the sole equipment grounding conductor,” and that is expressly prohibited by the last clause of this rule.

Such an earth return path has impedance that is too high, limiting the current to such a low value that the circuit protective device does not operate. In that case, a conductor that has faulted (made conductive contact) to a metal standard, pole, or conduit will put a dangerous voltage on the metal—exposing persons to shock or electrocution hazard as long as the fault exists. The basic concept of this problem—and Code violation—is revealed in [Fig. 250-41](#).

Fig. 250-41. Ineffective grounding creates shock hazards. (Sec. 250.54.)

This violation results from a fundamental confusion around the distinction between bonding requirements that create an effective ground-fault current path, and grounding requirements that create a local ground reference for reasons that have nothing to do with clearing faults. The 480-V panel in [Fig. 250-42](#) is an extreme electrocution hazard. The sketch in [Fig. 250-43](#) shows the correct procedure. Note that any acceptable equipment grounding conductor, including one of the metal raceways listed in 250.118, would produce a safe installation. The drawing in [Fig. 250-44](#) highlights some practical issues on terminating branch circuits at lighting equipment on poles. The caption focuses on a very common problem of how to deal with a metal conduit sweep inserted because of its resistance to damage from heavy pulling forces, and that is stranded in a nonmetallic conduit run.

Fig. 250-42. Driven ground rod (arrow) has conductor run to it from a large lug at the left rear of the enclosure. All of the equipment grounding conductors from UF 480-V circuits to pole lights are connected to that lug. But the ground rod and earth path are the sole return paths for fault currents. The two larger conductors make up a 480-V underground USE circuit, without the neutral or an equipment grounding conductor brought to the panel, leaving “earth” as the sole return path. (Sec. 250.54.)

Fig. 250-43. Equipment grounding conductor ensures effective fault clearing. (Sec. 250.54.)

Fig. 250-44. Watch out for grounding details like these! (Sec. 250.54.) With respect to the center call-out on a transition to nonmetallic conduit, there are important issues to consider. The bonding bushing at the bottom of the sweep almost certainly does not have a direct burial listing and would require modifications and inspection approval to be used in this way. A better approach is to put the bushing on the aboveground end of the conduit which, in an all-conduit run would only work with a box, which may be objectionable. There are other options. One is to use the exception in 250.102(E)

to route a bonding jumper from the sweep up the pole to a location where it can be connected to the equipment grounding conductor. There are “U-bolt” style ground clamps that are listed for direct burial. Another is to bury the sweep low enough so its upper end is still 450 mm (18 in.) below grade level, in which case bonding is not required. (250.86 Exception No. 3).

250.58. Common Grounding Electrode. The same electrode(s) that is used to ground the neutral or other grounded conductor of an ac system must also be used for grounding the entire system of interconnected raceways, boxes, and enclosures. The single, common grounding electrode conductor required by 250.24 connects to the single grounding electrode and thereby grounds the bonded point of the system and equipment grounds. See 250.50.

250.60. Use of Strike Termination Devices. This rule requires an individual “grounding electrode system” for grounding of the grounded circuit conductor (e.g., the neutral) and the equipment enclosures of electrical systems, and it prohibits use of the lightning ground electrode system for grounding the electrical system. Although this rule does *not* generally prohibit or require bonding between different grounding electrode systems (such as for lightning and for electric systems), it does note that the prohibition against using a lightning protection grounding system for power system grounding must not be read as prohibiting the required bonding of the two grounding systems, as covered in 250.106. And the note calls attention to the advantage of such bonding. There have been cases where fires and shocks have been caused by a potential difference between separate ground electrodes and the neutral of ac electrical circuits.

250.62. Grounding Electrode Conductor Material. Figure 250-45 shows the typical use of copper, aluminum, or copper-clad aluminum conductor to connect the bonded neutral and equipment ground terminal of service equipment to each of the one or more grounding electrodes used at a service. Controversy has been common on the permitted color of an insulated (or covered) grounding electrode conductor. 200.7(A) generally prohibits use of white or gray color for any conductor other than a “grounded conductor”—such as the grounded neutral or phase leg, as described in the definition of “grounded conductor.” Grounding conductors must usually be green if insulated, but there is no reciprocal limitation on the use of the color for other than ungrounded conductors. This means that although equipment grounding conductors must be green or bare, there is no Code rule clearly prohibiting a green grounding electrode conductor. Refer to 250.119. The 2014 **NEC** added the electrode extensions covered in 250.68(C) to this section as well; refer to that section for complete information.

Fig. 250-45. A grounding electrode conductor may be bare, covered, or insulated, and any color other than white or gray, which is reserved for grounded circuit conductors by 200.7(A). (Sec. 250.62.) The color green is permitted because 250.119 only excludes it for grounded or ungrounded circuit conductors, and a grounding electrode conductor is neither.

250.64. Grounding Electrode Conductor Installation. This section covers all grounding electrode conductor installations, whether for services, or for buildings or other structures supplied with a feeder or branch circuit when the requirements in 250.32 require such conductors, or for separately derived systems when provisions in 250.30 produce the same result. Part (A) limits the use of aluminum conductors, but only in part. First, bare aluminum or copper-clad aluminum conductors cannot be used in direct contact with masonry or the earth or where subject to corrosive conditions. (See [Fig. 250-46.](#)) Aluminum is a chemically reactive metal that relies on its oxide coating to retain its integrity. There are compounds in masonry and soils that will attack the oxide coating and the metal will corrode because of it. Insulated aluminum conductors are more forgiving, but where used outdoors, they must not be terminated within 450 mm (18 in.) above grade. (See [Fig. 250-47.](#))

NOTE: An insulated aluminum conductor or a bare conductor installed in conduit may not be subject to these limitations, depending upon the inspector's interpretation.

Fig. 250-46. The limitation to the left applies only to *bare* aluminum conductors. The limitation to the right literally applies only to aluminum terminations, and not the intervening route. However, it cannot be run in contact with masonry or earth if it is bare. [Sec. 250.64(A).]

Fig. 250-47. This has been accepted but does violate literal Code wording in an outdoor pad-mounted transformer if the X_0 termination is less than 450 mm (18 in.) above grade level. [Sec. 250.64(A).]

Part (B) covers the rules that limit exposure to physical damage, based on the size of the grounding electrode conductor. In all cases and sizes, the conductor must be securely fastened to any surface on which it runs. It may also pass through framing members. A 4 AWG or larger conductor can run without other limitation unless it is “exposed to physical damage.” Note that this provision used to say “severe physical damage.” The substantiation for the change (2005 **NEC**) was editorial, to the effect that any physical damage was unacceptable. However, whether it will be consistently applied that way in the field is uncertain. A 6 AWG conductor that is free of exposure to physical damage can

additionally run “along the surface of the building construction” without additional protection; this is generally understood to include the sides of floor joists but not from joist to joist. An 8 AWG conductor, the smallest size permitted by 250.66, must run in a raceway or cable armor. (See Fig. 250-48.) The larger conductors, where threatened with damage because of local conditions, must be protected with a raceway or cable armor as well.

Fig. 250-48. Protection for grounding electrode conductor. (Sec. 250.64.)

The 2014 **NEC** added a final sentence to this paragraph that definitively answers the question as to whether there is a mandated burial depth for a grounding electrode conductor run outdoors. The answer is no, because no depth is given, and a very clear statement is made that the burial depths specified for underground wiring in 300.5 do not apply to these conductors. They must, however, be buried at least to some extent or else otherwise protected if subject to damage.

Part (C) is the continuous length rule. This rule was reorganized for the 2008 **NEC**. Now the parts of the requirement chiefly involved with where the conductors originate, at service equipment and the like, remain here. Specifically, grounding electrode conductors are preferably run without joint or splice, but there are major exceptions to this. First, busbar segments must be bolted together in the field. Second, splices in a wire-type conductor must be made with a high degree of permanence, defined as having been made using the thermite (“exothermic welding”) process or a compression connector applied with a tool that makes it irreversible. Because grounding electrodes such as building steel and water pipes are now only those metallic elements in direct with earth, and because it is frequently necessary to create extensions of those electrodes, they are now to be described as some sort of grounding electrode conductor instead of a grounding electrode. Therefore, this section had to make allowances, because these extensions [see 250.68(C)] obviously cannot be installed without joints. Therefore, two additional allowances had to be made in this section for these

construction materials, first for building steel elements, and second for water piping, and they follow the traditional ones for busbars and wires. Note that no mention is included for concrete-encased electrode extension in this context. This is because the only permitted form for these extensions is the very end of an otherwise embedded rod, and there will be no splice. Refer to 250.68(C)(3) for the details.

The other half of this requirement, covering where and how these conductors end up arriving at the electrodes is now covered in 250.64(F). Specifically, the unspliced grounding electrode conductor can run to any convenient electrode (assuming more than one exists) in the grounding electrode system, provided these individual electrodes are bonded together per 250.53(C), and the size of any grounding electrode conductor employed is no smaller than the largest size conductor required among them by 250.66.

If, for instance, a grounding electrode system consists of a metal underground water-pipe electrode supplemented by a driven ground rod, the grounding electrode conductor to the water pipe would have to be sized from Table 250.66; and on, say, a 2000-A service, it would have to be a 3/0 AWG copper or 250-kcmil aluminum, connected to the water-pipe electrode, which would require that larger size of grounding electrode conductor. A bonding jumper from the bonded grounding terminal or bus in the SE equipment to the driven ground rod would not have to be larger than a 6 AWG copper or 4 AWG aluminum grounding electrode conductor, just as it would be if the ground rod is used by itself as a grounding electrode, provided it had a ground resistance, as established by testing, of 25 Ω , or less, to ground. A bonding jumper between the water-pipe electrode and the ground rod would also have to be that size. There is negligible benefit in running larger than a 6 AWG copper or 4 AWG aluminum to a rod, pipe, or plate electrode, because the rod itself is the limiting resistance to earth.

The other option is a ground bus spotted in an accessible location. The language makes it very clear that the unspliced grounding electrode conductor can terminate on the busbar, which must be made of copper or aluminum (only where over 450 mm [18 in.] above grade) and measure not less than 6 mm \times 50 mm (1/4 in. \times 2 in.) in cross section. Then bonding jumpers to individual or groups of grounding electrode conductors can leave the busbar as is convenient for the specific installation. Further, the termination rules allow for both exothermic welding terminations and “listed connectors” on this busbar. That includes most mechanical lugs without the requirement of irreversible crimping tools.

Part (D) covers services with multiple enclosures, as covered in 230.71(A). This presents a very large number of possible applications, since 230.2 allows multiple services for a variety of good reasons, only some of which imply that the service enclosures will be remote from each other. For example, if a facility had a 480Y/277-V and a 208Y/120-V service, the two sets of service equipment could be (but need not be) next to each other. Other rules allow two-to-six disconnecting means per set of service entrance conductors, such as 230.40 Exception No. 4 that allows an owner’s meter and service equipment in addition to the dwelling provisions all on a single set of service entrance conductors. In addition, absent from 230.71(A), is 230.40, Exception No. 2 where multiple disconnects next to each other are fed from multiple sets of service entrance conductors originating at one tap or lateral. In the 2008 **NEC**, (D)(1) opened with a reference to 230.40 Exception No. 2 but this was deleted in the 2011 **NEC** as an unnecessary reference due to the parent text of (D). The panel apparently failed to realize that 230.71(A) as referenced in (D) does not include 230.40 Exception No. 2 applications within its scope. This issue has been successfully addressed in the 2014

NEC through the removal of the reference to 230.71(A) in favor of a generic reference to plural enclosures fed by feeders or services.

Paragraph (D)(1) describes the tap method as shown in Fig. 250-49, lower left, with taps extending into each enclosure. The unspliced grounding electrode conductor, is sized by 250-66 based on the largest sum of the cross-sectional areas of each phase or line leg, calculated by each combined phase (for polyphase applications) or each combined line (for single-phase applications). Then taps run into each enclosure, sized by 250.66 based on the largest phase or line feeding each service enclosure. Figure 250-50 shows a detail of this process. The taps must be made without cutting the common grounding electrode conductor and the joints must be made either by exothermic welding or by splicing methods that are listed as grounding and bonding equipment under UL 467. There are mechanical split bolt connectors available that have UL 467 listings, so this need not involve compression tooling. In addition, a grounding busbar of the same type and dimensions, and using the same connectors as described in the earlier discussion of 250.64(F), can be used for this purpose, effective with the 2011 **NEC**. The 2014 **NEC** added a requirement that this busbar be long enough to accommodate the necessary terminations; this is obvious, but as of now uncorrelated with its counterpart in 250.64(F).

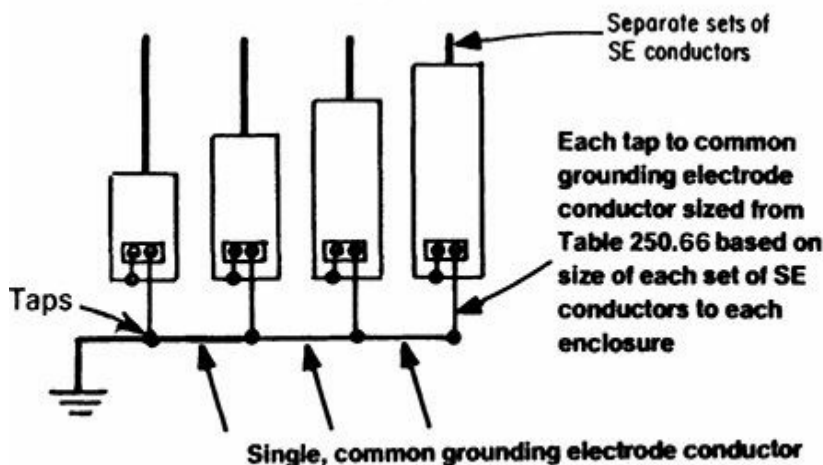

WHERE THE LAYOUT IS LIKE THIS . . .

... THE BASIC RULE CALLS FOR THIS, BUT ...

GROUNDING MAY BE DONE LIKE THIS . . .

... OR LIKE THIS

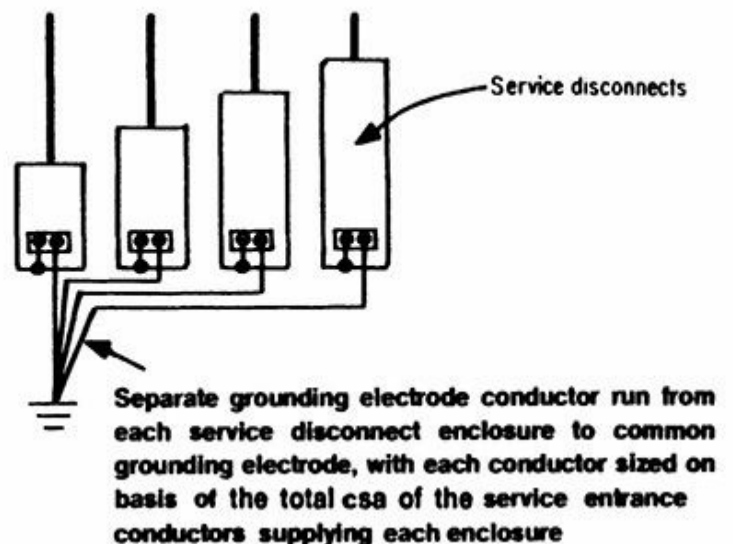

Fig. 250-49. Grounding electrode conductor may be tapped for multiple service disconnects. The procedure at the upper right will likely turn out to be impracticable in almost all cases due to termination limitations. (Sec. 250.64.) The text has generally been modified throughout 250.64(D) to provide the same coverage for installations for buildings and structures supplied by feeders as has always been the case for services, thereby filling an important gap.

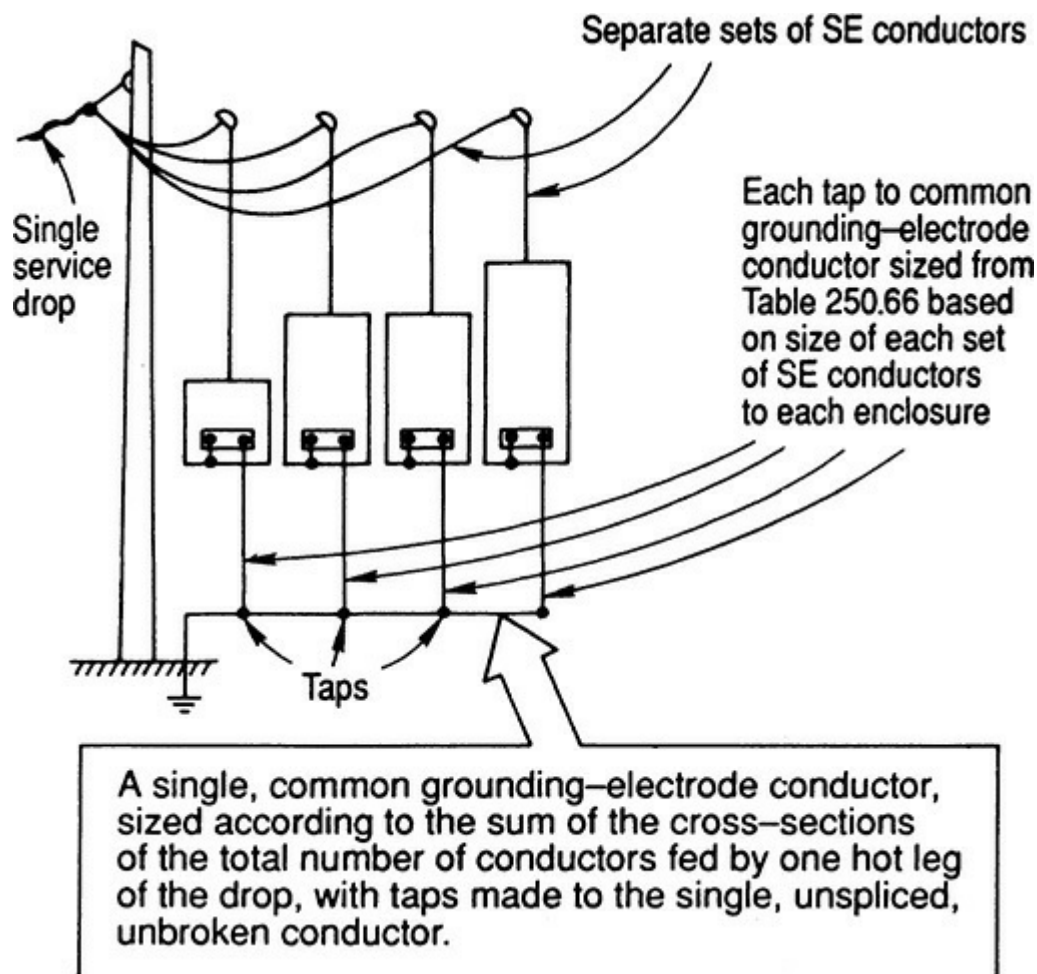

Fig. 250-50. Rule covers sizing main and taps of grounding electrode conductor at multiple-disconnect services. A single common grounding electrode conductor must be “without splice or joint,” with taps made to the grounding electrode conductor. (Sec. 250.64.)

Paragraph (D)(2) covers the case of running individual grounding electrode conductors, enclosure by enclosure, sized by 250.66 on the size of the supply conductors for that enclosure, as depicted in [Fig. 250-49](#), the lower right drawing.

Paragraph (D)(3) covers the case where a wireway or auxiliary gutter is installed adjacent to and on the supply side of the service line-up, or where manufactured equipment is preconfigured in this way such as on a multimetering setup with a tap enclosure connected to the common buswork. A common grounding electrode conductor is connected to the grounded service conductor that is common to the adjacent service equipment, using a connector that is listed as grounding and bonding equipment under UL 467. The common grounding electrode conductor is sized per 250.66 based on the largest ungrounded phase or line conductor supplying the common location.

Part (E) covers the critical importance of maintaining the electrical continuity of all ferrous metal enclosures from the point a grounding electrode conductor begins at a system enclosure, or the point any bonding jumper is attached to a grounding electrode conductor, all the way to the point where the

grounding electrode conductors and bonding jumpers terminate on an electrode. If this path is interrupted or left incomplete for any reason, the reactance will seriously degrade the performance of the grounding electrode, especially under high-fault conditions. [Figure 250-51](#) gives an overview of this procedure, and [Fig. 250-52](#) provides some construction detail on the process.

Fig. 250-51. Grounding electrode conductor must be electrically in parallel with enclosing ferrous raceway and other enclosures. (Sec. 250.64.)

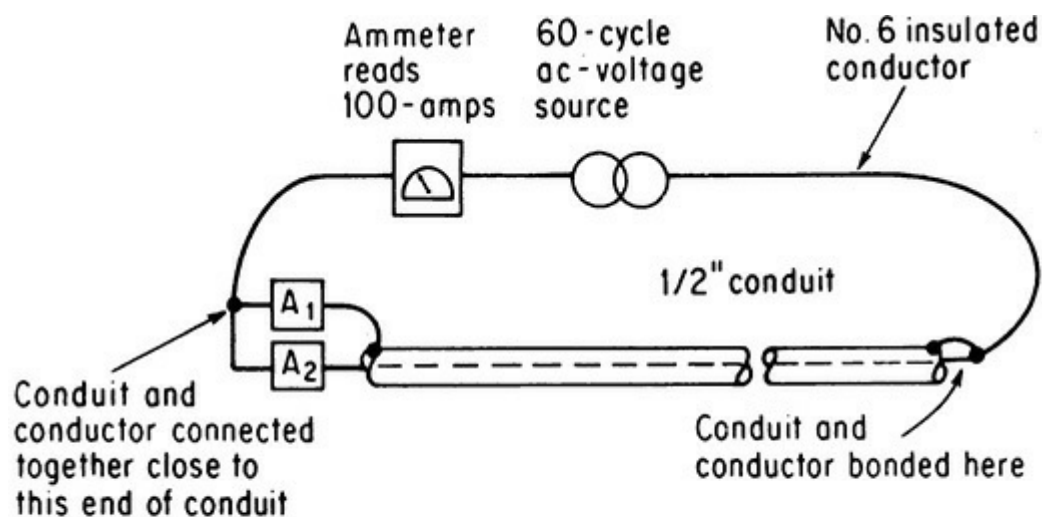

Fig. 250-52. Grounding-conductor enclosure must be “bonded” at both ends of ferrous metal enclosures. [Sec. 250.64(E)]

On alternating current circuits, when a steel conduit is properly bonded to an enclosed grounding electrode conductor at both ends and a fault develops, the current will not flow where you might expect. [Figure 250-53](#) shows the test setup to measure the results. Actual testing with 30 m (100 ft) of

metric designator 21 ($\frac{3}{4}$ trade size) rigid conduit enclosing 6 AWG copper wire showed that with 100 A of current entering the circuit, 97 A flows over the conduit and 3 A flows over the copper wire. Another test showed that with 2/0 AWG wire in the same length of metric designator 35 (trade size $1\frac{1}{4}$ in.) rigid conduit, 300 A of current pushed through resulted in 295 A over the conduit and 5A on the wire. If you break the continuity, the full current will flow through the copper wire, but at approximately double the impedance. Lightning and other electric discharges to earth through the grounding conductor will find a high-impedance path. [Figure 250-54](#) shows the correct procedure from a transformer enclosure for a separately derived system, and [Fig. 250-55](#) shows blatant, but distressingly common, violations of this rule.

Ammeter A₁ (indicates amount of current in conduit) = 97 amps

Ammeter A₂ (indicates amount of current in conductor) = 3 amps

Fig. 250-53. Enclosing conduit is more important than the enclosed grounding electrode conductor. (Sec. 250.64.)

Fig. 250-54. Protective metal conduit on grounding conductor must always be electrically in parallel with conductor. (Sec. 250.64.)

Fig. 250-55. Grounding electrode conductors are run in conduit from their connections to an

equipment grounding bus in an electrical room to the point where they connect to the grounding electrodes. Without a bonding jumper from each conduit to the ground bus, this is a clear VIOLATION of the second sentence rule of 250.64(C). (Sec. 250.64.)

The question has come up as to whether the required bonding jumper to a ferrous raceway might need to be larger than the enclosed grounding electrode conductor. This came up because bonding jumpers generally don't stop increasing in size at the 250.66 cut-off point; they keep increasing on the basis of one-eighth (12.5 percent) of the cross-sectional area of the largest phase or line conductor. At one time the literal text of the **NEC** did impose that requirement, even though it made no sense. Now 250.64(E) squarely ends that discussion by setting the size of the grounding electrode conductor as the size reference. [Figure 250-56](#) shows two more examples of the wrong way to terminate ferrous metal enclosures at grounding electrodes.

Fig. 250-56. Two examples of very clear violations of the rule that requires enclosing metal raceways (rigid metal conduit at top and flex at right) to be bonded at both ends to a grounding electrode conductor within the raceway. [Secs. 250.92 and 250.64(C).]

PVC conduit may be used to protect grounding electrode conductors of any size used in accordance with this section. Use of nonmetallic raceways for enclosing grounding electrode conductors will reduce the impedance below that of the same conductor in a steel raceway. The

grounding electrode conductor will perform its function whether enclosed or not, the principal function of the enclosure being to protect the conductor from physical damage. Rigid nonmetallic conduit will satisfy this function.

250.66. Size of Alternating-Current Grounding Electrode Conductor. For copper wire, a minimum size of No. 8 is specified in order to provide sufficient carrying capacity to ensure an effective ground and sufficient mechanical strength to be permanent. Where one of the service conductors is a grounded conductor, the same grounding electrode conductor is used for grounding both the system and the equipment. Where the service is from an ungrounded 3-phase power system, a grounding electrode conductor of the size given in Table 250.66 is required at the service.

If the sizes of service-entrance conductors for an ac system are known, the minimum acceptable size of grounding electrode conductor can be determined from **NEC** Table 250.66. Where the service consists of only one conductor for each hot leg or phase, selection of the minimum permitted size of grounding electrode conductor is a relatively simple, straightforward task. If the largest phase leg is, say, a 500-kcmil copper THW, Table 250.66 shows 1/0 AWG copper or No. 3/0 aluminum (reading across from “Over 350 kcmil thru 600 kcmil”) as the minimum size of a grounding electrode conductor.

But, use of the table for services with multiple conductors per phase leg (e.g., four 500 kcmil for each of three phase legs of a service) is more involved.

The heading over the left-hand columns of this table is “Size of Largest Service-Entrance Conductor or Equivalent for Parallel Conductors.” To make proper use of this table, the meaning of the word “equivalent” must be clearly understood. “Equivalent” means that parallel conductors per phase are to be converted to a single conductor per phase that has a cross-section area of its conductor material at least equal to the sum of the cross-section areas of the conductor materials of the two or more parallel conductors per phase. (The cross-sectional area of the insulation must be excluded.)

For instance, two parallel 500-kcmil copper RHH conductors in separate conduits would be equivalent to a single conductor with a cross-section area of $500 + 500$, or 1000 kcmil. From Table 250.66, the minimum size of grounding electrode conductor required is shown to be 2/0 AWG copper or 4/0 AWG aluminum—opposite the left column entry, “Over 600 kcmil thru 1,100 kcmil.” Note that use of this table is based solely on the size of the conductor material itself, regardless of the type of insulation. No reference is made at all to the kind of insulation.

Figure 250-57 shows a typical case where a grounding electrode conductor must be sized for a multiple-conductor service. A 208/120-V, 3-phase, 4-wire service is made up of two sets of parallel copper conductors of the sizes shown in the sketch. The minimum size of grounding electrode conductor which may be used with these service-entrance conductors is determined by first adding together the physical size of the two 2/0 AWG conductors which make up each phase leg of the service:

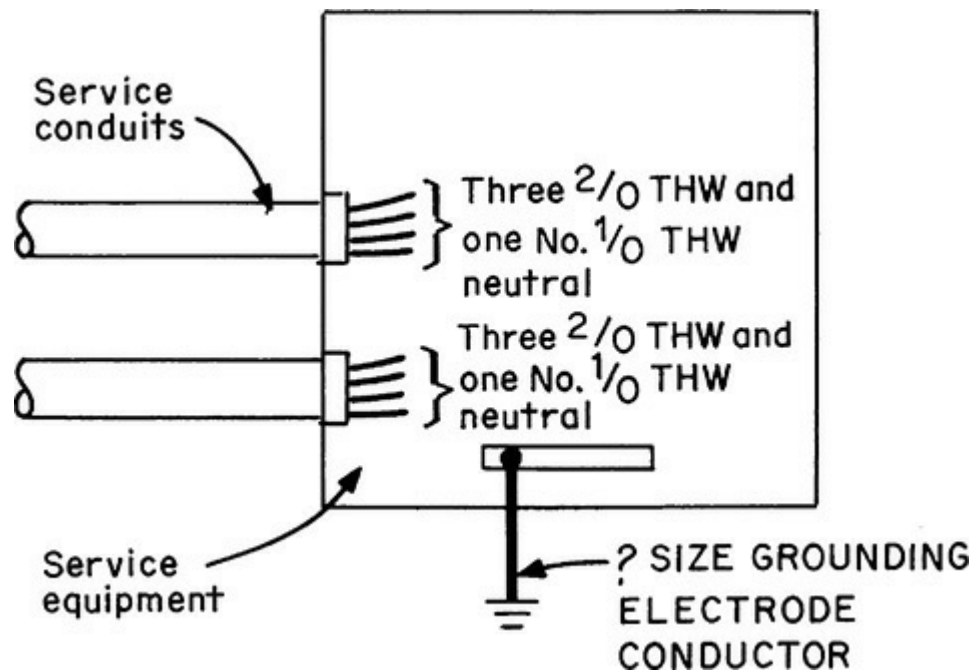

Fig. 250-57. Typical task of sizing the conductor to the grounding electrode. (Sec. 250.66.)

1. From **NEC** Table 8 in **Chap. 9** in the back of the Code book, which gives physical dimensions of the conductor material itself (excluding insulation cross-sectional area), each of the phase conductors has a cross-sectional area (csa) of 133,100 kcmil. Two such conductors per phase have a total csa of 266,200 kcmil.
2. The same table shows that the single conductor which has a csa at least equal to the total csa of the two conductors per phase is a 300-kcmil size of conductor. That conductor size is then located in the left-hand column of Table 250.66 to determine the minimum size of grounding electrode conductor, which turns out to be 2 AWG copper or 1/0 AWG aluminum or copper-clad aluminum.

Figure 250-58 shows another example of conductor sizing, as follows:

Fig. 250-58. Two different sizes of grounding electrode conductors are required for installations like this. (Sec. 250.66.)

1. The grounding electrode conductor A connects to the street side of the water meter of a metallic water supply to a building. The metallic pipe extends 30 ft (9.14 m) underground outside the building.
2. Because the underground metallic water piping is at least 10 ft (3.0 m) long, the underground piping system is a grounding electrode and must be used as such.
3. Based on the size of the service-entrance conductors (5×500 kcmil = 2500 kcmil per phase leg), the minimum size of grounding electrode conductor to the water pipe is 3/0 AWG copper or 250-kcmil aluminum or copper-clad aluminum.
4. The connection to the ground rod at B satisfies the rule of 250.53(D)(2), requiring a water-pipe electrode to be supplemented by another electrode.
5. But, the size of grounding electrode conductor B required between the neutral bus and the rod, pipe, or plate electrode is 6 AWG copper or 4 AWG aluminum, as covered by part (A) of 250.66. And the Code does not require the conductor to a rod, pipe, or plate electrode to be larger than 6 AWG, regardless of the size of the service phases. As discussed under Sec. 250.53(C) and shown in Fig. 250-40, the conductor at B in Fig. 250-58 can be considered to be a bonding jumper, as covered by the sizing rule in 250.64(F) which also says in effect that the conductor to the ground rod need not be larger than 6 AWG copper or 4 AWG aluminum due to the reference to 250.66(A). And the 2014 **NEC** has clarified that even if multiple rod, pipe, or plate electrodes, or any combination thereof are used with a grounding conductor, the size still need not increase above 6 AWG copper. Closing a minor loophole, the 2017 **NEC** placed clarifying language in all three of the special sizing allowances in (A), (B), and (C), to the effect that they could not be used if the electrode(s) in question were wired en route to another electrode that required a larger sized grounding electrode conductor.

Parts (B) and (C) of the rule make clear that a grounding electrode conductor does not have to be larger than a conductor-type electrode to which it connects. 250.52(A)(3) recognizes a “concrete-encased” electrode—which must be at least 20 ft (6.0 m) of one or more ½-in. (13-mm)-diameter steel reinforcing bars or rods in the concrete or at least 20 ft (6.0 m) of bare 4 AWG copper conductor (or a larger conductor), concrete-encased in the footing or foundation of a building or structure. Section 250.52(A)(4) recognizes a “ground-ring” electrode made up of at least 20 ft (6.0 m) of 2 AWG bare copper conductor (or larger), buried directly in the earth at a depth of at least 2½ ft (750 mm). Those electrodes described under 250.52(A)(1) through (4) are *not* “rod, pipe, or plate electrodes.” As electrodes from 250.52(A)(1) through (4), which must be bonded where present, such electrodes would normally be subject to the basic rule of 250.66, which calls for connection to any such electrode by a grounding electrode conductor sized from Table 250.66—requiring up to No. 3/0 copper for use on high-capacity services. *But*, that is not required, as explained in these paragraphs of the two parts.

Parts (B) and (C) recognize that there is no reason to use a grounding electrode conductor that is larger than a conductor-electrode to which it connects. The grounding electrode conductor need not be larger than 4 AWG copper for a 4 AWG concrete-encased electrode and need not be larger than 2 AWG copper if it connects to a ground-ring electrode—as in part (C) of 250.66. Where Table 250.66

would permit a grounding electrode conductor smaller than 4 AWG or 2 AWG (based on size of service conductors), the smaller conductor may be used—but the electrode itself must not be smaller than 4 AWG or 2 AWG. See [Fig. 250-36](#).

The first note under Table 250.66 correlates to 230.40, Exception No. 2, and 250.64(D), as follows:

When two to six service disconnects in separate enclosures are used at a service, with a separate set of SE conductors run to each disconnect, the size of a single common grounding electrode conductor must be based on the largest sum of the cross sections of the same phase leg of each of the several sets of SE conductors. When using multiple service disconnects in separate enclosures, with a set of SE conductors run to each from the drop or lateral (230.40, Exception No. 2) and using a single, common grounding electrode conductor, either run continuous and unspliced from one disconnect to another and then to the grounding electrode, as in the upper right drawing of [Fig. 250-49](#) (which will be impracticable in almost all cases due to termination restrictions in the enclosures), or with taps from each disconnect to a common grounding electrode conductor run to the electrode—as in 250.64(D)(1), this note is used to determine the size of the common grounding electrode conductor from Table 250.66. The “equivalent area” of the size of SE conductors is the largest sum of the cross-sectional areas of one ungrounded leg of each of the several sets of SE conductors.

250.68. Grounding Electrode Conductor Connection and Bonding Jumper

Connections to Grounding Electrodes. The rule requires that the connection of a grounding electrode conductor to the grounding electrode “shall be accessible” ([Fig. 250-59](#)). [250.104(A) also requires that any clamp for a bonding jumper to interior metal water piping must be accessible.] Inspectors want to be able to see and/or be able to get at any connection to a grounding electrode. But because there are electrodes permitted in 250.52 that would require underground or concrete-encased connections, an exception was added to the basic rule to permit inaccessible connections in such cases ([Fig. 250-60](#)). Electrode connections that are *not* encased or buried—such as where they are made to exposed parts of electrodes that are encased, driven, or buried—*must* be accessible. This section now places the burden on the installer to make such connections accessible wherever possible.

Fig. 250-59. Whenever possible, connections to grounding electrodes must be “accessible.” Note that the water-pipe clamp, if used on copper water tubing as opposed to heavy-wall red brass or galvanized steel pipe, must be marked for this service, as required by the UL Grounding and Bonding Standard, #467. [Secs. 250.68. and 110.3(B).]

The second exception to 250.68(A) covers accessibility when connections are made to steel framing members that will be subsequently encased in fireproofing compounds, rendering such connections inaccessible. In such cases, there are often two connection issues in the same location. The first issue is the connection of the grounding electrode connection to a lug, which must be an exothermic weld or an irreversible crimp in order to be acceptable without remaining accessible. The second issue is how the lug is attached to the metal framing. In this case any mechanical connection is acceptable, even if reversible.

The second part of this section requires an effective grounding path, and to make this to be the case on a metal piping system electrode, use the proper clamp shown in Fig. 250-59. If the connection is to be remote from the point of entry for the water pipe into the building, as shown in Fig. 250-60, make sure the interior home run for the piping qualifies in terms of access to the piping and the qualifications of those supervising the installation, as covered in 250.68(C)(1) Exception. In addition, add bonding jumpers around any insulated joints or around equipment likely to be removed for repair, as also covered in 250.53(D)(1). In a typical case of grounding for a local transformer within a building, 250.30(A)(4)(1) and 250.68(C)(1) note that grounding of the secondary neutral, where there is no building steel available, must be made to the water pipe within 1.5 m (5 ft) from its point of entry in the building unless the piping qualifies for the exception in 250.68(C). And 250.68(B) requires that bonding jumpers be used to ensure continuity of the ground path back to the underground pipe for that portion permitted to serve as a grounding electrode by 250.52(A)(1) wherever the piping may contain insulating sections or is liable to become disconnected. Bonding jumpers around unions, valves, water meters, and other points where a water piping system electrode might be opened must have enough slack to permit removal of the part. Hazard is created when bonding jumpers are so short that they have to be removed to remove the equipment they jumper. Dangerous conditions have been reported about this matter. Bonding jumpers must be long enough to ensure grounding integrity along piping systems under any conditions of maintenance or repair.

Fig. 250-60. Although required, bonding of metal piping can pose problems. And even though the connection to the pipe may be made without regard to the pipe's point of entry in some occupancies, that permission only applies to water pipes that are supervisable. Unless this is an "industrial" or "commercial" installation with qualified maintenance people and the water pipe is completely exposed and visible for the entire distance from its point of entry to the grounding electrode conductor connection, such connection from the grounded conductor must be made no further than 5 ft (1.52 m) from the pipe's entry point. (Sec. 250.68(C)(1) Exception.)

Part (C) of 250.68 is the logical culmination of numerous discussions over many code cycles regarding an interesting question: What is the boundary, the physical extent, of an electrode? For example, a standard plumbing trade length of rigid pipe, whether ABS sewer pipe or copper water tubing, is 20 ft. If 17 ft of a standard trade length of copper pipe is in the earth, and the remaining 3 ft sticks out and enters a water meter, how long is the electrode, 17 ft or 20 ft? The answer now is, 17 ft. Only the portion of any conductive object used as an electrode that is actually in contact with the

earth counts as an electrode.

From this result, which has good internal logic, it is apparent that the exposed portion of a metal object being used as an electrode is something else, requiring adjustments in the **NEC** to correlate with this outcome. Those adjustments are in this subsection. The parent language describes, for a water pipe, a “conductor” and for building steel a “bonding conductor.” It should also be noted that all of the water pipe content describing connections to the electrode have been relocated here from their former home in 250.52(A)(1), for the same reason. If what you are connecting to is not the electrode, then don’t describe it in terms of being a part of the electrode. These issues chiefly concern building steel and water pipes, so they are the ones addressed at this point.

Paragraph (1) covers water pipes, and the default allowance over many cycles continues: You can make connection within the first 5 ft (1.5 m), but note the literal text: you are connecting to “water piping that is electrically continuous with a metal underground water pipe ...” For dwelling occupancies, including large multifamily buildings, this is all that is available.

The exception covers the nondwelling occupancy allowance to use a longer conductor, one which is a “bonding conductor to interconnect electrodes” as long as it is exposed over its entire length. Since the spaces above suspended ceilings with lift-out panels qualify under the definition of “exposed,” those locations are acceptable as well. Obviously, a wall or floor penetration would make the pipe run concealed for the short passage through the partition, but such short passages directly through the partition are acceptable as well. However, a pipe which is concealed in the long dimension of a fixed partition loses its eligibility for a remote grounding electrode conductor attachment at that point. In probably the great majority of cases, however, a main water service pipe will make it far into the building before it loses this qualification. The other qualification that applies to this method is that there must be a showing that those servicing the installation are qualified persons.

Paragraph (2) covers a structural metal building frame. As of the 2014 edition, it no longer matters whether connected structural steel building elements are themselves extended into physical contact with soil. It only matters that they are elements of a structural building framework presumed to be inherently conductive. And if they are, then quite properly they are capable of providing a bonding path between electrodes, even as 250.30(A)(4) allows this by right for separately derived system connections. If one end of a building has a water or a sprinkler entrance or both, then those pipe electrodes may be connected to local building steel. And that steel may be relied upon to then bond those electrodes to whatever other qualified electrodes are available at the service location, or even to a connection to the service itself. Additional text in this paragraph arrived in the 2017 edition, after being relocated from 250.52(A)(2). It describes how the hold-down bolts that secure the upper building structure are to be connected to a concrete-encased electrode to provide continuity to earth.

Paragraph (3) explicitly recognizes a useful method of establishing a connection to a concrete-encased electrode that avoids the necessity for making the electrical connection ahead of the actual concrete pour. If a conductive element is extended up and out so it has an end that will be accessible afterwards, then the connection out of the pour is permitted.

250.70. Methods of Grounding and Bonding Conductor Connection to

Electrodes. Because 250.53(G) requires *buried* or protected connections of grounding electrode conductors to ground rods, the third sentence of this section requires that a buried ground clamp be of such material and construction that it has been designed, tested, and marked for use directly in the earth. And any clamp that is used with two or more conductors must be designed, tested, and marked for the number and types of conductors that may be used with it. This is shown in the bottom drawing of [Fig. 250-61](#). Connections depending on solder cannot be used due to the likelihood that the solder will melt during a sustained fault. [Figure 250-59](#) gives some listing information about water-pipe clamps.

Fig. 250-61. Encased and buried electrode connections are permitted by exception to the basic rule. The bonding bushing at the bottom of the sweep almost certainly does not have a direct burial listing and would require modifications and inspection approval to be used in this way. A better option in

this case would be a “U-bolt” style ground clamp around the conduit at the end of the sweep. They are available in constructions that are listed for direct burial. Another option would be to use PVC conduit and skip the bonding issue altogether. (Sec. 250.68.)

250.86. Other Conductor Enclosures and Raceways. The basic rule requires all enclosures and raceways to be grounded. But, Exception No. 1 permits the installation of short runs as extensions from existing open wiring, knob-and-tube work, or nonmetallic-sheathed cable without grounding where there is little likelihood of an accidental connection to ground or of a person touching both the conduit, raceway, or armor and any grounded metal or other grounded surface at the same time. Additionally, the exception permits “short sections” of enclosures and raceways to be used as sleeving or to otherwise support cables. The exact length of such ungrounded metallic enclosures and raceways is *not* given. That determination will ultimately be made by the local electrical inspector.

The last exception covers instances where metal conduit sweeps are inserted into nonmetallic conduit runs to prevent the pulling rope, when under high tension, from sawing through the inner radius of the bend and destroying the integrity of the conduit system. If the sweep is buried low enough so its upper end is still 450 mm (18 in.) below grade level, or if it is entirely encased including the ends in 50 mm (2 in.) of concrete (i.e., the concrete has to encase the steel/PVC raceway system so it overlaps the ends of the steel sweep by at least 50 mm [2 in.]), bonding is not required. The 2017 **NEC** extended this concept of isolated metal conduit elbows to metal components generally. The same extension of concept was made for service applications in 250.80.

Part V. Bonding

250.90. General. One of the most interesting and controversial phases of electrical work involves the grounding and bonding of secondary-voltage service-entrance equipment. Modern practice in such work varies according to local interpretations of Code requirements and specifications of design engineers. In all cases, however, the basic intent is to provide an installation which is essentially in compliance with **National Electrical Code** rules on the subject, using practical methods for achieving objectives.

In order to ensure electrical continuity of the grounding circuit, bonding (special precautions to ensure a permanent, low-resistance connection) is required at all conduit connections in the service equipment and where any nonconductive coating exists which might impair such continuity. This includes bonding at connections between service raceways, service cable armor, all service-equipment enclosures containing service-entrance conductors, including meter fittings, boxes, and the like.

The need for effective grounding and bonding of service equipment arises from the electrical characteristics of utility-supply circuits. In the common arrangement, service conductors are run to a building and the service overcurrent protection is placed near the point of entry of the conductors into the building, at the load end of the conductors. With such a layout, the service conductors are not properly protected against ground faults or shorts occurring on the supply side of the service overcurrent protection. Generally, the only protection for the service conductors is on the primary side of the utility’s distribution transformer. By providing “bonded” connections (connecting with special care to reliable conductivity), any short circuit in the service-drop or service-entrance

conductors is given the greatest chance of burning itself clear—because there is no effective overcurrent protection ahead of those conductors to provide opening of the circuit on such heavy fault currents. And for any contact between an energized service conductor and a grounded service raceway, fittings, or enclosures, bonding provides discharge of the fault current to the system grounding electrode—and again burning the fault clear. This condition of services is shown in Fig. 250-62.

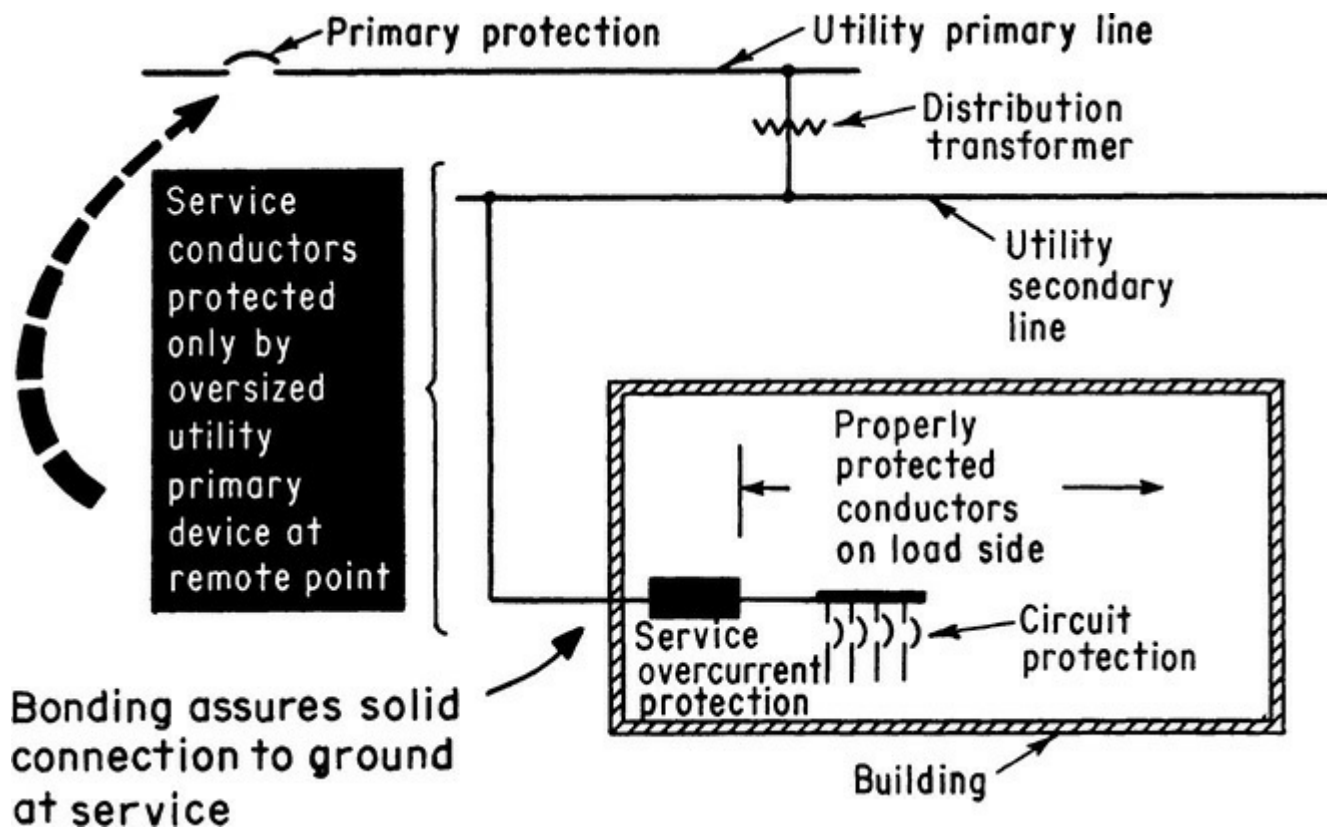

Fig. 250-62. Service bonding must ensure burn-clear on shorts and grounds in service conductors. (Sec. 250.90.)

250.92. Services. Because of the requirement set forth in 250.92, all enclosures for service conductors must be grounded to prevent a potential above ground on the enclosures as a result of fault—which would be a very definite hazard—and to facilitate operation of overcurrent devices anywhere on the supply side of the service conductors. However, because of the distant location of the protection and the normal impedance of supply cables, it is important that any fault to an enclosure of a hot service conductor of a grounded electrical system find a firm, continuous, low-impedance path to ground to ensure sufficient current flow to operate the primary protective device or to burn the fault clear quickly. This means that all enclosures containing the service conductors—service raceway, cable armor, boxes, fittings, cabinets—must be effectively bonded together; that is, they must have low impedance through themselves and must be securely connected to each other to ensure a continuous path of sufficient conductivity to the conductor which makes the connection to ground (Fig. 250-63).

Fig. 250-63. Bonding ensures low-impedance path through all service conductor enclosures. (Sec. 250.92.)

The spirit of the Code and good engineering practice have long recognized that the conductivity of any equipment ground path should be at least equivalent to 25 percent of the conductivity of any phase conductor with which the ground path will act as a circuit conductor on a ground fault. Or, to put it another way, making the relationship without reference to insulation or temperature rise, the impedance of the ground path must not be greater than four times the impedance of any phase conductor with which it is associated.

In ungrounded electrical systems, the same careful attention should be paid to the matter of bonding together the noncurrent-carrying metal parts of all enclosures containing service conductors. Such a low-impedance ground path will quickly and surely corner ground any hot conductor which might accidentally become common with the enclosure system, and if a second fault occurs from a different phase, the low-impedance path will pass enough current so the fault will burn free.

Specific **NEC** requirements on grounding and bonding are as follows:

1. 250.80 requires that metal enclosures and raceways for service conductors as well as service equipment be grounded, either to the grounded circuit conductor (grounded systems) or to the grounding electrode conductor (ungrounded systems). And, the Code requires that flexible metal conduit or liquidtight flexible metal conduit used in a run of service raceway must be bonded around (Fig. 250-64). 230.43 states that rule on flex and lists the *only* types of raceway that may enclose service-entrance conductors.

Fig. 250-64. Flex may be used as a service raceway, with a jumper. (Sec. 250.92.)

2. 250.92 sets forth the service equipment which must be bonded—that is, the equipment for which the continuity of the grounding path must be specifically ensured by using specific connecting devices or techniques. As indicated in Fig. 250-65, this equipment includes (1) service raceway, cable trays, cable sheath, and cable armor; and (2) all service-equipment enclosures containing service-entrance conductors, including meter fittings, boxes, etc., interposed in the service raceway or armor. There is what is effectively an exception for 250.80. Presumably this is to correlate with the optional unbonded metal elbow in the exception, and that would be correct. However, before the 2011 **NEC**, this language pointed to what is now 250.84, which addresses lead-sheathed cables. Removing this reference was incorrect, what should have happened was to refer both sections. However, since for environmental reasons lead-sheathed cables are no longer used, there will be little practical effect.

Fig. 250-65. “Bonding” consists of using prescribed fittings and/or methods for connecting components enclosing SE conductors. (Sec. 250.92.)¹

250.92(B) covers “Method of Bonding at the Service.” 250.92(A) is very specific in listing the many types of equipment that require bonding connections, but the actual “how to” is often hazy. For virtually every individual situation where a bonding connection must be made, there is a variety of products available in the market which present the installer with a choice of different methods.

This section sets forth the specific means which may be used to connect service-conductor enclosures together to satisfy the bonding requirements of 250.92(A). These means include:

1. Bonding equipment to the grounded service conductor by means of suitable lugs, pressure connectors, clamps, or other approved means—except that soldered connections must not be used. 250.142 permits grounding of meter housings and service equipment to the grounded service conductor on the supply side of the service disconnecting means.
2. Threaded couplings in rigid metal conduit or IMC (intermediate metal conduit) runs and threaded bosses on enclosures to which rigid metal conduit or IMC connects.
3. Threadless couplings and connectors made up tight for rigid metal conduit, IMC, or electrical metallic tubing, or for metal-clad cables.
4. Other devices (not standard locknuts and bushings) listed for the purpose, such as bonding locknuts, wedges, and bushings.

In general, bonding jumpers must be used around concentric or eccentric knockouts which are punched or otherwise formed in such a manner that would impair the electrical current flow through the reduced cross section of metal that bridges between the enclosure wall and punched ring of the KO (knockout). The 2011 **NEC** included reducing washers at this point; they are not listed for use in

service bonding applications for good reason because they are notoriously poor at maintaining continuity, especially on enameled enclosures that are commonplace in service work. Very few inspectors ever accepted them without bonding jumpers anyway. And the bonding jumpers must be sized from 250.102(C).

Based on those briefly worded Code requirements, modern practice follows more or less standard methods.

Where a rigid conduit is the service raceway, threaded or threadless couplings are used to couple sections of a conduit together. A conduit connection to a meter socket may be made by connecting a threaded conduit end to a threaded hub or boss on the socket housing, where the housing is so constructed; by a locknut and bonding bushing; by a locknut outside with a bonding wedge or bonding locknut and a standard metal or completely insulating bushing inside; or sometimes by a locknut and standard bushing where the socket enclosure is bonded to the grounded service conductor. Conduit connections to KOs in sheet metal enclosures can be made with a bonding locknut (Fig. 250-66), a bonding wedge, or a bonding bushing where no KO rings remain around the opening through which the conduit enters and where the box is listed for such use, even where the KOs have not all been removed. But, generally, where a KO ring does remain around the conduit entry hole, a bonding bushing or wedge with a jumper wire must be used to assure a path of continuity from the conduit to the enclosure. Figure 250-67 summarizes the various acceptable techniques. It should be noted that the use of the common locknut and bushing type of connection is not allowed. Neither is the use of double locknuts—one inside, one outside—and a bushing, although that is permitted on the load side of the service equipment. The special methods set forth in 250.92(B) are designed to prevent poor connections or loosening of connections due to vibration. This minimizes the possibility of arcing and consequent damage which might result when a service conductor faults to the grounded equipment.

Fig. 250-66. Bonding locknut is a recognized method for bonding a service conduit nipple to a meter socket, when the KO is clean (no rings left in enclosure wall) or is cut on the job. With plastic bushing permitted, this is the most economical of the several methods for making a bonded conduit termination. (Sec. 250.92.)

Similar provisions are used to ensure continuity of the ground path when EMT is the service raceway or when armored cable is used. EMT is coupled or connected by threadless devices—compression-type, indenter-type, or set-screw type, using raintight type outdoors. Although a threadless box connector is suitable to provide a bonded connection of the connector to the metal raceway (rigid metal, IMC, EMT), it is also necessary to provide a “bonded” connection between the connector and the metal enclosure. A threadless box connector on the end of EMT used as a service raceway provides satisfactory bonding of the EMT to the connector, but the last sentence of this rule says that a standard locknut or a standard bushing connected to the threaded end of the connector does not provide the required bonding of the connector to the metal service equipment to which the connector is connected. On the end of the connector, a bonding locknut or bonding bushings with or without jumpers must be used if the knockout is clean (all rings punched out or clean knockout punched on the job). If concentric or eccentric rings are left, a grounding locknut with a jumper, a

grounding bushing with a jumper, or a grounding wedge with a jumper must be used to provide bonded connection around the perforated knockout. And fittings used with service cable armor must assure the same degree of continuity of the ground path.

The use of bonding bushings, bonding wedges, and bonding locknuts is recognized without reference to types of raceways or types of connectors used with the raceways or cable armor. As a result, common sense and experience have molded modern field practice in making raceway and armored service cable connection to service cabinets. The top of Fig. 250-68 shows how a bonding wedge is used on existing connections at services or for raceway connections on the load side of the service—such as required by 501.30(B) for Class I hazardous locations. A bonding bushing with provision for connecting a bonding jumper, is the common method for new service installations where some of the concentric or eccentric “doughnuts” (knockout rings) are left in the wall of the enclosure, therefore requiring a bonding jumper. Great care must be taken to ensure that each and every type of bushing, locknut, or other fitting is used in the way for which it is intended to best perform the bonding function.

Figure 250-69 shows detailed application of the preceding rules to typical meter-socket installations. Meter-enclosure bonding techniques are shown in Fig. 250-70. Bonding details for current-transformer installations are shown in Fig. 250-71. Those illustrations are intended to portray typical field practice aimed at satisfying the various Code rules.

250.94. Bonding for Communications Systems. This section calls for a ready, effective “intersystem” bonding and grounding of communications systems, such as telephone, and community antenna television (CATV) systems at the service equipment for *all* buildings, not just dwellings, and at both services and at building disconnects. The rule requires that there be an “intersystem bonding termination ... accessible for connection and inspection ... [with the] capacity for connection of not less than three intersystem bonding conductors.” This makes provision for bonding metal enclosures of, say, telephone equipment to metal enclosures of electrical system components to reduce voltage differences between such metal enclosures as a result of lightning or power contacts. This rule was placed in the **NEC** because 800.100(D) and 800.100(B)(1) require bonding interconnection between a building’s power grounding electrode system and the “protector ground” (grounding electrode conductor) of telephone and other communications systems, and because making that bonded interconnection has become more difficult. Both 810.21(J) and 810.21(F)(1) and 820.100(D) and 820.100(B)(1) require such grounding interconnections, as does 830.100(D) and 830.100(B)(1), which cover “Network-Powered Broadband Communications Systems.” This section in the 2014 and prior editions referred to “other” rather than “communications” systems. Several attempts to make the Code hospitable to landing other systems, such as bonding wires from CSST (corrugated stainless steel tubing) for gas lines were rejected, and this section was retitled as a result. Two panel statements are worthy of note:

“Intersystem bonding terminations are required to be listed per **NEC** 250.94. These products are listed in accordance with UL467 Grounding and Bonding Equipment. Intersystem bonding terminations were created by the telecommunications industry to provide a bonding location for their systems. Expanding this application could reduce the product capacity for telecom circuits and add the possibility of the introduction of noise into the communications system.”

“The NFPA research report indicates that the bonding that is needed for CSST systems has many more restrictions than what is permitted for the connections to the grounding electrode system of a structure for communication systems which utilize an IBT. For induced and indirect lightning bonding at the entrance of the installation will help, however the IBT mandated by the **NEC** is not required to be at the entrance of the CSST. Bonding should also be limited to short lengths with minimum number of bends, but tests have not determined the recommended lengths yet nor maximum number of bends or permitted bending radii. The IBT is defined in

both UL 467 and the **NEC** as an intersystem bonding device for communication systems which does not include the bonding of other systems that may need to be bonded.”

The proposal for this Code addition in its original form for the 1981 **NEC** included the following commentary:

In the past, the bond between communications and power systems was usually achieved by connecting the communications protector grounds to an interior water pipe. Where the power was grounded to a ground rod, the bond was connected to the power grounding-electrode conductor or to metallic service conduit, which were usually accessible. With growing use of plastic water pipe, the tendency for service equipment to be installed in finished areas where the grounding electrode conductor is often concealed, and the use of plastic entrance conduit, communications installers no longer have an easily identifiable point for connecting bonds or grounds.

Where lightning or external power fault currents flow in protective grounding systems, there can be dangerous potential differences between the equipment of those systems. Even with the required common or bonded electrodes, lightning currents flowing in noncommon portions of the grounding system result in significant potential differences as a result of inductive voltage drop in the noncommon conductor. If a current flows through a noncommon grounding conductor 10 ft (3.05 m) long, there can be an inductive voltage drop as high as 4000 volts. If that noncommon conductor is either the power grounding-electrode conductor or the communications-protector grounding conductor, the voltage will appear between communication-equipment and power-equipment enclosures. The best technical solution to minimizing that voltage is with a short bond between the service equipment and the communications-protector ground terminal. The conductor to the grounding electrode is then common, and the voltage drop in it does not result in a potential difference between systems.

An externally accessible point for intersystem bonding should be provided at the electrical service if accessible metallic service-entrance conduit is not present or if the grounding-electrode conductor is not accessible. This point could be in the form of a connector, tapped hole, external stud, a combination connector-SE cable clamp, or some other approved means located at the meter base or service equipment enclosure.

Prior to the 2008 **NEC** intersystem bonding terminations were done using exposed portions of service equipment, or grounding electrode conductors, and if they were not accessible for external connections, as in finished basements, then a short length of 6 AWG was to be left or other approved means. Where this has been done in existing construction, it can remain by virtue of an exception that, in effect, was the prior rule.

A definite shock hazard can arise if a *common* grounding electrode conductor is *not* used to ground *both* the bonded service neutral *and* the communications protector. The problem can be solved by simply bonding the ground terminal of the protector to a grounded enclosure of the service equipment (the service panelboard enclosure or the meter socket) and not using the separate telephone grounding electrode conductor. The basic concept has been in the **NEC** for a very long time. The changes in 2008 mandated specific design components and performance criteria, including the requirement that the terminating device not obstruct the opening of an enclosure. Note that many manufacturers have come to market with intersystem-bonding equipment, however, any terminal bar listed as grounding and bonding equipment should be acceptable (inspector’s decision) as long as it is applied within its ratings and installed in accordance with the rules for these connections. Examples for dry locations include those readily available as equipment grounding bars from panelboard manufacturers.

The 2017 **NEC** has added the usage of a customary grounding electrode termination plate [250.64(D)(1)(3)] for this purpose in the new 250.94(B) as another option. Note that, perhaps at cross purposes to the panel objections (quoted at length just previously) regarding electrical noise injection into communications systems, the 250.94(B) busbar terminations are not literally limited to communications systems as long as the three-terminal minimum is met. Arguably, one of these busbars could even be used for CSST bonding. This will undoubtedly receive more attention in the 2020

NEC.

250.96. Bonding Other Enclosures. Metal raceways, cable sheaths, equipment frames and enclosures, and all other metal noncurrent-carrying parts must be carefully interconnected with Code-recognized fittings and methods to ensure a low-impedance equipment grounding path for fault current—whether or not an equipment grounding conductor (a ground wire) is run within the raceway and connected enclosures. The interconnected system of metal raceways and enclosures must itself form a Code-conforming equipment grounding path—even if a “supplementary equipment grounding conductor” is used within the metal-enclosure grounding system (Fig. 250-72).

The rule of 250.96(B) recognizes that to help reduce electromagnetic noise or interference on a grounding circuit, an insulating “spacer or fitting” may be used to interrupt the electrical continuity of a metallic raceway system used to enclose the branch-circuit conductors at the point of connection to the metal enclosure of a single piece of equipment.

This rule permits interrupting the current path between a metal equipment enclosure and the metal conduit that supplies the enclosure—but *only* if the metal conduit is grounded at its supply end *and* an equipment grounding conductor is run through the conduit into the metal enclosure and is connected to an equipment grounding terminal of the enclosure, to provide safety grounding of the metal enclosure. Provisions for an equipment ground reference separate from the metallic raceway system are covered by 250.146(D) for electronic equipment that is cord-and-plug-connected. This rule covers a separate equipment ground reference for hard-wired-sensitive electronic equipment.

250.97. Bonding for Over 250 Volts. Single locknut-and-bushing terminations are permitted for 120/240- and 120/208-V systems. Any 480/277-V grounded system, 480-V ungrounded system, or higher must generally use double locknut-and-bushing terminals on clean knockouts of sheet metal enclosures (no concentric rings in wall) for rigid metal conduit and IMC (Fig. 250-73).

Where good electrical continuity is desired on installations of rigid metal conduit or IMC, two locknuts should always be provided on clean knockouts (no rings left) of sheet metal enclosures so that the metal of the box can be solidly clamped between the locknuts, one being on the outside and one on the inside. The reason for not relying on the bushing in place of the inside locknut is that both the conduit and the box may be secured in place and if the conduit is placed so that it extends into the box to a greater distance than the thickness of the bushing, the bushing will not make contact with the inside surface of the box. But that possible weakness in the single-locknut termination does not exclude it from use on systems up to 250 V to ground.

The Exception to the main rule here has the effect of requiring that a bonding jumper must be used around any “oversized, concentric, or eccentric knockouts” in enclosures for circuits over 250 V to ground that are run in a metal raceway or cable unless the enclosure or fittings have been investigated and listed for use without a bonding jumper. Many such enclosures and fittings are so listed and are readily available, in particular, most conventional steel outlet boxes with concentric knockouts. Clearly, the use of that equipment will serve to reduce labor costs. But, generally for such circuits, a bonding jumper must be used at any conduit or cable termination in other than a clean, unimpaired opening in an enclosure (Fig. 250-73). For example, the majority of larger enclosures with concentric knockouts, including most panelboards and wireways, are not listed as providing the required continuity and a bonding jumper will be required.

In any case where all the punched rings (the “doughnuts”) are not removed and the box is *not* listed for use without a bonding jumper, or, where all the rings are removed but a reducing washer is used to accept a smaller size of conduit, a bonding jumper must be installed from a suitable ground

terminal in the enclosure to a lug on the bushing or locknut of the termination of any conduit or cable containing conductors operating at over 250 V to ground. Such circuits include 480/277-V circuits (grounded or ungrounded); 480-, 550-, 600/347-, and 600-V circuits; and higher-voltage circuits. A bonding jumper is not needed for terminations of conduit that carry such circuits through KOs that are punched on the job to accept the corresponding size of conduit. *But*, double locknuts (one inside and one outside the enclosure) must be used on threaded conduit ends, or suitable threadless connectors or other fittings must be used on rigid or flexible conduit, EMT, or cable.

250.98. Bonding Loosely Jointed Metal Raceways. Provision must be made for possible expansion and contraction in concrete slabs due to temperature changes by installing expansion joints in long runs of raceways run through slabs. See 300.7(B). Because such expansion joints are loosely jointed to permit back-and-forth movement to handle changes in gap between butting slabs, bonding jumpers must be used for equipment grounding continuity (Fig. 250-74). Expansion fittings may be selected as vibration dampers and deflection mediums as well as to provide for movement between building sections or for expansion and contraction due to temperature changes in long conduit runs. The fitting diagrammed in Fig. 250-74 provides for movement from the normal in all directions plus 30° deflection, is available up to 4-in. (101.5 mm) in diameter, and may be installed in concrete. Expansion fittings are available from some manufacturers that have special internal designs and which have enabled them to be listed as providing the required continuity without the use of supplemental bonding jumpers.

250.100. Bonding in Hazardous (Classified) Locations. All raceway terminations in hazardous locations must be made by one of the techniques shown in Fig. 250-67 for service raceways. And as required by 501.30(A) such bonding techniques must be used in “all intervening raceways, fittings, boxes, enclosures, etc., between hazardous areas and the point of grounding for service equipment.” Refer to 501.30(A), 502.30(A), 503.30(A), 505.25, and 506.25 (Fig. 250-75).

FOR CIRCUITS OPERATING OVER 250 VOLTS TO GROUND — IN CONDUIT TERMINATING THROUGH OTHER THAN A CLEAN KNOCKOUT (NO RINGS LEFT)

Fig. 250-73. For circuits over 250 V to ground, a bonding jumper may be needed at conduit termination. (Sec. 250.97.)

Fig. 250-74. Conduit expansion fitting includes bonding jumper for ground continuity. (Sec. 250.98.)

NOTE: Connection of threaded rigid metal conduit or IMC to a threaded boss or hub is considered to be a bonded conduit termination.

Fig. 250-75. Bonded raceway terminations must be used at sheet metal KOs in hazardous areas. (Sec. 250.100.)

Fig. 250-76. Sizing main bonding jumper and other jumpers at service equipment. (Sec. 250.102.)

250.102. Grounded Conductors, Bonding Conductors, and Jumpers. The jumper shown in [Fig. 250-76](#) running from one conduit bushing to the other and then to the equipment ground

bus is defined by the **NEC** as an “equipment bonding jumper.” Equipment bonding jumpers must be made of copper or other corrosion-resistant material, and they can be in the form of wires, busbars, screws, or any other suitable conductor. They must be connected using one of the methods in 250.8 (or 250.70 if connecting to a grounding electrode). The rest of this section covers sizing calculations on the supply side of the service (Part C), sizing calculations on the load side of the service (Part D), and how to install these jumpers in the event they run with their associated conductors (Part E) instead of simply making bonding connections at terminations, as shown in [Fig. 250-76](#).

Part (C) applies to the supply side of services. As of the 2014 **NEC**, the content of Table 250.66, with additional notes and requirements to reflect that resulting conductor sizes increase beyond those of grounding electrode conductors, has been placed here in a new Table 250.102(C)(1).

Part (C)(2) covers paralleled installations. It actually, incorporates many different calculations in one paragraph. The first involves one jumper to all the raceways of the circuit ([Fig. 250-76](#)). Since, in the process of making its connection to the bus, it sees all the raceways, it is sized on the basis of the entire service, for which the largest phase conductor (in this as in most cases all are equal) is $3 \times 500 \text{ kcmil} = 1500 \text{ kcmil}$. Since this is larger than the coverage of Table 250.102(C)(1), its size must be calculated on the basis of $\frac{1}{8}$ (12.5 percent) of the phase area just determined. $1,500,000 \text{ cm} \div 8 = 187,500 \text{ cm}$. Consulting Table 8 in [Chap. 9](#) of the **NEC**, the next larger wire size is 4/0 copper, and that is the size required for this wire. This procedure is identical to the one in 250.28(D)(1) for a main bonding jumper.

In the sketch of [Fig. 250-76](#), if each of the three 4-in. (101.5-mm) conduits has a separate bonding jumper connecting each one individually to the equipment ground bus, then part (C)(2) may be applied to an individual bonding jumper for each separate conduit ([Fig. 250-77](#)). The size of a separate bonding jumper for each conduit in a parallel service must be not less than the size of the grounding electrode conductor for a service of the size of the phase conductor used in each conduit. Referring again to Table 250.102(C)(1), a 500-kcmil copper service calls for at least a No. 1/0 grounding electrode conductor. Therefore, the bonding jumper run from the bushing lug on each conduit to the ground bus must be at least a No. 1/0 copper (or 3/0 aluminum). Since these are bonding jumpers and not grounding electrode conductors, on a very large service or if multiple parallel sets of conductors ran in single conduits, the area of the largest phase conductor might exceed the reach of Table 250.102(C)(1), and in such an instance the $\frac{1}{8}$ (12.5 percent) procedure would apply to determine the area of the bonding conductor.

Fig. 250-77. An individual bonding jumper may be used for each conduit (left) and *must* be used as shown at right. [Sec. 250.102(C).]

Part (C)(2) *requires* separate bonding jumpers when the service is made up of multiple conduits and the equipment bonding jumper is run within each raceway (such as plastic pipe) for grounding service enclosures. According to part (C), when service-entrance conductors are paralleled in two or more raceways, a supply-side bonding jumper that is routed within the raceways must also be run in parallel, one in each raceway, as at the right in Fig. 250-77. This clarifies application of nonmetallic service raceway where parallel conduits are used for parallel service-entrance conductors. As worded, the rule applies to both nonmetallic and metallic conduits where the bonding jumper is run within the raceways rather than from lugs on bonding bushings on the conduit ends. But for metallic conduits stubbed up under service equipment, if the conduit ends are to be bonded to the service equipment enclosure by jumpers from lugs on the conduit bushings, either a single large common bonding jumper may be used—from one lug, to another lug, to another, and so on, and then to the ground bus—or an individual bonding jumper (of smaller size from Table 250.66, based on the size of conductors in each conduit) may be run from each bushing lug to the ground bus.

Do not confuse a supply-side bonding jumper run in a raceway with a grounded circuit conductor run in the same raceway. For grounded systems, that will be the usual application, and the only equipment bonding will be to the metallic service raceways in the event a metallic wiring method is in use. Remember that the grounded circuit conductor is permitted to, and usually does provide, the supply-side bonding in upstream enclosures such as metering cabinets, as covered in 250.142(A)(1). This rule generally applies to ungrounded or impedance-grounded services where there are no grounded circuit conductors running through the raceways, and the necessity is to maintain bonding of conductive surfaces upstream of the service disconnect.

One other point in this regard. These wires are bonding jumpers, not circuit conductors. The normal 1/0 AWG lower threshold for paralleled “phase, polarity, neutral, or grounded circuit conductors” [310.10(H)(1)] does not apply in this case. For example, if the conduit fill consisted of sets of 350 kcmil, the Table 250.102(C)(1) result for the bonding conductors would be 2 AWG, and

they could be run in the conduit without being increased to 1/0 AWG.

Note 2 to Table 250.102(C)(1) sets minimum sizes of copper *and* aluminum service-entrance conductors above which a service bonding jumper must have a cross-sectional area “not less than 12½ percent of the area of the largest phase conductor.” And the rule states that if the service conductors and the bonding jumper are of different material (i.e., service conductors are copper, say, and the jumper is aluminum), the minimum size of the jumper shall be based on the assumed use of phase conductors of the same material as the jumper and with an ampacity equivalent to that of the installed phase conductors (Fig. 250-78). In this case, three sets of 750 kcmil aluminum at 75°C have a combined ampacity of 1155 A. A copper service equal to or above this number would be three sets of 600 kcmil, or 1,800,000 cm. $1,800,000 \div 8$ (or, $\times 0.125$) = 225,000 cm. Reviewing Table 8 in Chap. 9, the next large size wire would be a 250 kcmil copper bonding jumper. The 2017 **NEC** further clarified this note by conditioning it on the supply conductors being above 1100 kcmil copper or 1750 kcmil aluminum because below these sizes, whether or not the materials are mixed the table should still be used.

Fig. 250-78. Sizing a copper bonding jumper for aluminum service conductors. [Sec. 250.102(C).]

Part (D) requires a bonding jumper on the load side of the service to be sized as if it were an equipment grounding conductor for the largest circuit with which it is used. And sizing would have to be done from Table 250.122, as follows.

Figure 250-79 shows a floor trench in the switchboard room of a large hotel. The conductors are feeder conductors carried from circuit breakers in the main switchboard (just visible in upper right corner of photo) to feeder conduits going out at left, through the concrete wall of the trench, and under the slab floor to the various distribution panels throughout the building. Because the conduits

themselves are not metallically connected to the metal switchboard enclosure, bonding must be provided from the conduits to the switchboard ground bus to ensure electrical continuity and conductivity as required by **NEC** Secs. 250.4(A)(5), 250.86, 250.110(5), 250.120, and 250.134.

Fig. 250-79. Conduits in trench carry feeder conductors from switchboard at right (arrow) out to various panels and control centers. A single, common bonding jumper—run continuously from bushing to bushing—may be used to bond all conduits to the switchboard ground bus. [Sec. 250.102(D).]

1. The single, common, continuous bonding conductor that bonds all the conduits to the switchboard must be sized in accordance with **NEC** Table 250.122, based on the highest rating of CB or fuses protecting any one of the total number of circuits run in all the conduits.
2. Sizing of the single, common bonding jumper would be based on the highest rating of overcurrent protection for any one of the circuits run in the group of conduits. For instance, some of the circuits could be 400-A circuits made up of 500 kcmil in individual 3-in. (76-mm) conduits, and others could be parallel-circuit makeups in multiple conduits—such as 800-A circuits, with two conduits per circuit, and 1200-A circuits, with three conduits. If, for instance, the highest-rated feeder in the group was protected by a 2000-A circuit breaker, then the single, common bonding jumper for all the conduits would have to be 250-kcmil copper or 400-kcmil aluminum—determined readily from Table 250.122, by simply going down the left column to the value of “2000” and then reading across. The single conductor is run through a lug on each of the conduit bushings and then to the switchboard ground bus.

In the case shown in [Fig. 250-79](#), however, because the bonding jumper from the conduit ends to

the switchboard is much longer than a jumper would be if the conduits stubbed up under the switchboard, better engineering design might dictate that a separate equipment grounding *conductor* (rather than a “jumper”) be used for each individual circuit in the group. If one of the conduits is a metric designator 78 (trade size 3) conduit carrying three 500-kcmil conductors from a 400-A CB in the switchboard, the minimum acceptable size of bonding jumper (or equipment grounding conductor) from a grounding bushing on the conduit end to the switchboard ground bus would be a 3 AWG copper or 1 AWG aluminum or copper-clad aluminum, as shown opposite the value of 400 A in the left column of Table 250.122. If another two of the metric designator 78 (trade size 3) conduits are used for a feeder consisting of two parallel sets of three 500-kcmil conductors (each set of three 500-kcmil conductors in a separate conduit) for a circuit protected at 800 A, a single bonding jumper could be used, run from one grounding bushing to the other grounding bushing and then to the switchboard ground bus. This single bonding jumper would have to be a minimum 1/0 AWG copper, from **NEC** Table 250.122 on the basis of the 800-A rating of the feeder overcurrent protective device.

With such a long run for a jumper, as shown in [Fig. 250-79](#), Code rules could be interpreted to require that the bonding jumper be subject to the rules of 250.122; that is, use of a bonding jumper must conform to the requirements for equipment grounding conductors. As a result, bonding of conduits for a parallel circuit makeup would have to comply with part **(F)** in 250.122, which requires equipment grounding conductors to be run in parallel “where conductors are run in parallel in multiple raceways... .” That would then be taken to require that bonding jumpers *also* must be run in parallel for multiple-conduit circuits.

That interpretation is incorrect. The rules in 250.122(F) assure an appropriate fault current path based on the possibility of backfeed into a fault from a downstream parallel bus connection, resulting in the maximum current flow from the overcurrent protective device. Therefore the equipment grounding conductor in each parallel raceway will be paralleled and will be based on the full trip setting of the breaker. When the parallel raceways reach the switchboard the equipment grounding conductors no longer need to be paralleled; they only need to remain sized based on Table 250.122 for the overcurrent device. This is entirely consistent with 250.122(C), which expressly allows a single equipment grounding conductor to protect any number of circuits as long as it is sized based on the highest rating of overcurrent protection on any of the associated conductors. However, it is certainly permissible to run individual conductors. [Figure 250-80](#) shows the two possible arrangements.

Fig. 250-80. One jumper may be used to bond two or more conduits on the load side of the service. [Sec. 250.102(D).]

Part (E) of 250.102 follows the thinking that is described in 250.136 for external grounding of equipment attached to a properly grounded metal rack or structure. A short length of flexible metal conduit, liquidtight flex, or any other raceway may, if the raceway itself is not acceptable as a grounding conductor, be provided with grounding by a “bonding jumper” (*note: not an “equipment grounding conductor”*) run *either* inside or *outside* the raceway or enclosure PROVIDED THAT the *length of the equipment bonding jumper is not more than 6 ft (1.8 m)* and the jumper is routed with the raceway or enclosure.

Where an equipment bonding conductor is installed within a raceway, it must comply with all the Code rules on identification of equipment grounding conductors. A bonding jumper installed in flexible metal conduit or liquidtight flex serves essentially the same function as an equipment grounding conductor. For that reason, a bonding jumper should comply with the identification rules of 250.119—on the use of bare, green-insulated, or green-taped conductors for equipment grounding.

Note that this application has limited use for the conditions specified and is a special variation from the concept of 250.134(B), which requires grounding conductors run inside raceways. Its big application is for external bonding of short lengths of liquidtight or standard flex, under those conditions where the particular type of flex itself is not suitable for providing the grounding continuity required by 348.60 and 350.60. Refer also to 250.64.

The top of Fig. 250-81 shows how an external bonding jumper may be used with standard flexible metallic conduit (so-called Greenfield). If the length of the flex is not over 6 ft (1.8 m), but the conductors run within the flex are protected at more than 20 A, a bonding jumper *must* be used either inside or outside the flex. An outside jumper must comply as shown. For a length of listed flex not over 6 ft (1.8 m), containing conductors that are protected at not more than 20 A and used with

conduit termination fittings that are approved for grounding, a bonding jumper is *not* required.

Jumper sized from Table 250.66

Straight, stretched-out length of bonding jumper must not exceed 6 feet

Fittings must have lugs and be approved for this use

Box, enclosure or fitting each end of flex

6-ft bonding jumper

Jumper must be wrapped around or attached to flex so it is "routed with it" as required in 250.102(E)

Flex over 6 ft long

THIS IS A VIOLATION!
Bonding jumper not routed with flex and external bonding jumper is not permitted for any length of flex over 6 ft

Bonding jumper required for flex may be outside the flex.

Liquidtight flex larger than 1¼ in. size must have bonding jumper — inside or outside — in any length up to 6 ft.

Fig. 250-81. Bonding jumper rules for standard flex and liquidtight flex. [Sec. 250.102(E).]

The bottom of Fig. 250-81 shows use of an external bonding jumper with liquidtight flexible metallic conduit. If liquidtight flex is not over 6 ft (1.8 m) long *but* is larger than 1¼-in. trade size, a bonding jumper must be used, installed *either* inside or outside the liquidtight. An outside jumper must comply as shown. If a length of liquidtight flex larger than 1¼ in. is short enough to permit an external bonding jumper that is not more than 6 ft (1.8 m) long between external grounding-type connectors at the ends of the flex, an external bonding jumper may be used. **BUT WATCH OUT!** The rule says the *jumper*, not the flex, must not exceed 6 ft (1.8 m) in length *AND* the jumper “shall be routed with the raceway”—that is, run along the flex surface and not separated from the flex.

The exception at the end of this section provides some practical assistance to isolated steel sweeps that are frequently installed in runs of nonmetallic conduit to avoid problems associated with pulling ropes sawing through the inner radius of a nonmetallic sweep during a heavy pull. Since these sweeps are seldom located where a box could be conveniently located, making a connection to the enclosed equipment grounding conductor is problematic. In addition to the isolation provisions of 250.80 Exception and 250.86 Exception No. 3, the exception at this location provides help on a steel sweep positioned at the base of a pole. The exception also covers instances where not only the elbow is steel, but the first pipe section on the pole is steel as well, for mechanical strength. The exception allows a bonding jumper to be attached to the steel at a convenient location, and then run up the pole to a point where the enclosed equipment grounding conductor (load side of service) or grounded circuit conductor (supply side of service) is available for connection, even if the length exceeds 1.8 m (6 ft).

250.104. Bonding of Piping Systems and Exposed Structural Metal. This section on bonding of piping systems in buildings begins with two parts—metal *water* piping and *other* metal piping. This section is a rather elaborate sequence of phrases that may be understood in several ways. Of course, the basic concept is to ground any metal pipes that would present a hazard if energized by an electrical circuit. In general, bear in mind that these bonding requirements apply to “piping systems.” With the increasing use of nonmetallic piping in many occupancies, controversies are arising over how short a section of piping has to be before it no longer qualifies as a “piping system.” This is a decision for the inspector, perhaps based in part on the proximity to other electrical equipment or wiring. However, it is quite clear that an isolated chrome faucet does not create a metal piping system, but metal piping covering an entire floor presumably is a system. The third part of the section covers interconnected structural metal framing that supports a building, and the section concludes by correlating the grounding rules for separately derived systems in 250.30 with the bonding rules in this part of the article.

Part (A) requires any “metal water piping system(s) installed in or attached to a building or structure” to be bonded to the service-equipment enclosure, the grounded conductor (usually, a neutral) at the service, the grounding electrode conductor, *or* the one or more grounding electrodes used (with the obvious proviso that GEC to the electrode be of the appropriate size). All points of attachment of bonding jumpers for metal water piping systems must be accessible. Only the connections (and not the entire length) of water-pipe bonding jumpers are required to be accessible for inspection. This rule applies where the metal water piping system does not have 10 ft (3.0 m) of metal pipe buried in the earth and is, therefore, not a grounding electrode. In such cases, though, this rule makes clear that the water piping system must be bonded to the service grounding arrangement.

And the bonding jumper used to connect the interior water piping to, say, the grounded neutral bus or terminal (or to the ground bus or terminal) must be sized from Table 250.102(C)(1) based on the size of the service conductors. The jumper is sized from that table because that is the table that would have been used *if* the water piping had 10 ft (3.0 m) buried under the ground, making it suitable as a grounding electrode. Note that the “bonding jumper” is sized from Table 250.102(C)(1), which means it never has to be larger than 3/0 AWG copper or 250-kcmil aluminum. Refer to the illustrations for 250.52 and 250.53, which also cover bonding of water piping.

Note that the status of the water piping system as a bonding conductor used to extend the connection to the actual water pipe electrode, particularly where compliance with 250.68(C)(1) Exception has been achieved, frequently extends very long distances into a building. Other sections of the **NEC** allow users to count on this when grounding other systems, including separately derived systems as covered in 250.30(A)(4)(1). If the appropriate bonding has not been performed and another system is connected, the result will be a hazard.

Part **(A)(2)** permits “isolated” metal water piping to be bonded to the main electrical enclosure (panelboard or switchboard) in each unit of a multitenant building—such as in each apartment of an apartment house, each store of a shopping center, or each office unit of a multitenant office building. See the top of [Fig. 250-82](#). This rule is intended to provide a realistic and effective way to bond interior metal water piping to the electrical grounding system in multitenant buildings where the metal water piping in each tenant’s unit is fed from a main water distribution system of nonmetallic piping and is isolated from the metal water piping in other units. In apartment houses, multistory buildings, and the like, it would be difficult, costly, and ineffective to use long bonding jumpers to tie the isolated piping in all the units back to the equipment grounding point of the building’s service equipment—as required by the basic rule of Sec. 250.104(A). The objective of the basic rule is better achieved in such cases by simply bonding the isolated water piping in each occupancy to the equipment ground bus of the panelboard or switchboard serving the occupancy. The bonding jumper must be sized from Table 250.122 (*not* 250.66)—based on the rating of the protective device for the circuit supplying the occupancy.

Fig. 250-82. Certain techniques are permitted as alternatives to the basic rules on grounding of metal piping systems. (Sec. 250.104.)

Part (A)(3) covers instances where multiple buildings or structures under common ownership have water piping systems. In such cases the bonding follows the rules for isolated tenancies in one building, as just covered, except that the reference point in this case is the building disconnect, and the sizing applies Table 250.102(C)(1) to the size of the feeder or branch-circuit conductors that supply the building, and not larger than the supply conductors. If there is no building disconnect the connection can be made to the equipment grounding conductor of the supply circuit, or to the

grounding electrode conductor for the building served.

Part **(B)** requires a bonding connection from “other” (than water) metal piping systems—such as process liquids or fluids—that “is likely to become energized” to the grounded neutral, the service ground terminal, the grounding electrode conductor, or the grounding electrodes. *But*, for these *other* piping systems the bonding jumper is sized from Table 250.122, using the rating of the overcurrent device of the circuit that *may* energize the piping. Since as a practical matter it is almost impossible to wire anything without an equipment grounding conductor in the circuit, and since equipment grounding conductors must be sized in accordance with 250.122, if there is any conductive connection between the equipment supplied by the branch circuit and the piping system, the equipment grounding connection will automatically bond the piping with no further effort required. Most solenoids and other control devices for piping qualify as bonded under this principle (see bottom of [Fig. 250-82](#)).

The phrase “likely to become energized” is used frequently in electrical standards. It basically means that it is capable of being energized if a single insulation failure occurs. For example, a motor supplied by a conventional motor circuit is “likely to become energized” because a single insulation failure on an ungrounded conductor in the usual metal termination box will energize the motor frame, subject to the operation of OCPDs. Double-insulated appliances are not “likely to become energized” because the supply conductors enter a nonmetallic housing, and two points of insulation failure (the conductor insulation and the nonmetallic connection housing) would have to fail before a voltage could be present on the surface of the equipment.

Part **(C)** of 250.104 requires exposed building steel that is *not* effectively grounded to be bonded to the grounding electrode system. The connection may be made at the service equipment, to the grounded conductor, to the grounding electrode conductor where the grounding electrode conductor is “of sufficient size,” or to any of the electrodes used. If the building or structure is supplied from another, as covered in 250.32, then the bonding may be made to the local building disconnect. The reference to “sufficient size” for connection to the grounding electrode conductor is intended to indicate that such a conductor must be sized per 250.102(C)(1) based on the size of the largest service phase conductor. But, where, say, 6 AWG copper is used for connection to a driven ground rod—as permitted in part **(A)** to 250.102(C)(1)—the bonding jumper from the nongrounded building must *not* be connected to that 6 AWG conductor, unless it also satisfies the basic rule in 250.102(C)(1). The same concept applies to connections to concrete-encased electrodes and ground rings, which have permission for less than full-sized conductors and therefore may or may not satisfy the “of sufficient size” criterion.

In part **(D)**, this section puts forth the bonding requirements for separately derived systems in three parts. Paragraph **(1)** provides that the grounded conductor must be bonded to the interior metal water piping system within the area served by the separately derived system. This is in addition to the bonding connection required between the grounded conductor and the building steel, or where no building steel is available, the connection to the water pipe, not more than 5 ft from its point of entry. This local connection ensures that the metal water piping within the area supplied by the separately derived system is at the same potential with respect to ground as the metal enclosures and raceways associated with the separately derived system. Further, the electrical connections to both the bonding conductor and the grounding electrode conductor must occur at the same point. For example, if the grounding electrode conductor is connected in the secondary compartment of a transformer, then the bonding conductor must be connected in the same transformer compartment. The bonding conductor size is governed by Table 250.102(C)(1) based on the largest ungrounded conductor of the derived

system.

If the provisions of 250.68(C)(1) Exception successfully apply as far as the separately derived system location, then this bonding connection will also qualify as the termination point for the grounding electrode conductor. Since the wiring and sizing rules are the same for both, no adjustments are necessary. On the other hand, if 250.68(C)(1) Exception does not apply, then the grounding electrode connection and the bonding connection will usually be in two entirely different areas. In addition, if the grounding electrode for the derived system is local building steel, and the steel is bonded to the local water piping system, there is no point in making a second bonding connection to water piping in the area served.

Paragraph (2) covers structural metal framing that is exposed in an area supplied by a separately derived system. Here again the system grounded conductor and the conductive framing must be bonded in the area served, and both the bonding connection and the grounding electrode connection to this conductor must occur at the same point. For example, if in this case the grounding electrode conductor connection takes place in the main disconnect enclosure for the derived system, then the bonding connection must connect there and not in the transformer housing. If the local metal framing is the grounding electrode for the derived system, then an additional bonding connection is not required for obvious reasons. Likewise, if the local water piping system is the grounding electrode for the derived system, and the water system and the metal framing are bonded in the area served by the derived system, then no further bonding is required. Here again, the bonding conductor size is governed by Table 250.102(C)(1) based on the largest ungrounded conductor of the derived system.

Paragraph (3) covers bonding in areas where a common grounding electrode conductor is available, such as might be run vertically in a high-rise building, as discussed in 250.30(A)(6). In this case, the derived system will be using the common grounding electrode conductor as its ground reference point. Both the local water piping (if any in the area served) and the local exposed structural metal framing (if any in the area served) must be bonded to the derived system. Presumably (although the **NEC** does not specifically say this) the connection should be made at the same location in the derived system as where the grounding electrode connection is made, in order to correlate this requirement with the other two. If these connections are separated, there is a possibility of a potential difference and circulating currents that would be objectionable under 250.6(A).

250.106. Lightning Protection Systems. Lightning discharges, with their steep wave fronts, build up tremendous voltages to metal near the strike termination devices and the down conductors. Although the grounding electrode systems will be bonded, the actual electrodes must be separated, and **NFPA 780**, Standard for Lightning Protection Systems has detailed information on grounding, bonding, sideflash distances, and required spacings for the safe operation of these systems. Former specific references to such dimensions as “1.8 m (6 ft)” have been removed from the associated notes in this section, because they are far too simplistic to be of any real value,

250.110. Equipment Fastened in Place (Fixed) or Connected by Permanent Wiring Methods. The word “fixed” as applied to equipment requiring grounding now applies to “equipment supplied by or enclosing conductors or components that are likely to become energized” as covered in the section title and shown in [Fig. 250-83](#). This is another example of the “likely to become energized” phrasing; refer to the discussion at 250.104(B) for an explanation of this concept. As noted in Exception No. 3, enclosures for listed equipment—such as information technology equipment and listed office equipment—operating at over 150 V to ground do not have to be grounded if protected by a system of double insulation or its equivalent. Since equipment grounding

conductors travel with circuit conductors almost everywhere in modern wiring, item (5) alone on the list mandates an equipment grounding connection, even if the equipment does not meet the vertical or horizontal parameters in item (1).

Fig. 250-83. “Fixed” equipment is now clearly and readily identified for grounding rules. (Sec. 250.110.)

250.112. Specific Equipment Fastened in Place (Fixed) or Connected by Permanent Wiring Methods. This section presents what amounts to an incomplete, yet binding, roster of equipment that must be connected to an equipment grounding conductor. The various subparts identify those items that are *specifically* required to be grounded.

Part (I) requires special commentary because of its close and often poorly understood connection with 250.20(A) and 250.162. If system grounding is required by either of these rules, then the remote control, signaling, or fire alarm circuit supplied must incorporate an equipment grounding conductor. For example, a 277-V duct heater with an integral Class 2 transformer to run the thermostatic control circuit, or some Class 2 or Class 3 lighting controls connected to 277-V branch circuits will qualify for mandatory system grounding, with the associated identified grounded circuit conductor.

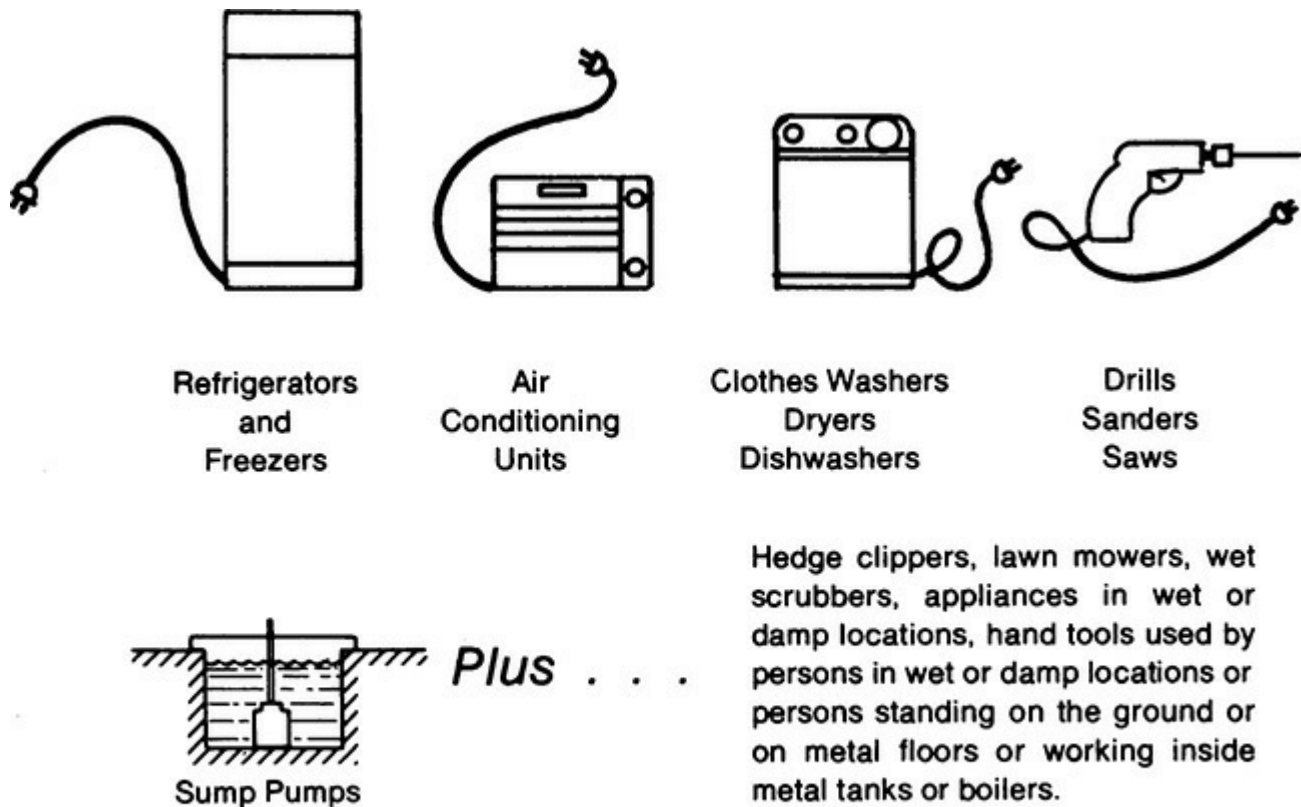

Should such an application arise, there are additional considerations. Such a grounded system must be connected to a grounding electrode, although this is seldom a problem because the systems normally qualify as separately derived, and **NEC 250.30(A)(5) Exception No. 3** generally allows the use of the equipment grounding conductor connection for the supply transformer (limited in the exception to 1 kVA) to function as a grounding electrode conductor in such cases. Another wrinkle is the requirement here that these systems incorporate an equipment grounding conductor. Such a conductor must be colored green unless it is uninsulated because 250.119 Exception correlates with 250.112(I) and preserves the color code in these applications. Note also that the size of this wire can

be the same as the others in the circuit because 250.122(A) never requires an equipment grounding conductor to be larger than the associated circuit conductors. In addition, the color white (or gray) will be reserved for the grounded circuit conductor, because 200.7(B) reserves that color when, you guessed it, system grounding is required by 250.20(A). The likely result is two wires in the power-limited cable assembly (white and green) will have code required functions and connections at odds with the traditional color code for HVAC wiring diagrams. Take care to plan accordingly.

As required by part (L), motor-operated water pumps, including the submersible type, must have their metal frames grounded. This Code rule clarifies an issue that was a subject of controversy. It means that a circuit down to a submersible pump in a well or cistern must include a conductor to ground the pump's metal frame, even though the frame is not accessible or exposed to contact by persons. This is why the parent sentence of the rule refers to exposed conductive parts on items (A) through (K), and all such parts of items (L) and (M). The water pump and the well casing must be bonded even if not exposed to direct contact.

Notice, too, that 250.112(M) makes grounding of metal well-casings mandatory for ALL types of occupancies. The grounding of metal well-casings was formerly specified for "Agricultural Buildings" in 547.8(D) until the issuance of the 1996 **NEC**. In recognition of the fact that the shock hazard exists where a metal well-casing is used—regardless of the type of occupancy or installation—this section requires grounding ALL metal well-casings used with "submersible pumps." However, that rule in Art. 547 was eliminated because it was viewed as redundant. Remember, according to the rule of 90.3, any requirements put forth in [Chaps. 1](#) to 4 apply to those special occupancies covered in [Chap. 5](#), unless otherwise modified by the rules in [Chap. 5](#). Therefore, extension of this requirement to other occupancies by inclusion in 250.112 made the wording in 547.8(D) superfluous and that section was deleted.

250.114. Equipment Connected by Cord and Plug. Figure 250-84 shows cord-connected loads that must either be operated grounded or be double insulated. Except when supplied through an isolating transformer as permitted by the exception following (4)(g) of this section, the frames of portable tools should be grounded by means of an equipment grounding conductor in the cord or cable through which the motor is supplied. Portable hand lamps used inside boilers or metal tanks should preferably be supplied through isolating transformers having a secondary voltage of 50 V or less, with the secondary ungrounded. Code-recognized double-insulated tools and appliances may be used in all types of occupancies other than hazardous locations, in lieu of required grounding. Note that cord-and-plug-connected equipment operating over 150 V to ground in instances where it consists of motors that are guarded, or if it consists of metal-framed electrically heated appliances exempted by special permission, and where the frames are permanently insulated from ground, is exempted from the usual equipment grounding requirement.

NOTE: USE OF DOUBLE INSULATION ON TOOLS OR APPLIANCES ELIMINATES NEED FOR GROUNDING.

Fig. 250-84. Grounding cord and plug cap are required for shock protection. (Sec. 250.114.)

OSHA regulations have made **NEC 250.114** retroactive, requiring grounded operation of cord- and plug-connected appliances in all existing as well as new installations. Check on local rulings on that matter.

250.118. Types of Equipment Grounding Conductors. This section describes the various types of conductors and metallic cables or raceways that are considered suitable for use as equipment grounding conductors. And the Code recognizes cable tray as an equipment grounding conductor as permitted by Art. 392.

250.118(5), (6), and (7) recognize listed flexible metal conduit, listed liquidtight flexible metal conduit, and flexible metallic tubing, with termination fittings UL-listed for use as a grounding means (without a separate equipment grounding wire) if the total length of flexible methods is not over 6 ft (1.8 m) and the contained circuit conductors are protected by overcurrent devices rated at 20 A or less.

Standard flexible metal conduit (also known as “Greenfield”) must be listed by UL but the former allowance for flex listed as a grounding means has been deleted because none has, shall we say, a credible listing. However, part (5) permits flex to be used without any supplemental grounding conductor when any length of flex in a ground return path is not over 6 ft (1.8 m) and the conductors contained in the flex are protected by overcurrent devices rated not over 20 A and the *fittings* are listed as suitable for grounding (Fig. 250-85). The **NEC** rules follow:

Flex not over 6 ft long is suitable as a grounding means (without a separate ground wire) if the conductors in it are protected by OC devices rated not more than 20 amps.

Fig. 250-85. Standard flex is limited in use without an equipment ground wire. (Sec. 250.118.)

1. When conductors within a length of flex up to 6 ft (1.83 m) are protected at more than 20 A, equipment grounding may not be provided by the flex, but a separate conductor must be used for grounding. If a length of flex is short enough to permit a bonding jumper not over 6 ft (1.83 m) long to be run between external grounding-type connectors at the flex ends, while keeping the jumper *along* the flex, such an external jumper may be used where equipment grounding is required—as for a short length of flex with circuit conductors in it protected at more than 20 A. Of course, such short lengths of flex may also be “bonded” by a bonding jumper inside the flex, instead of external. Refer to 250.102(E).
2. Any length of standard flex that would require a bonding jumper longer than 6 ft (1.8 m) may not use an external jumper. In the Code sense, when the length of such a grounding conductor exceeds 6 ft (1.8 m), it is *not* a BONDING JUMPER BUT IS AN EQUIPMENT GROUNDING CONDUCTOR AND MUST BE RUN ONLY *INSIDE* THE FLEX, AS REQUIRED BY 250.134(B). Combining UL data with the rule of Sec. 250.102, *every* length of flex that is over 6 ft (1.8 m) must contain an equipment grounding conductor run *only* inside the flex (Fig. 250-86).

Fig. 250-86. Internal equipment grounding is required for any flex over 6 ft (1.8 m) long. (Sec. 250.118.)

In part (5)(c), the 2017 **NEC** has now ratified an earlier posting in the UL guide card limitations

for flex that additionally condition the equipment grounding suitability on not being more than a maximum raceway size, in this case 1¼ trade size. Even if the circuit protection is held at 20 amps as been acceptable for generations, now larger trade sizes must have a separate equipment grounding conductor installed.

In part **(5)(d)**, it should be noted that exemption from the need for an equipment grounding conductor applies only to flex where there is not over 6 ft (1.8 m) of “total length in the same ground return path.” That means that from any branch-circuit load device—lighting fixture, motor, and so forth—all the way back to the service ground, the total permitted length of flex without a ground wire is 6 ft (1.8 m). In the total circuit run from the service to any outlet, there could be one 6-ft (1.8-m) length of flex or two 3-ft (900-mm) lengths or three 2-ft (600-mm) lengths or a 4-ft (1.2-m) and a 2-ft (600-mm) length—where the flex lengths are in series as equipment ground return paths. In any circuit run—feeder to subfeeder to branch circuit—any length of flex that would make the total series length over 6 ft (1.8 m) would have to use an internal or external bonding jumper, regardless of any other factors. Further, this principle extends to all varieties of flex covered here, taken in their collective lengths. For example, 600 mm (2 ft) of flexible metal conduit plus the same length of liquidtight flexible metal conduit plus the same length of flexible metallic tubing just equals the longest permitted length (1.8 m [6 ft]) without a separate equipment grounding conductor. If any one of the three wiring methods in this example were even slightly longer in the same fault current path, then a separate grounding conductor would be required.

In all cases, sizing of bonding jumpers for all flex applications is made according to Sec. 250.102, which requires the same minimum size for bonding jumpers as is required for equipment grounding conductors, or grounding electrode conductors for service applications as allowed in 230.43(15). In such cases, the size of the conductor is selected from Table 250.122, based on the maximum rating of the overcurrent devices protecting the circuit conductors that are within the flex. For service work, substitute Table 250.66 for obvious reasons.

In part **(5)(e)**, the flex will require a separate equipment grounding conductor, regardless of whether it would otherwise qualify in terms of length or circuit protection, if “flexibility is necessary ... after installation.” A run to a swinging sign is a clear application of this principle. The 2011 **NEC** has clarified that the phrase “flexibility is necessary” includes a run of flex used as a vibration isolator for a transformer. A short run at a motor to allow flexibility so a belt can be tightened would also void the exemption from running a separate equipment grounding conductor. The “after installation” provision is in the **NEC** in order to protect a run of flex that has been installed as part of a fixed raceway layout to get around an obstruction. Flexibility was clearly required to install the flex; that is why it was installed in the first place, but just as clearly after the installation is complete it will never move again, and there will be no motion stress applied to its connecting fittings.

Part **(6)** presents conditions under which *liquidtight* flexible metal conduit may be used without need for a separate equipment grounding conductor:

1. Both part **(6)** and the UL’s Guide Card information [see discussion at 110.3(B) for details] note that any listed liquidtight flex in metric designator 35 (trade size 1¼) and smaller, in a length not over 6 ft (1.8 m), may be satisfactorily used as a grounding means through the metal core of the flex, without need of a bonding jumper (or equipment grounding conductor) either internal or external (**Fig. 250-87**), depending on the rating of the overcurrent device ahead of it (next paragraph). The permitted length is exactly the same, and involves the other flexible metal raceways in exactly the same way, as flexible metal conduit, analyzed previously. In addition,

there is an identical limitation for uses where flexibility is required after installation.

Fig. 250-87. Liquidtight flex may be used with a separate ground wire. (Sec. 250.118.)

Where terminated in fittings investigated for grounding and where installed with not more than 6 ft (1.8 m) (total length) in any ground return path, liquidtight flexible metal conduit in the metric designators 12 and 16 (trade sizes $\frac{3}{8}$ and $\frac{1}{2}$) is suitable for grounding where used on circuits rated 20 A or less, and the metric designators 21, 27, and 35 (trade sizes $\frac{3}{4}$, 1, and $1\frac{1}{4}$) are suitable for grounding where used on circuits rated 60 A or less. See the category “Conduit Fittings” (DWTT) with respect to fittings suitable as a grounding means.

The following are not considered to be suitable as a grounding means:

- a. The metric designator 41 (trade size $1\frac{1}{2}$) and larger sizes
 - b. The metric designators 12 and 16 (trade sizes $\frac{3}{8}$ and $\frac{1}{2}$) where used on circuits rated higher than 20 A, or where the total length in the ground return path is greater than 6 ft (1.8 m)
 - c. The metric designators 21, 27, and 35 (trade sizes $\frac{3}{4}$, 1, and $1\frac{1}{4}$) where used on circuits rated higher than 60 A, or where the total length in the ground return path is greater than 6 ft (1.8 m)
2. For liquidtight flex over metric designator 35 (trade size $1\frac{1}{4}$), UL does not list any as suitable for equipment grounding, thereby requiring use of a separate equipment grounding conductor installed in *any* length of the flex, as required by Code. If a length of liquidtight flex larger than this is short enough to permit an external bonding jumper not more than 6 ft (1.8 m) long between external grounding-type connectors at the ends of the flex, an external bonding jumper may be used. **BUT WATCH OUT!** The rule says the *jumper*, not the flex, must not exceed 6 ft (1.8 m) in length **AND** the jumper “shall be routed with the raceway”—that is, run along the flex surface and not separated from the flex.
 3. If any length of flex is *over* 6 ft (1.8 m), then the flex is not a suitable grounding conductor, regardless of the trade size of the flex, whether it is larger or smaller than metric designator 35 (trade size $1\frac{1}{4}$). In such cases, an *equipment grounding conductor* (not a “bonding jumper”—

the phrase reserved for short lengths) must be used to provide grounding continuity and IT MUST BE RUN *INSIDE* THE FLEX, NOT EXTERNAL TO IT, IN ACCORDANCE WITH 250.134(B).

4. The rule for combining lengths of the three flexible wiring method raceways in the 6-ft limitation, and the clarification that the use for vibration isolation requires a separate equipment grounding conductor, apply to this wiring method as well. Refer to the discussion on flexible metal conduit for more information.

Part (10) covers metal-clad cable. After years of discussion, this part of 250.118 finally gives clear, unambiguous recognition (in “b.”) to the new style of MC cable that includes a bare equipment grounding conductor immediately beneath its interlocking armor. As such, it is somewhat analogous to Type ac cable, except that the bonding tape is replaced by a full-size, usually aluminum conductor.

At conventional terminations, this aluminum is simply cut off and does not need to enter the enclosure. However, at panelboard enclosures and other large cabinets and pull boxes where the inner portions of concentric knockouts are not recognized for equipment grounding continuity (see the discussion at 250.97), the aluminum conductor is not cut off at the connector, but allowed to enter the enclosure and thereby bond around the impaired connection point. The armor on this cable is also available for health-care facility use because of its independent qualification as an equipment grounding conductor [see 517.13(A)]; such make-ups have a conventional green-insulated separate equipment grounding conductor within them to meet 517.13(B).

The first paragraph of this metal-clad cable provision (“a.”) primarily covers conventional interlocking-armor metal-clad cable that contains a normally sized equipment grounding conductor, which always enters the wired enclosures for termination. The third paragraph (“c.”) covers smooth and corrugated styles of metal-clad cable that in many sizes and configurations have no separate equipment grounding conductors at all, because their armor has enough metal in its cross section to fully qualify as an equipment grounding conductor. However, some larger sizes of this cable (for larger feeders) still require an internal grounding conductor and the wording allows for this.

250.119. Identification of Equipment Grounding Conductors. Although the default identification for equipment grounding conductors is green (next paragraph), what if equipment grounding is not required? This is indeed the case on many Class 2 and Class 3 control circuit applications supplied by the secondary of a 120-V transformer. Many air-conditioning and other applications use standard color codes for thermostat and related wiring that include the color green as an ungrounded control conductor, which may violate both 250.112(I) and 250.119 here. A new exception allows this use on power limited circuits. The 2011 **NEC** correlated the wording of the exception with 250.112(I) so these two provisions are synchronized. Review the discussion at 250.112(I) for a detailed analysis of the code rules that intersect in this area.

The 2014 **NEC** added two other exceptions here. The first, relatively trivial example, involves flexible cord with no equipment ground and a monolithic green color to the insulation; such cords as the 2-conductor parallel cords frequently used as extension cords, especially during the Christmas holidays. The second is very important because it resolves a conflict that has caused periodic inspectional problems for many decades. The standard default color code for the ungrounded conductors run from traffic signal control cabinets and the the actual signals follows the color of the displayed signal. So, a red light is usually powered with a red wire along with the white wire, and a yellow light is usually connected to a yellow wire, and, you guessed it, a green light is usually powered with a green ungrounded conductor. Virtually every traffic signal is wired this way, and

now the **NEC** squarely addresses the topic. Because the color green is used in this way, the **NEC** goes on to require that yes, there will be an equipment grounding connection meeting 250.118, and if it is of the wire type (the usual case) it will be either bare or green with one or more yellow stripes. Usually, the equipment grounding wires bond the metal pole bases and that is sufficient given the robust mechanical connections between powered components and the poles. Sec. 396.30(C) would recognize a span wire as an equipment ground if need be, but the elevation would likely excuse a connection in such cases given 250.110(1).

Part (A) recognizes conductors of colors other than green for use as equipment grounding conductors if the conductor is stripped for its exposed length within an enclosure, so it appears bare, or if green coloring, green tape, or a green label is used on the conductor at the termination. As shown in Fig. 250-88, the phase legs may or may not be required to be “identified by phase and system” [see 210.5(C)]. If color coding is used, the phase legs may be any color other than white, gray, or green. The neutral may be white or gray or any other color than green if it is larger than No. 6 and if white tape, marking, or paint is applied to the neutral near its terminations. The grounding conductor may be green or may be any insulated conductor of any color if all insulation is stripped off for the exposed length. Alternatives to stripping the black insulated conductor used for equipment ground include (1) coloring the exposed insulation green or (2) marking the exposed insulation with green tape or green adhesive labels; however, any marking must “encircle” the grounding conductor. Relief is granted to the marking rule on conductors larger than 6 AWG where they pass through conduit bodies that have no unused hubs and no splices.

EXAMPLE

Fig. 250-88. Equipment grounding conductor larger than No. 6 may be a stripped conductor of any color covering. (Sec. 250.119.)

Part (B) permits specific on-the-job identification of an insulated conductor used as an equipment grounding conductor in a multiconductor cable. Such a conductor, regardless of size, may be

identified in the same manner permitted by 250.119(A) for conductors larger than No. 6 used in raceway. The conductor may be stripped bare or colored green to indicate that it is a grounding conductor. But such usage of multiconductor cables is recognized only for commercial, institutional-, and industrial-type systems under conditions of qualified maintenance and supervision. Such field-applied re-identification must encircle the conductor.

250.120. Equipment Grounding Conductor Installation. This rule contains a number of crucial requirements. Part (A) requires equipment grounding conductors in the form of raceways or cable assemblies to be installed with their code requirements. The last sentence, however, is a favorite with the inspection community: “All connections, joints, and fittings shall be made tight using suitable tools.” This is the requirement that directly reaches every untightened set-screw and every loose locknut. Attention to detail is absolutely critical in constructing an effective ground-fault current path required [250.4(A)(5)] on every part of every grounded electrical system, and the low-impedance path for fault current required [250.4(B)(4)] on every ungrounded system. A single poor connection can be the one that delays the operation of a circuit protective device such that a fire or even worse results.

This part also includes an informational note pointing to “Electrical Circuit Protective Systems.” If one of these systems is being used, it can affect, in surprising ways, numerous aspects of the process of providing an equipment grounding return path. For example, it may affect the choice of a raceway wiring method, the methods by which segments of such a wiring method are joined together, and even the choice of insulation type used on an equipment grounding conductor run within the raceway. Refer to more complete coverage of this topic at 728.4 in this book.

Part (B) correlates the equipment grounding rules for aluminum with the comparable rules for aluminum used for grounding electrode conductors, in 250.64(A). The analysis at that location also applies here.

Part (C) states the requirement that equipment grounding conductors must be protected within cable armor or raceway unless run within hollow walls or other locations where not subject to damage. The hollow-wall allowance primarily applies to where an old branch circuit with no equipment grounding conductor is being extended and a grounding conductor needs to be fished in to make it comply, as covered in 250.130(C).

250.121. Use of Equipment Grounding Conductors. This section, new as of the 2011 **NEC**, prohibits the use of an equipment grounding conductor as a grounding electrode conductor. Occasionally particularly creative electricians have figured out how to take a wire sized for grounding electrode conductor purposes (and generally larger than that required for the equipment grounding purpose at hand) and install it between the required equipment grounding termination points and then continue it without splice to a grounding electrode, in full conformity with the rules for both conductors.

This was difficult, but occasionally easier than installing an additional raceway or creating a passage for a required grounding electrode conductor, perhaps from a transformer used to originate a separately derived system. No rule expressly prohibited this. In the 2014 **NEC**, by virtue of a new exception, this practice is once again allowable, and now very clearly so, provided there are no objectionable currents introduced [hence the reference to 250.6(A)] and the arrangements meet all requirements for both functions.

250.122. Size of Equipment Grounding Conductors. When an individual equipment

grounding conductor is used in a raceway—either in a nonmetallic raceway or in a metal raceway where such a conductor is used for grounding reliability even though 250.118 usually accepts metal raceways as a suitable grounding conductor—the grounding conductor must have a minimum size as shown in Table 250.122.

The basic rules are covered in 250.122(A), and one of the more important is this: In no case is an equipment grounding conductor required to be larger than its associated circuit conductors. This can come up on motor circuits, where the short-circuit and ground-fault protective device settings may be high enough to cause this problem. For example, a motor circuit using nontime-delay fuses for 12 AWG THHN wire [75°C ampacity, per 110.14(C)(1)(4) = 25 A] could be protected with a 80 A fuse per 430.52(C)(1) Exception No. 1. This circuit, by 250.122(A), should normally have an 8 AWG equipment grounding conductor run with the 12 AWG motor circuit conductors; this rule avoids that and would allow a 12 AWG grounding conductor for this purpose.

Part (G) covers another application of this concept, where wire-type equipment grounding conductors run with feeder taps are sized in accordance with the rating of the protective device next back on the line. Here again, the size of an equipment grounding conductor selected for this purpose need not exceed the size of the ungrounded tap conductors with which it is associated. Raceway-type equipment grounding conductors recognized in 250.118 may always be used without consideration as to their size (unless so required in 250.118) and are not subject to this rule.

Part (A) also contains the allowance for equipment grounding conductors made up in multiconductor cable to be sectioned, and therefore run in parallel with individual wires smaller than the Table 250.122 specifications. This is often done in larger metal-clad cables to assist with the internal geometry and efficiency of cable manufacturing. The allowance is not new to the **NEC**, but was relocated from Art. 310 because it only applies to equipment grounding conductors.

The minimum acceptable size of an equipment grounding conductor is based on the rating of the overcurrent device (fuse or CB) protecting the circuit, run in the same raceway, for which the equipment grounding conductor is intended to provide an effective ground-fault current path (Fig. 250-89). Each size of grounding conductor in the table is adequate to carry enough current to blow the fuse or trip the CB of the rating indicated beside it in the left-hand column. In Fig. 250-89, if the fuses are rated at 60 A, Table 250.122 shows that the equipment grounding conductor used with that circuit must be at least a 10 AWG copper or a 8 AWG aluminum or copper-clad aluminum.

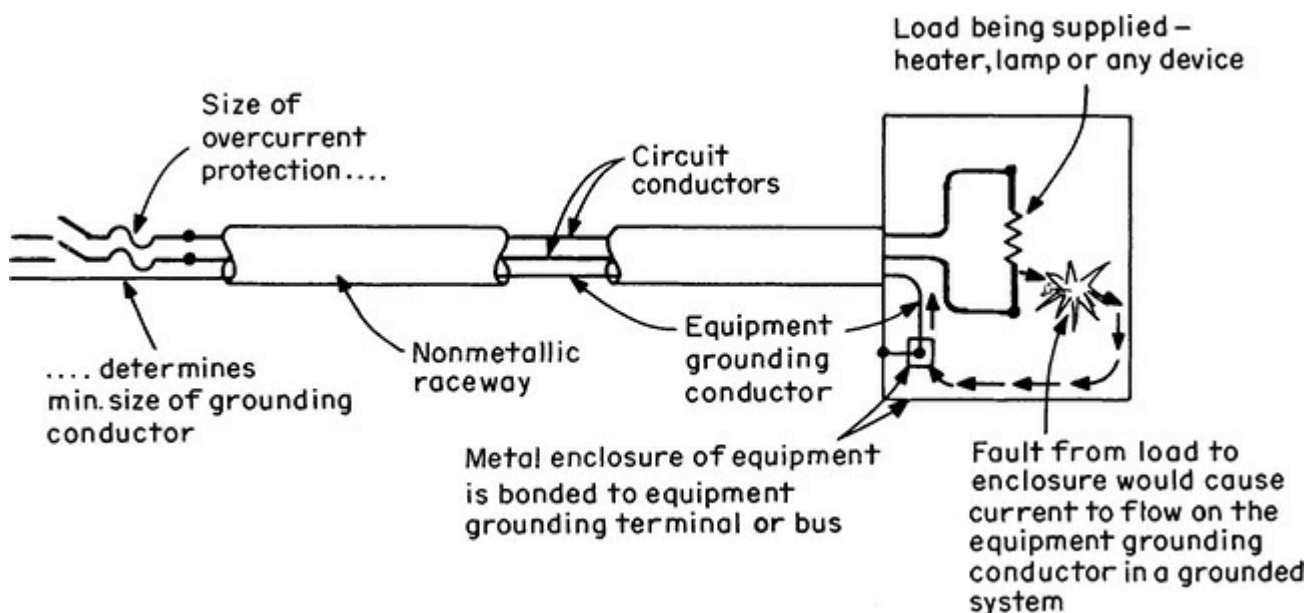

Fig. 250-89. Size of grounding conductor must carry enough current to operate circuit overcurrent device. (Sec. 250.122.)

Whenever an equipment grounding conductor is used for a circuit that consists of only one conductor for each hot leg (or phase leg), the grounding conductor is sized simply and directly from Table 250.122, as described. When a circuit is made up of parallel conductors per phase, say an 800-A circuit with two conductors per phase, an equipment grounding conductor is also sized in the same way and would, in that case, have to be at least a 1/0 AWG copper or 3/0 AWG aluminum. *And* if all the paralleled conductors run together in one raceway or cable assembly, only one equipment grounding conductor of the prescribed size is required. *But*, if such a circuit is made up using two conduits—that is, three phase legs and a neutral in each conduit—250.122(F) requires that an individual grounding conductor be run in each of the conduits *and* each of the two grounding conductors must be at least 1/0 AWG copper or 3/0 AWG aluminum (Fig. 250-90). Another example is shown in Fig. 250-91, where a 1200-A protective device on a parallel circuit calls for a 3/0 AWG copper or 250-kcmil aluminum grounding conductor.

Fig. 250-90. Grounding conductor must be used in each conduit for parallel conductor circuits. (Sec. 250.122.)

Fig. 250-91. Using equipment grounding conductors in parallel. (Sec. 250.122.)

Part **(F)** covering parallel setups, as of the 2017 **NEC**, separates rules for equipment grounding conductors serving conventional raceway installations [in what is now Part **(1)**] and as previously covered here, and those involving large circuits using paralleled cable assemblies, now covered in a new **(2)** with four paragraphs. Taking the provisions one at a time, but not in order, **(d)** sets what is in effect the default arrangement: Each cable assembly must be arranged with an equipment grounding conductor in each cable sized in accordance with Table 250.122 based on the full ampere rating circuit overcurrent protective device. This is identical to the rules in (1) for raceway installations using single conductors. Two of the other three paragraphs do not break new ground either: **(c)** effectively enforces the 4 AWG minimum size threshold for single equipment grounding conductors run in cable tray [392.10(B)(1)(c)] and **(a)** reinforces the general rule in 310.10(H)(1) that parallel runs have all the originating wire ends tied together and likewise for the terminating ends.

Paragraph **(b)** does break new ground, however, because it provides a path to utilize multiple cable assemblies with conventional (not special order) make-ups. These are generally designed for one cable on one circuit, with the incorporated equipment grounding conductor sized out of Table 250.122 for that typical circuit size, and not a much larger circuit comprised of paralleled conductors. The new procedure is to run the full parallel make-up in a single raceway or cable tray, provide a full-sized single equipment grounding conductor along with the cable assemblies, and then wire this added equipment grounding conductor in parallel with the grounding conductors in each paralleled assembly. In the case of a conventional raceway, the 310.15(B)(3)(a) derating penalties would generally make this option a non-starter. However, in cable tray as covered in 392.80(A)(1)(a) there would be no penalty, and a wireway could be considered as well up to the 30-conductor limitation [376.22(B)].

Part **(D)** of 250.122 covers another concern for unnecessarily oversizing equipment grounding conductors. Because the minimum acceptable size of an equipment grounding conductor is based on the rating of the overcurrent protective device (fuse or CB) protecting the circuit for which the equipment grounding conductor is intended to provide a path of ground-fault return, a problem arises when a motor circuit is protected by a magnetic-only (a so-called instantaneous) circuit breaker. Because 430.52 and Table 430.52 permit an instantaneous-trip CB with a setting of 800 percent of (8 times) the motor full-load running current—and even up to 1700 percent for an instantaneous CB or MSCP (motor short-circuit protector), if needed to handle motor inrush current—use of those high values of current rating permitted in Table 430.52 would result in excessively large equipment grounding conductors. Because such large sizing is unreasonable and not necessary, the rule says when sizing an equipment grounding conductor from Table 250.122 for a circuit protected by an instantaneous-only circuit breaker or by an MSCP, there is a special calculation procedure which has significantly changed in the 2008 **NEC**.

Begin with the ampacity for the applicable size of the motor circuit conductors. Multiply the ampacity [using the 75°C column for all sizes, per 110.14(C)(1)(4)] by the percentage stated for a dual-element (time-delay) fuse in Table 430.52 (usually 175 percent). In accordance with 430.52(C)(1) Exception No. 1, round the resulting number up to the next higher standard sized fuse, as listed in 240.6(A), if it does not correspond to a standard size. This result, and not the much lower setting of the running overload protection as had been allowed in the **NEC** for the six previous cycles, is the one that you use to enter Table 250.122 ([Fig. 250-92](#)).

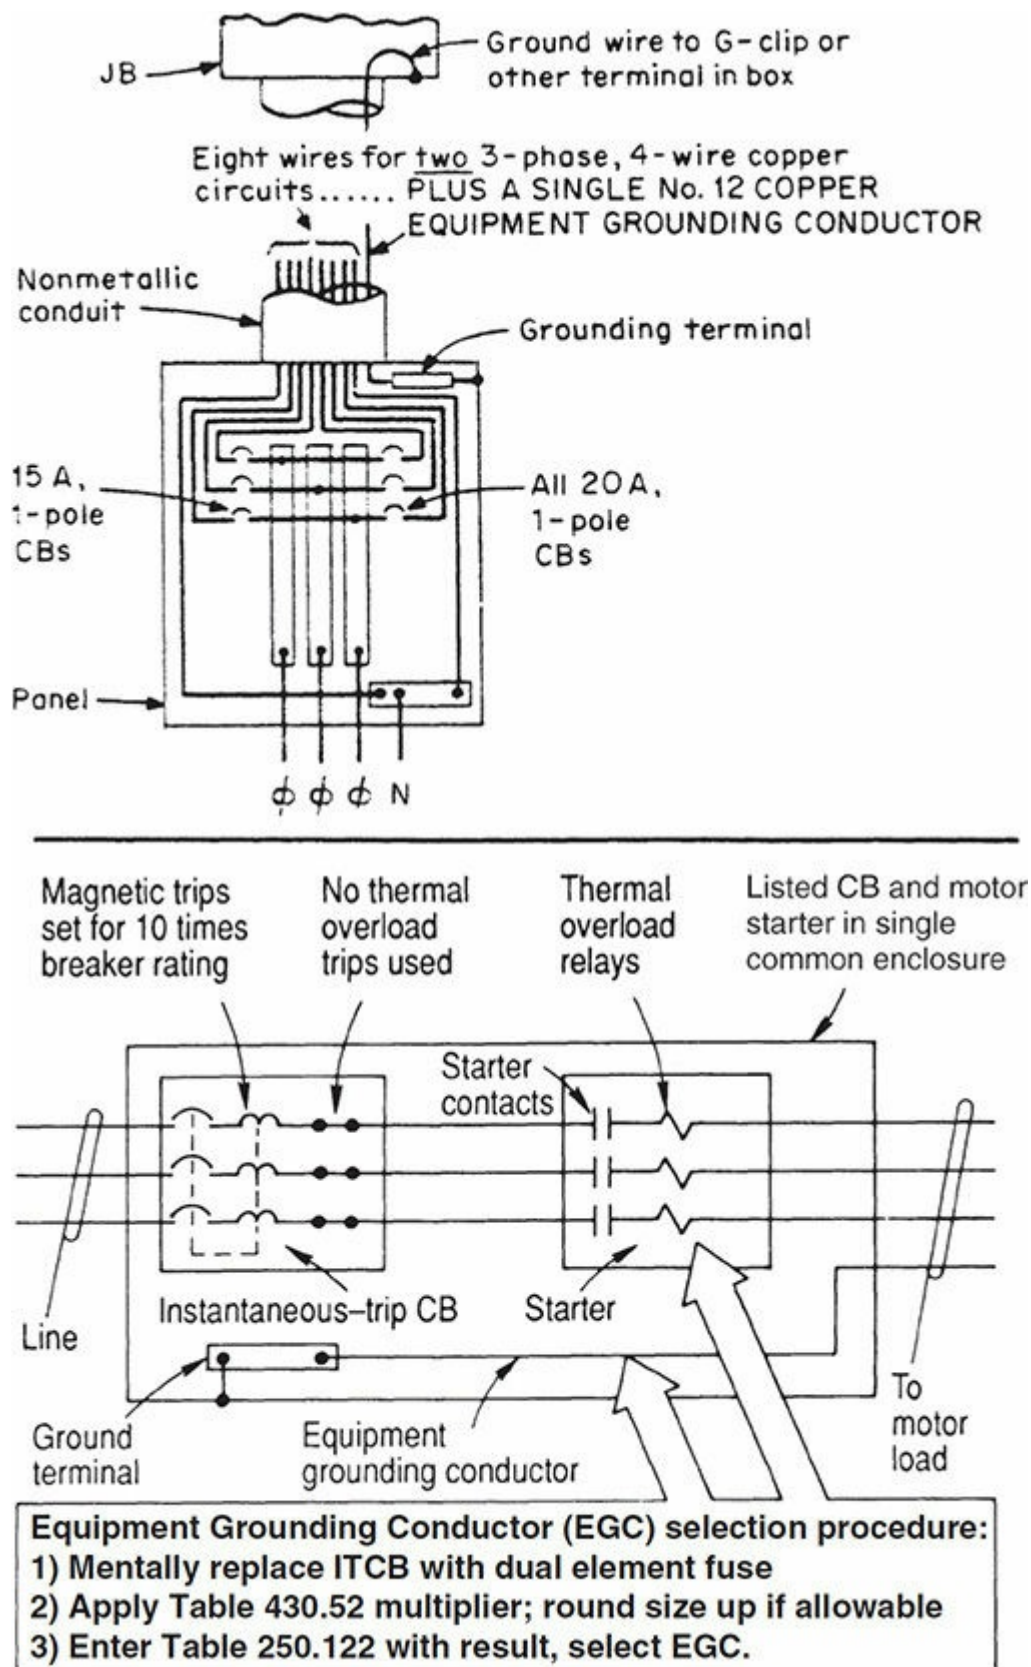

Fig. 250-92. These applications are covered by parts (C) and (D) of 250.122. (Sec. 250.122.)

The last sentence of 250.122(A) points out that metal raceways and cable armor are recognized as equipment grounding conductors; Table 250.122 does not apply to them. However, they must still provide an effective fault current path, as covered in the note at the bottom of Table 250.122.

In 250.122(B), the Code places a mandatory requirement for equipment grounding conductors to be “increased in size” where the phase conductors are “upsized” for any reason, but traditionally to overcome voltage drop on long runs. Where any upsizing is provided to ensure adequate voltage at

the point of equipment installation, the equipment grounding conductor must also be upsized to ensure adequate current flow under fault conditions. That is, if voltage drop presents a problem for the phase conductors, then it also presents a problem to the equipment grounding conductors, because the grounding conductors will be run for the same distance as the phase conductors.

The current rule to increase an equipment grounding conductor if the other circuit conductors, quite simply, are “increased in size” was unclear and required field interpretation, particularly in the event the increase was simply to satisfy the minimum size requirements in the **NEC**. The 2014 **NEC**, by adding text to the effect that the floor for beginning an up-size analysis is the minimum **NEC** required ampacity for the intended installation, has clarified that size increases required to overcome ampacity deratings for high ambient temperatures and mutual conductor heating do not provoke an increase in equipment grounding conductor sizing. For example, suppose a 3-phase, 4-wire wye-connected feeder runs with significant harmonic loading. The ampacity of the conductors must be derated in accordance with 310.15(B)(5)(c) and 310.15(B)(3)(a). The conductor size must be increased to overcome the mandatory derating factor applied. It is now clear that this “increase in size” does not invoke a larger equipment grounding conductor.

It can be shown that when conductors are increased to counteract issues of ambient temperature and mutual conductor heating, the result tends to be a net decrease in the total impedance in the fault current path (i.e., from the fuse or circuit breaker out to a fault on a power conductor and back on an equipment grounding conductor), even when that conductor is taken straight from Table 250.122 with no adjustments. In Annex D, Example D3(a) there are comprehensive calculations that address problems of continuous loading, termination issues, etc. This issue is more fully examined there.

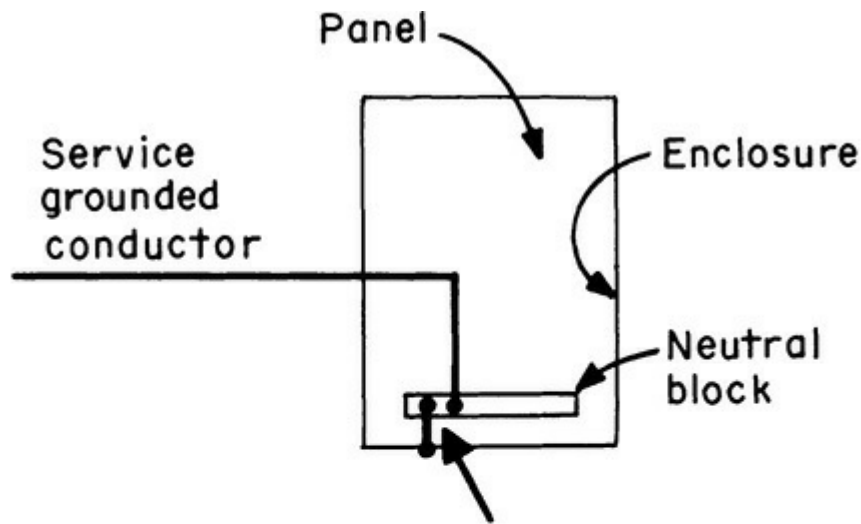

Calculation example: Suppose you have a feeder that would, in its most basic application, use 1 AWG conductors, and they are being increased to 2/0 conductors to decrease voltage drop. The Table 250.122 equipment grounding result based on the circuit protection is 6 AWG. Here is how to figure proportional increases to an equipment grounding conductor size if necessary. Perform the following calculation, using the numbers in Table 8 of **NEC Chap. 9**, where “CSA” means “cross-sectional area” and “EGC” means “equipment grounding conductor”:

$$\text{New EGC CSA} = \frac{\text{ungrounded conductor CSA} \times \text{base EGC CSA}}{\text{CSA of base ungrounded conductors from table}}$$
$$\text{New EGC} = \frac{(2/0 \text{ AWG} = 133100 \text{ cmil}) \times (6 \text{ AWG} = 26240 \text{ cmil})}{(1 \text{ AWG} = 83690 \text{ cmil})}$$
$$= (41740 \text{ cmil} = 4 \text{ AWG})$$

Figure 250-92 shows details of a controversy that often arises about 250.122(C) and 250.134. When two or more circuits are used in the same conduit, it is logical to conclude that a single equipment grounding conductor within the conduit may serve as the required grounding conductor for each circuit if it satisfies Table 250.122 for the circuit with the highest rated overcurrent protection. The common contention is that if a single metal conduit is adequate as the equipment grounding conductor for all the contained circuits, a single grounding conductor can serve the same purpose

when installed in a nonmetallic conduit that connects two metal enclosures (such as a panel and a home-run junction box) where both circuits are within both enclosures. As shown, a 12 AWG copper conductor satisfies Table 250.122 as an equipment grounding conductor for the circuit protected at 20 A. The same 12 AWG also may serve for the circuit protected at 15 A, for which a grounding conductor must not be smaller than 14 AWG copper. Such an application is specifically permitted by part (C) of 250.122. Although this will have primary application with PVC conduit where an equipment grounding conductor is required, it may also apply to circuits in EMT, IMC, or rigid metal conduit when an equipment grounding conductor is run with the circuit conductors to supplement the metal raceway as an equipment grounding return path.

250.130. Equipment Grounding Conductor Connections. Part (A) requires that the equipment grounding conductor at a service—such as the ground bus or terminal in the service-equipment enclosure, or the enclosure itself—must be connected to the system *grounded* conductor (the neutral or grounded phase leg). The equipment ground and the neutral or other grounded leg must be bonded together and it must be done on the supply side of the service disconnecting means—which means either *within* or *ahead* of the enclosure for the service equipment (Fig. 250-93).

Bonding is the insertion of a bonding screw into the panel neutral block to connect the block to the panel enclosure, or it is use of a bonding jumper from the neutral block to an equipment grounding block that is connected to the enclosure.

NOTE: Bonding—the connection of the neutral terminal to the enclosure or to the ground terminal that is, itself, connected to the enclosure—might also be done in an individual switch or CB enclosure.

Bonding of the neutral is the connection between the neutral bus and the equipment grounding bus or between the neutral bus and the metal enclosure itself.

Fig. 250-93. Equipment ground must be “bonded” to grounded conductor at the service equipment. (Sec. 250.130.)

Part **(B)** requires the ground bus or the enclosure to be simply bonded to the grounding electrode conductor within or ahead of the service disconnect for an ungrounded system.

As shown at the top of Fig. 250-94, some switchboard sections or interiors include neutral busbars factory-bonded to the switchboard enclosure and are marked “suitable for use only as service equipment.” They may not be used as subdistribution switchboards—that is, they may not be used on the load side of the service except where used, with the inspector’s permission, as the first disconnecting means fed by a transformer secondary or a generator and where the bonded neutral satisfies 250.30 for a separately derived system.

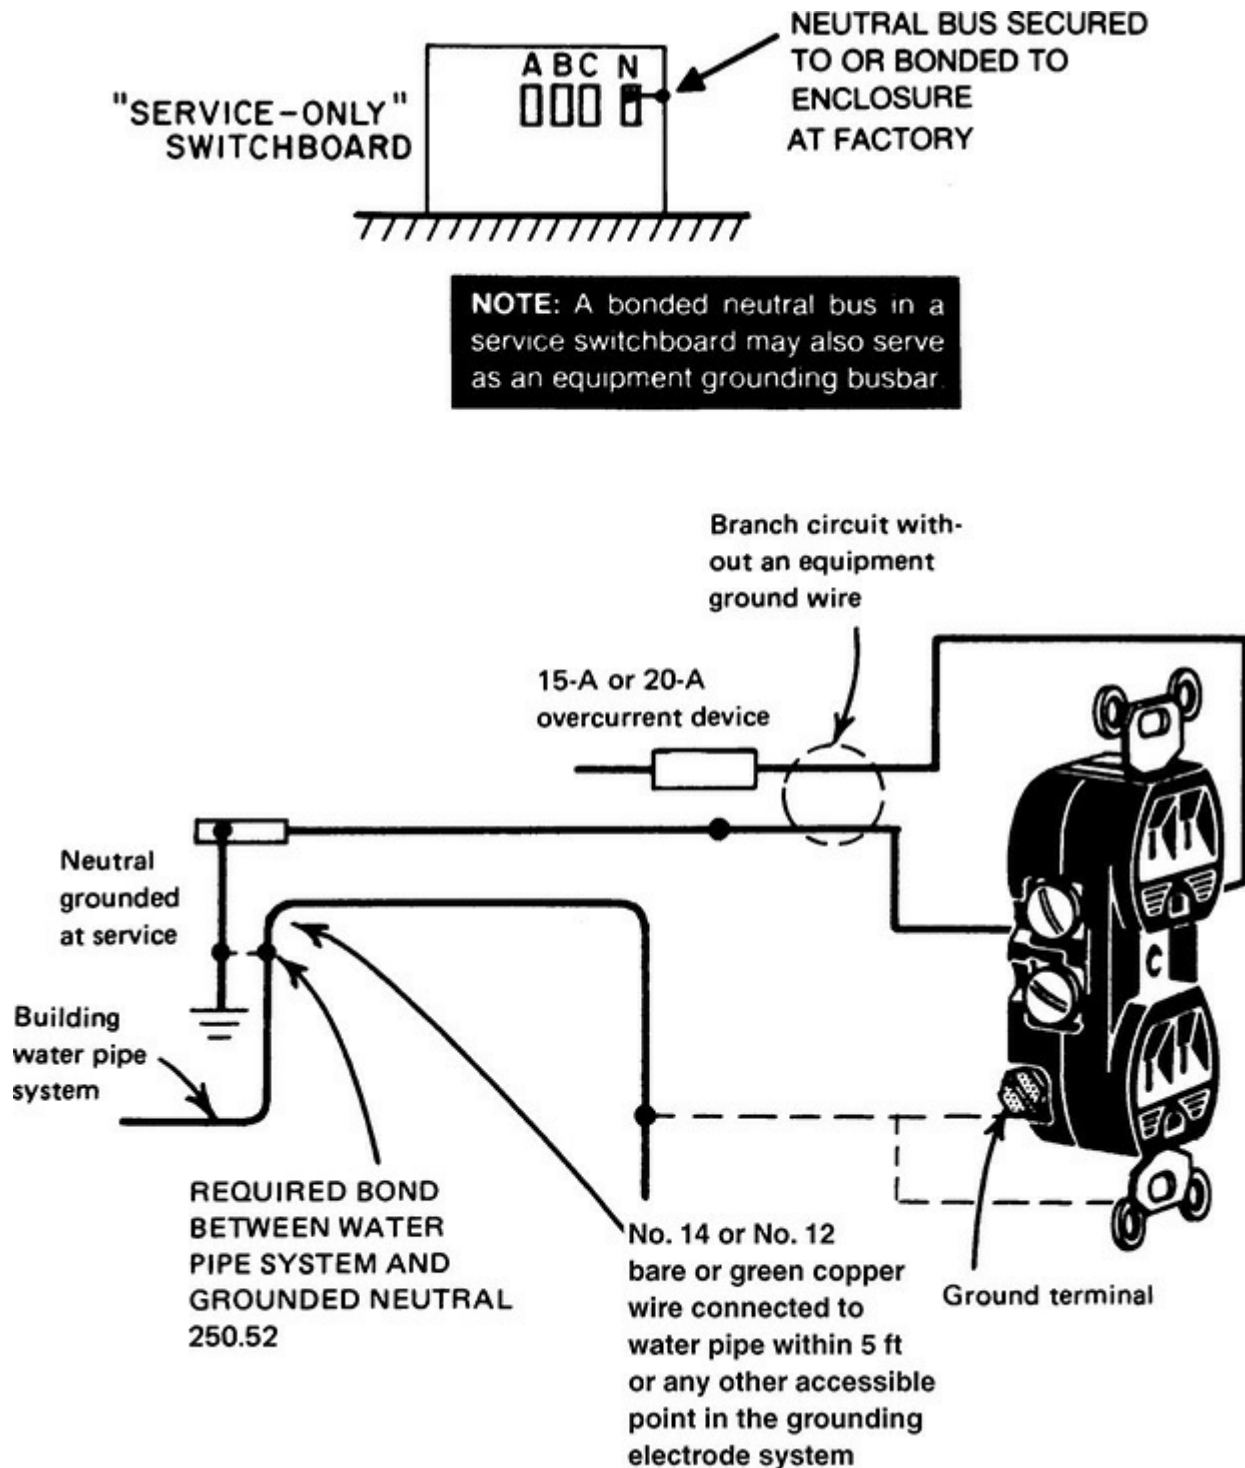

Fig. 250-94. These are bonding and grounding details covered by 250.130(C).

Part (C) covers the retrofit of equipment grounding connections for receptacles connected to, or for extensions of, *existing* branch circuits that do not include any recognized equipment grounding conductor (Fig. 250-94, bottom), such as concealed knob-and-tube wiring (Art. 394). An equipment

grounding conductor can be brought to these locations without rewiring the circuit, and used to make a grounding connection on a receptacle grounding terminal, or to the equipment grounding provisions of a wiring method being used to extend an existing branch circuit. For example, if a concealed knob-and-tube circuit were being extended with Type NM cable, which includes a bare copper wire for equipment grounding, an equipment grounding conductor could be fished to the location of the branch circuit being extended.

The equipment grounding conductor, presumably a 12 or 14 AWG wire, would be run to the location, probably using the provisions of 250.120(C) that give a waiver on raceway or cable armor protection in such cases for runs within hollow walls or joist cavities, or where otherwise protected from damage. It must originate from one of the following locations: (1) the grounding electrode system at an accessible point, or on the grounding electrode conductor; (2) the equipment grounding terminal bar within the enclosure where the circuit originates; (3) the service equipment grounding terminal bar (ungrounded systems) or the grounded service conductor within the service equipment, or the equivalent grounding terminal within the service equipment for ungrounded systems. The 2014 **NEC** added a connection to an equipment grounding conductor of any other branch circuit that originates within the same enclosure as where the branch circuit being extended (or supporting the receptacle being grounded) originates.

At one time, this rule allowed connections to nearby water pipes, but not since the 1993 **NEC**. Now all the likely connection points are in a basement or the first level. You are unlikely to be searching for a method of grounding concealed knob-and-tube wiring in a steel-frame building. Rather you will be attempting this in old wood-frame buildings, probably residential. In such occupancies, even if the water supply lateral is metallic, the water piping system ceases to be considered as an electrode beyond 5 ft from the point of entry. This means fishing into the basement. If you can fish a ground wire down into the basement, you can fish a modern circuit up in the reverse direction and avoid all the problems. Meanwhile, the note at the end of this part points to the procedure in 406.4(D) that allows grounding-configured GFCI receptacles to be installed with no equipment ground provided. This entire procedure is of marginal significance today. The 2014 **NEC** modification does have the virtue of possibly allowing a connection point potentially closer to the work being undertaken.

250.134. Equipment Fastened in Place or Connected by Permanent Wiring Methods (Fixed)—Grounding. This section requires that metal equipment enclosures, boxes, and cabinets to be grounded must be grounded by metal cable armor or by the metal raceway that supplies such enclosures (rigid metal conduit, intermediate metal conduit, EMT, flex or liquidtight flex), *or* by an equipment grounding conductor, such as where the equipment is fed by rigid nonmetallic conduit. Refer to 250.118. As illustrated at the bottom of [Fig. 250-94](#), Exception No. 1 for parts (A) and (B) recognizes the accepted technique given in 250.130—for using grounding-type receptacles for replacement of existing nongrounding devices or for circuit extensions—on wiring systems that do not include an equipment grounding conductor.

In Sec. 250.134(B), the rule explicitly requires that *when* a separate equipment grounding conductor (i.e., other than the metal raceway or metal cable armor) is used for alternating-current circuits, it *must* be contained *within* the same raceway, cable, or cord or otherwise run with the circuit conductors ([Fig. 250-95](#)). External grounding of equipment enclosures or frames or housings is a violation for ac equipment. It is not acceptable, for instance, to feed an ac motor with a nonmetallic conduit or cable, without a grounding conductor in the conduit or cable, and then provide grounding

of the metal frame by a grounding conductor connected to the metal frame and run to building steel or to a grounding-grid conductor. An equipment grounding conductor *must always* be run with the circuit conductors.

If equipment grounding conductor (other than raceway) is used to ground motor, it must be run in raceway with circuit wires

Fig. 250-95. Equipment grounding conductor must be in raceway or cable with circuit conductors for ac equipment. (Sec. 250.134.)

The rule in Sec. 250.134(B) which insists on keeping an equipment grounding conductor physically close to ac circuit supply conductors is a logical follow-up to the rules of 250.4 which call for minimum impedance in grounding current paths to provide most effective clearing of ground faults. When an equipment grounding conductor is kept physically close to any circuit conductor that would be supplying the fault current (i.e., the grounding conductor is in the “same raceway, cable, or cord or otherwise run with the circuit conductors”), the impedance of the fault circuit has minimum inductive reactance and minimum ac resistance because of mutual cancellation of the magnetic fields around the conductors and the reduced skin effect. Under such condition of a “low-impedance circuit” the meaning of 250.4(A)(5) is best fulfilled—voltage to ground is limited to the greatest extent, the fault current is higher because of minimized impedance, the circuit overcurrent device will operate at a faster point in its time-current characteristic to ensure maximum fault-clearing speed, and the entire effect will be “facilitating the operation of the overcurrent device... .”

The arrangement shown in [Fig. 250-96](#) violates the basic rule of 250.134(B) because the lighting fixture, which must be grounded to satisfy 250.112, is not grounded in accordance with 250.134 and 250.118 or by an equipment grounding conductor contained within the cord, as noted in 250.138.

EXTERNAL EQUIPMENT GROUNDING IS A VIOLATION!

Fig. 250-96. Supply to ac equipment must include equipment grounding conductor. (Sec. 250.134.)

Note that 250.134(B) refers very clearly to an “equipment grounding conductor contained within the same raceway, cable, or otherwise run with the circuit conductors.” Except for dc circuits, replacement receptacles [250.130(C)], and isolated, ungrounded power sources [517.19(G)], an equipment grounding conductor of any type must not be run separately from the circuit conductors. The engineering reason for keeping the ground return path and the phase legs in close proximity (i.e., in the same raceway) is to minimize the impedance of the fault circuit by placing conductors so their magnetic fields mutually cancel each other, keeping inductive reactance down, and allowing sufficient current to flow to “facilitating the operation of the overcurrent device....” as required by 250.4(A) (5).

The hookup in Fig. 250-96 also violates the rule of the last sentence in 250.136(A), which prohibits use of building steel as the equipment grounding conductor for ac equipment. And the rules of 250.136 often have to be considered in relation to the rules of 250.134.

Note: CARE MUST BE TAKEN TO DISTINGUISH BETWEEN AN “EQUIPMENT GROUNDING CONDUCTOR” AS COVERED BY 250.134 AND AN “EQUIPMENT BONDING JUMPER” AS COVERED BY 250.102(E). A “BONDING JUMPER” MAY BE USED EXTERNAL TO EQUIPMENT BUT IT MUST NOT BE OVER 6 ft (1.8 m) LONG.

250.136. Equipment Considered Grounded. This rule clarifies the way in which structural metal may be used as an equipment grounding conductor, consistent with the rule of 250.134(B) requiring a grounding conductor to be kept physically close to the conductors of any ac circuit for which the grounding conductor provides the fault return path.

Part (A) notes that if a piece of electrical equipment is attached and electrically conductive to a metal rack or structure supporting the equipment, the metal enclosure of the equipment is considered suitably grounded by connection to the metal rack, PROVIDED THAT the metal rack itself is effectively grounded by metal raceway enclosing the circuit conductors supplying the equipment or by an equipment grounding conductor run with the circuit supplying the equipment. An example of such application is shown in Fig. 250-97. Although this example shows grounding of lighting fixtures to a rack, the Code rule recognizes any “electric equipment” when this basic grounding concept is observed. It is important to note that if a ground fault developed in equipment so grounded (as at point A), the fault current would take the path indicated by the small arrows. In such case, although the fault-current path through the steel rack is not close to the hot conductor in the flexible cord that is

feeding the fault—as normally required by 250.134(B)—the distance of the external ground path is not great, from the fixture to the panel enclosure or box. Because such a short external ground path produces only a relatively slight increase in ground-path impedance, 250.136(A) permits it. The permission for external bonding of flexible metal conduit and liquidtight flex in 250.102(E) is based on the same acceptance of only slight increase of overall impedance of the ground path.

Fig. 250-97. This use of metal rack as equipment ground is permitted. [Sec. 250.136(A).]

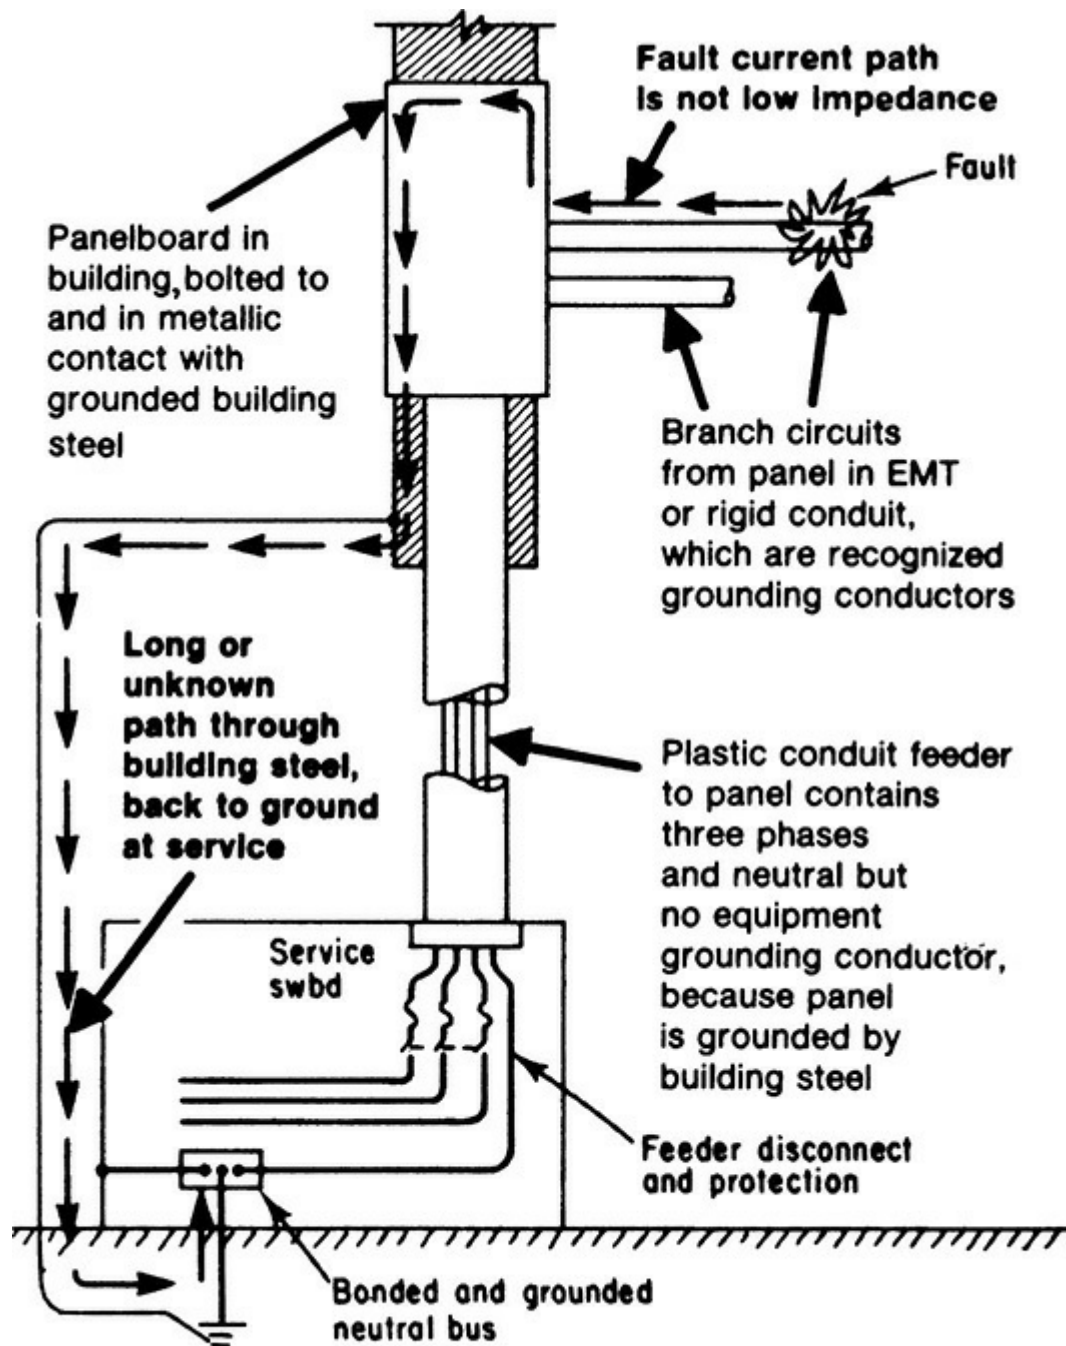

The second sentence of 250.136(A) clearly prohibits using structural building steel as an equipment grounding conductor for equipment mounted on or fastened to the building steel—IF THE SUPPLY CIRCUIT TO THE EQUIPMENT OPERATES ON ALTERNATING CURRENT. BUT, structural building steel that is effectively grounded and bonded to the grounded circuit conductor of a

dc supply system may be used as the equipment grounding conductor for the metal enclosure of dc-operated equipment that is conductively attached to the building steel.

It is important to understand the basis for the Code rules of 250.134(B) and 250.118 and their relation to the concept of 250.136(A):

Note that 250.134(B) refers very clearly to an “equipment grounding conductor contained within the same raceway or cable or otherwise run with the circuit conductors.” Except for dc circuits (250.168) and for isolated, ungrounded power sources [517.19(F) and (G)], an equipment grounding conductor of any type must not be run separately from the circuit conductors. Keeping the ground return path and the phase legs in close proximity (i.e., in the same raceway) minimizes the impedance of the fault circuit by placing conductors so their magnetic fields mutually cancel each other, keeping inductive reactance down and allowing sufficient current to flow to “facilitating the operation of the overcurrent device...” as required by 250.4(A)(5).

The second sentence of 250.136(A) applies the concept of ground-fault impedance to the metal frame of a building and prohibits its use as an equipment grounding conductor for ac equipment enclosures. As shown in [Fig. 250-98](#), use of building steel as a grounding conductor provides a long fault return path of very high impedance because the path is separated from the feeder circuit hot legs—thereby violating 250.4. Ground-fault current returning over building steel to the point where the building steel is bonded to the ac system neutral (or other grounded) conductor is separated from the circuit conductor that is providing the fault current. Impedance is, therefore, elevated and the optimum conditions required by 250.4 are not present, so that the grounding cannot be counted on for “facilitating the operation” of the fuse or CB protecting the faulted circuit. The current may not be high enough to provide fast and certain clearing of the fault.

THIS LAYOUT IS A VIOLATION

Fig. 250-98. Building metal frame is not an acceptable grounding conductor for ac equipment. [Sec. 250.136(A).]

The first sentence of 250.136(A) accepts a limited variation from the basic concept of keeping circuit hot legs and equipment grounding conductors physically close to each other. When equipment is grounded by connection to a “metal rack or structure” that is specifically provided to support the equipment and *is* grounded, the separation between the circuit hot legs and the rack, which serves as the equipment grounding conductor, exists only for a very short length that will not significantly raise the overall impedance of the ground-fault path. [Figure 250-99](#) shows another application of that type, similar to the one shown in [Fig. 250-97](#). Although this shows a 2-wire cord as being acceptable, use of a 3-wire cord (two circuit wires and an equipment grounding wire) is better practice, at very slight cost increase.

Fig. 250-99. This satisfies basic rule of 250.136(A). [Sec. 250.136(A).]

Aside from the limited applications shown in [Figs. 250-97](#) and [250-99](#), *required* equipment grounding must always keep the equipment grounding conductor alongside the circuit conductor for grounded ac systems. Of course, as long as required grounding techniques are observed, there is no objection to additional connection of equipment frames and housings to building steel or to grounding grids to provide equalized potentials to ground. But the external grounding path is not suitable for clearing ac equipment ground faults.

250.138. Cord-and-Plug-Connected Equipment. The proper method of grounding portable equipment is through an extra conductor in the supply cord. Then if the attachment plug and receptacle comply with the requirements of 250.138, the grounding connection will be completed when the plug is inserted in the receptacle.

A grounding-type receptacle and an attachment plug should be used where it is desired to provide for grounding the frames of small portable appliances. The receptacle will receive standard 2-pole attachment plugs, so grounding is optional with the user. The grounding contacts in the receptacle are electrically connected to the supporting yoke so that when the box is surface-mounted, the connection to ground is provided by a direct metal-to-metal contact between the device yoke and the box. For a recessed box a grounding jumper must be used on the receptacle or a self-grounding receptacle must be used. See 250.146 and 250.148.

Figure 250-100 shows a grounding-type attachment plug with a movable, self-restoring grounding member—as previously covered in an exception to this section. Although previously recognized, availability of such a device is questionable, and use of such a product is no longer permitted.

Fig. 250-100. This type of plug cap is no longer recognized on cords for tools and appliances. However, the exception in 250.138(A) *does* recognize “moveable” ground pins on “grounding-type, plug-in” GFCIs where the voltage is not greater than 150 V. [Sec. 250.138(A) Exception.]

250.140. Frames of Ranges and Clothes Dryers. Prior to the 1996 edition of the **NEC**, the frame of an electric range, wall-mounted oven, or counter-mounted cooking unit could be grounded by direct connection to the grounded circuit conductor (the grounded neutral) and thus could be supplied by a 3-wire cord set and range receptacle irrespective of whether the conductor to the receptacle contains a separate grounding conductor.

The **NEC** prohibits such applications except on “existing branch circuits.” That wording doesn’t permit grounding of ranges or dryers with the neutral, unless the circuit itself—not the occupancy—is an existing circuit. For *all* new circuits and new construction, the neutral may *not* be used as a grounding conductor.

Where permitted to be so grounded parts (1) and (2) clarify the use of a No. 10 or larger grounded neutral conductor of a 120/208- or 120/240-*V* circuit for grounding the frames of electric ranges, wall-mounted ovens, counter-mounted units, or clothes dryers. This method is acceptable whether the 3-wire supply is 120/208 or 120/240 V. Normally, the grounded conductor must be insulated. However, a provision, applicable to both 3-wire supply voltages, does require that when using service-entrance cable having an uninsulated neutral conductor, the branch circuit must originate at the service-entrance equipment. The purpose of this provision is to prevent the uninsulated neutral from coming in contact with a panelboard supplied by a feeder and a separate grounding conductor (in the case of nonmetallic-sheathed cable). This would place the neutral in parallel with the grounding conductor, or with feeder *metal* raceways or cables if they were used. Insulated neutrals in such situations will prevent this (Fig. 250-101).

This permission is limited to existing circuits only!

Conditions when grounded neutral conductor (No. 10 or larger) may be used to ground metal frames of specified appliances.

Fig. 250-101. Ranges and dryers may be grounded to the circuit neutral, but only on existing circuits. All new installations must provide an equipment grounding conductor with the 3-wire supply to the range or dryer. (Sec. 250.140.)

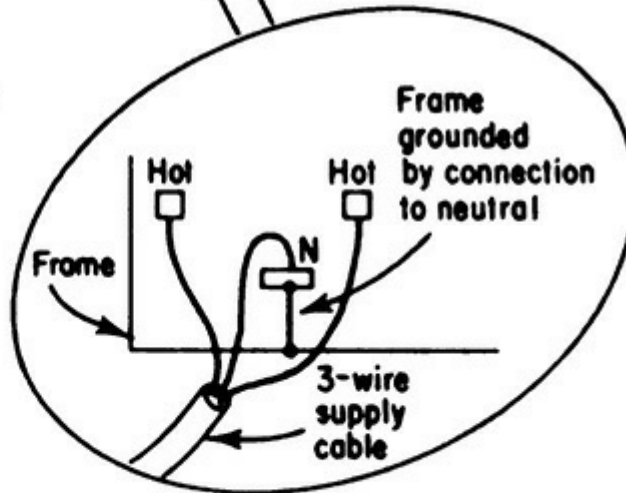

Wording of the rule that permits frames of ranges and clothes dryers to be grounded by connection to the grounded neutral conductor of their supply circuits also permits the same method of grounding of “outlet or junction boxes” serving such appliances. The rule permits grounding of an outlet or junction box, as well as cooking unit or dryer, by the circuit grounded neutral (Fig. 250-102). That practice has been common for many years but has raised questions about the suitability of the neutral for such grounding. However, the wording of this rule makes clear that such grounding of the box is acceptable. Figure 250-103 shows other details of such application. Without this permission to ground the metal box to the grounded neutral, it would be necessary to run a 4-wire supply cable to the box, with one of the wires serving as an equipment grounding conductor sized from Table 250.122, which is always required for other than existing branch circuits that supply dryers and ranges.

This permission is limited to existing circuits only!

* Nonmetallic jacketed
3-wire supply circuit,
two hot legs plus neutral
(without grounding conductor)

Grounding of metal
junction box or outlet
box may be made to
the neutral of supply
cable

* Service cable or NM or NMC cable. But NM
or NMC cable must have an insulated
neutral.

Fig. 250-102. Neutral may be used to ground boxes as well as appliances. (Sec. 250.140.)

FIXED CONNECTION

Watch Out! Although generally permitted in the past, the Code now prohibits such practice, except for *existing circuits!*

CORD CONNECTION

Fig. 250-103. These techniques may be used to ground boxes on existing circuits only! (Sec. 250.140.)

Important: As shown in the asterisk note under [Fig. 250-102](#), if a nonmetallic-sheathed cable was used, say, to supply a wall oven or cooktop, such cable is required by 250.140 to have an *insulated* neutral. It would be a violation, for instance, to use a 10/2 NM cable with a bare 10 AWG grounding conductor to supply a cooking appliance—connecting the two insulated 10 AWG wires to the hot terminals and using the bare 10 AWG as a neutral conductor to ground the appliance. An uninsulated grounded neutral may be used only when part of a service-entrance cable. Where an existing branch circuit is made up with 10/2 Type NM cable, a new branch circuit with an equipment ground must be installed to supply the dryer or range.

250.142. Use of Grounded Circuit Conductor for Grounding Equipment. Part (A) permits connection between a grounded neutral (or grounded phase leg) and equipment enclosures, for the purpose of grounding the enclosures to the grounded circuit conductor. The grounded conductor (usually the neutral) of a circuit may be used to ground metal equipment enclosures and raceways on the supply side of the service disconnect or the supply side of the first disconnect fed from a separately derived transformer secondary or generator output or on the supply side of a main disconnect for a separate building. The wording here includes the supply side of a separately derived system as a place where metal equipment parts or enclosures may be grounded by connection to the grounded circuit conductor (usually a neutral). It is important to note that, in the meaning of the code (as covered in 250.30 and in 250.24), the phrase “on the supply side of the disconnecting means” includes connection within the enclosure of the disconnecting means. Note that the supply side of the separately derived system language correlates with the permission in 250.30(A) (1) to locate the system bonding jumper at a point from the source to the first system disconnecting means. Also the permission on outbuildings reflects a continuing, but now extremely limited, permission in those areas to reground a neutral on existing premises wiring systems only.

Figure 250-104 shows such applications. At A, the grounded service neutral is bonded to the meter housing by means of the bonded neutral terminal lug in the socket—and the housing is thereby grounded by this connection to the grounded neutral, which itself is grounded at the service equipment as well as at the utility transformer secondary supplying the service. At B, the service equipment enclosure is grounded by connection (bonding) to the grounded neutral—which itself is grounded at the meter socket and at the supply transformer. These same types of grounding connections may be made for CT cabinets, auxiliary gutters, and other enclosures on the line side of the service-entrance disconnect means, including the enclosure for the service disconnect. In some areas, the utilities and inspection departments will not permit the arrangement shown in [Fig. 250-104](#) because the connecting lug in the meter housing is not always accessible for inspection and testing purposes. At C, equipment is grounded to the neutral on the line (supply) side of the first disconnect fed from a step-down transformer (a separately derived system).

Fig. 250-104. Using grounded circuit conductor to ground equipment housings on line side of service or separately derived system. (Sec. 250.142.)

Aside from the permission given in the three exceptions to the rule of part **(B)**, and separately derived systems or main building disconnects (250.30 and 250.32), the wording of part **(B)** prohibits connection between a grounded neutral and equipment enclosures on the load side of the service. The wording supports the prohibition in 250.24(A)(5) and 250.30(A) of grounding connections. So aside from the few specific exceptions mentioned, bonding between any system grounded conductor, neutral or phase leg, and equipment enclosures is prohibited on the load side of the service (Fig. 250-105). The use of a neutral to ground panelboard or other equipment (other than specified in the exceptions) on the load side of service equipment would be extremely hazardous if the neutral became loosened or disconnected. In such cases any line-to-neutral load would energize all metal components connected to the neutral, creating a dangerous potential above ground. Hence, the prohibition of such a practice. This is fully described in Fig. 250-11.

If feeder and/or branch circuits are in nonmetallic cable or conduit and contain any equipment grounding conductors, an approved grounding block or busbar *must* be used and bonded to the enclosure (408.40).

NEUTRAL BLOCK OR BUSBAR MUST NOT BE BONDED TO ENCLOSURE TO PROVIDE GROUNDING OF THE ENCLOSURE

Fig. 250-105. Panel, switchboard, CB, and switch on load side of service within a single building. (Sec. 250.142.)

When a circuit is run from one building to another, it may be necessary, simply permissible, or expressly prohibited to connect the system “grounded” conductor to a grounding electrode at the other building—as covered by 250.32. Separately derived systems—as covered in 250.30—are also exempted from the basic requirement by the first sentence of 250.142(B).

Although this rule of the Code prohibits neutral bonding on the load side of the service, 250.130(A) and 250.24(A) clearly require such bonding at the service entrance. And the exceptions to prohibiting load-side neutral bonding to enclosures are few and very specific:

- Exception No. 1 of 250.142(B) permits frames of ranges, wall ovens, countertop cook units, and clothes dryers to be “grounded” by connection to the grounded neutral of their supply circuit, but only for *existing* circuits (250.140).
- Exception No. 2 to 250.142(B) permits grounding of meter enclosures to the grounded circuit conductor (generally, the grounded neutral) on the *load side* of the service disconnect if the meter enclosures are located immediately adjacent to the service disconnect, the service is not equipped with ground-fault protection, and the neutral is not less than the minimum required by 250.122, based on the rating of the service overcurrent device. This rule applies, of course, to multioccupancy buildings (apartments, office buildings, etc.) with individual tenant metering (Fig. 250-106).

Fig. 250-106. Grounding meter enclosures to grounded conductor on *load side* of service disconnect, with meters located “immediately adjacent” to the service disconnect. (Sec. 250.142.)

- Exception No. 3 permits dc systems to be grounded on the load side of the service disconnect as described in 250.164.
- Exception No. 4 permits medium-voltage electrode-type boilers to operate with their neutral conductors bonded to the pressure vessel and with ancillary electrical equipment bonded to the vessel or to the equipment, as covered in Part V of Art. 490.

If a meter bank is on the upper floor of a building, as in a high-rise apartment house, or otherwise away from service disconnect, such meter enclosures would not meet the rule that they must be “immediately adjacent to” the service disconnect. In such cases, the enclosures must not be grounded to the neutral. And if the service has ground-fault protection, meter enclosures on the load side must not be connected to the neutral, even if they are “immediately adjacent to” the service disconnect.

250.146. Connecting Receptacle Grounding Terminal to Box. The first paragraph requires that a jumper be used when the outlet box is installed in the wall (Fig. 250-107). Because boxes installed in walls are very seldom found to be perfectly flush with the wall, direct contact between device screws and yokes and boxes is seldom achieved. Screws and yokes currently in use were designed solely for the support of devices rather than as part of the grounding circuit. Although the general rule states that a flush-type box, installed in a wall for a receptacle outlet, does require a bonding jumper from a grounded box to the receptacle grounding terminal, part (A) pertains to surface-mounted boxes and eliminates the need for a separate bonding jumper between a surface-mounted box and the receptacle grounding terminal under the conditions described. But, where such grounding is selected, at least one of the insulating washers must be removed from the device’s securing screws.

Fig. 250-107. Bonding jumper connects receptacle ground to grounded box. (Sec. 250.146.)

Although part (A) generally exempts surface-mounted boxes from the need for a bonding jumper from the box to the ground terminal of a receptacle installed in the box—because there is solid contact between the receptacle’s grounded mounting yoke and the ears on the box when installed—that is not applicable to a receptacle mounted in a raised box cover. (See Fig. 250-108.) There are several issues to consider with respect to mounting receptacles in raised covers. The first is 406.5(C), which requires (generally) no fewer than two screws to hold the receptacle in place. Contrary to common belief, this rule has nothing to do with grounding; it has to do with documented loss experience where a single screw holding the center of a duplex receptacle loosened to the point of allowing the receptacle to fall far enough behind the cover that it would begin to twist. If a plug were inserted at the time (and this happened a number of times), and the twist occurred in the direction of the ungrounded blade on the plug, and if the plug were even slightly loose, the energized

blade would contact the grounded cover at the edge of the duplex punch-out. The result, of course, would be the complete destruction of the plug, the receptacle, the cover, and quite a few items nearby. The double-screw rule has ended this problem.

**EMT, BX, NM
or other method**

6-32 screws secure
receptacle yoke to box
with direct metal-to-metal

mounted utility box

Receptacle
does not require a bonding
jumper between box and
receptacle grounding terminal.

A jumper wire to connect the grounding-screw terminal to the grounded box is not required with a surface-mounted box, but is required when receptacle is used in a recessed box

**JUMPER FROM RECEPTACLE
GROUND SCREW TO BOX**

**These covers, even if made to comply with 406.5(C)
(two-screw support rule) do not qualify for the omission
of bonding jumpers because they do not have flat
corners where the mounting screws attach.**

Listed, raised covers with flat corners and "screw locking" means for receptacle attachments, no fewer than two points of support, now recognized for receptacle mounting without bonding jumpers.

Fig. 250-108. Typical applications where a surface box does and does not need a receptacle bonding jumper. (Sec. 250.146.)

The reluctance to recognize the cover as the grounding contact has more to do with the permanence of the entire setup. The language in Part A about a box and cover combination being listed as providing acceptable continuity has never been of much help; it went into the **NEC** to protect certain explosionproof receptacles from needing bonding jumpers to their heavily bolted supports. This problem has been addressed in the 2008 **NEC**, however, through additional language in Part A. Now, for the first time a raised cover is permitted to support receptacles without bonding jumpers to the box, provided it is of “crushed corner” construction. If the cover has totally flat corners, there will be no spring in the sheet metal, and the 8-32 corner screws on the box will hold securely. The cover must be listed and with no fewer than two fastening points for the receptacle. The support hardware must either be permanent, such as a rivet, or use “thread locking” or “screw locking” means. Thread locking means presumably a jam nut of some type, and it would be somewhat difficult to get hold of between the edge of the receptacle and the raised part of the cover. Screw locking was clarified by adding the words “or nut” and thereby includes the current raised cover designs, which come with knurled 6-32 nuts that grab the underside of the yoke when the screw is tightened.

Figure 250-109 illustrates a grounding device which is intended to provide the electrical grounding continuity between the receptacle yoke and the box on which it is mounted and serves the dual purpose of both a mounting screw and a means of providing electrical grounding continuity in lieu of the required bonding jumper. As shown in the sketch, special wire springs and four-lobed machine screws are part of a receptacle design for use without a bonding jumper to box. This complies with 250.146(B).

Fig. 250-109. Self-grounding screws ground receptacle in recessed box without bonding jumper. (Sec. 250.146.)

250.146(C) permits non-self-grounding receptacles without an equipment grounding jumper to be

used in floor boxes which are designed for and listed as providing proper continuity between the box and the receptacle mounting yoke.

Part **(D)** of 250.146 allows the use of a receptacle with an isolated grounding terminal (no connection between the receptacle grounding terminal and the yoke). Sensitive electronic equipment that is grounded normally through the building ground is often adversely affected by pickup of transient signals, which cause an imbalance in the delicate circuits. This is particularly true with highly intricate medical and communications equipment, which often picks up unwanted currents, even of very low magnitude.

The use of an isolated grounding receptacle allows a “pure” path to be established back to the system grounding terminal, in the service disconnecting means, without terminating in any other intervening panelboard. In [Fig. 250-110](#), a cutaway of an isolated grounding receptacle shows the insulation between the grounding screw and the yoke (top), and the hookup of the insulated grounding conductor to the common neutral-equipment-ground point of the electrical system (bottom).

Insulation separates ground terminal from metal mounting strap for "quiet" grounding

250.146(D). A QUIET GROUND MUST MEET THESE CONDITIONS.

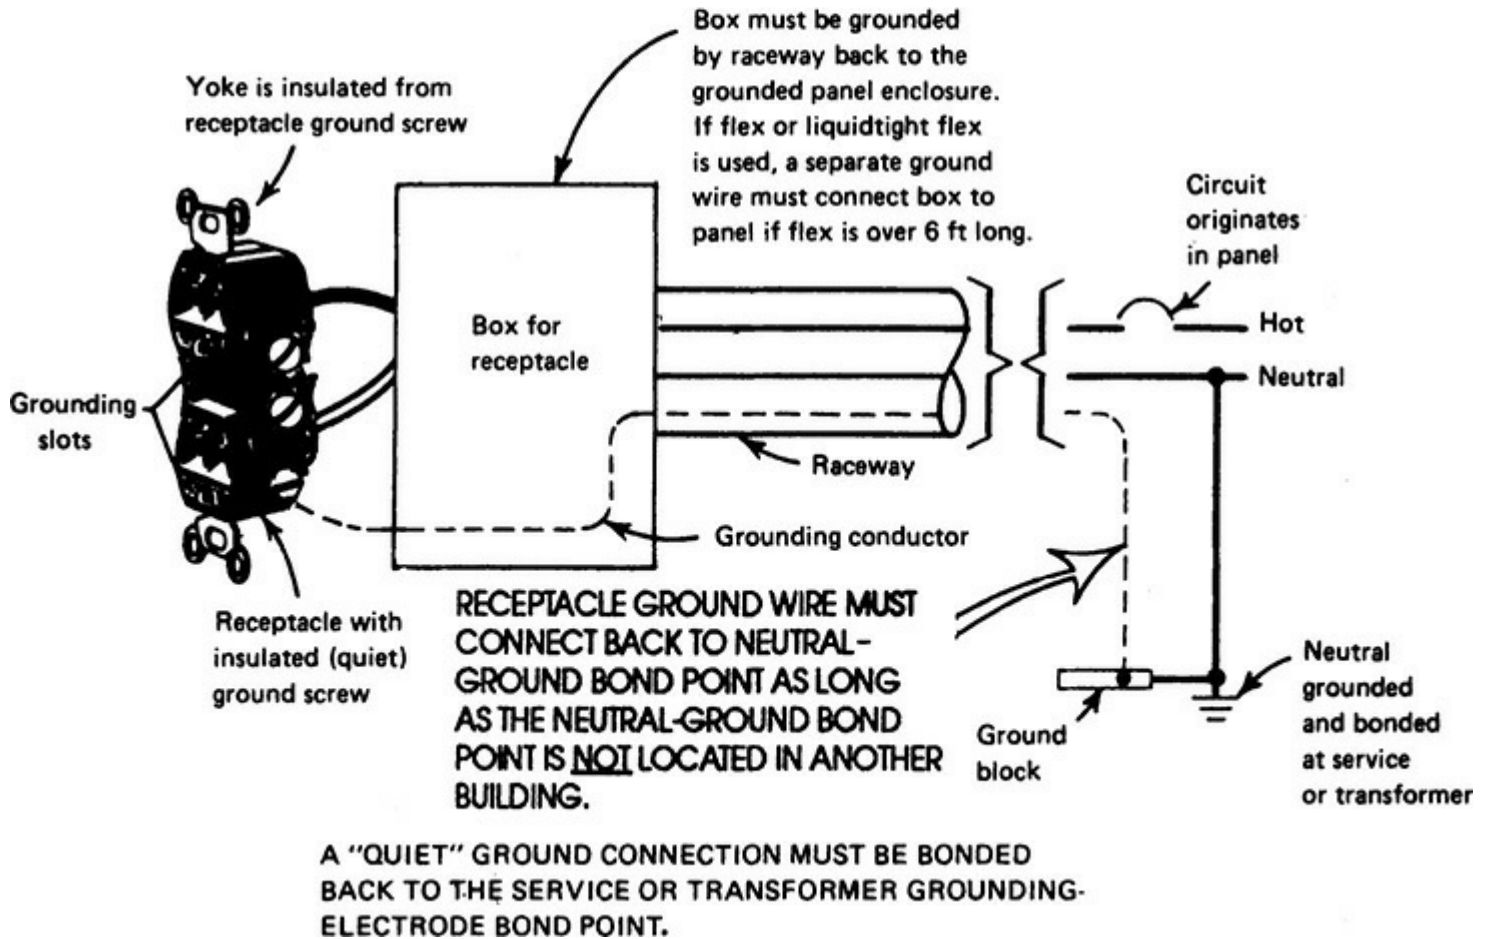

Fig. 250-110. Receptacles with isolated ground terminal are used with "clean" or "quiet" ground. (Sec. 250.146.)

The last sentence of part (D) permits an equipment grounding conductor from the insulated (quiet) ground terminal of a receptacle to be run, unbroken, all the way back to the ground terminal bus that is bonded to the neutral at the service equipment or at the secondary of a step-down transformer—but in no case may the isolated ground extend beyond the building in which it is used. That is, it must be bonded to a ground bus within the building it is run in, even if the "service equipment" is located in another building. Or the equipment grounding conductor may be connected to any ground bus in an intermediate panelboard fed from the service or transformer. *But*, the important point is to be sure the insulated ground terminal of the receptacle does tie into the equipment ground system that is bonded to the neutral.

This rule must be observed very carefully to avoid violations that have been commonly

encountered in the application of branch circuits to computer equipment—where manufacturers of computers and so-called computer power centers specified connection of “quiet” receptacle ground terminals to a grounding electrode that is independent of (not bonded to) the neutral and bonded equipment ground bus of the electrical system. This practice developed to eliminate computer operating problems that were attributed to “electrical noise.” Such isolation of the receptacle ground terminal does not provide an effective return path for fault-current flow and, therefore, constitutes a hazard.

Any receptacle grounding terminal (the green hex-head screw)—whether it is the common type with the mounting yoke or the type insulated from the yoke—must be connected back to the point at which the system neutral is bonded to the equipment grounding terminal and to the grounding electrode, thereby providing the “effective ground-fault current path.” That common (bonded) point may be at the service equipment (where there is no voltage step-down from the service to the receptacle), or the common neutral-equipment-ground point may be at a panelboard fed from a step-down transformer (as used in computer power centers).

When an isolated ground connection is made for the receptacle ground terminal, the box containing the receptacle must be grounded by the raceway supplying it and/or by another equipment grounding conductor run with the circuit wires. And those grounding conductors must tie into the same neutral-equipment-ground point to which the receptacle isolated ground terminal is connected. The equipment grounding conductor that actually lands on the grounding terminal of the receptacle, in addition to passing through intervening panels without joining with other equipment grounding conductors, is also permitted (2008 **NEC** clarification) to pass through intervening boxes and other enclosures, also without bonding at those intermediate points. This was always implied in the rule but it is now expressly stated.

See comments that follow 408.40, Exception.

250.148. Continuity and Attachment of Equipment Grounding Conductors to

Boxes. The basic rule requires that if circuit conductors enter a box and get spliced or terminated on equipment in or supported by the box, all equipment grounding conductors *associated with those conductors* must be connected as well, in accordance with five specific provisions (below). This wording means that when wires pass directly through a box, there is no requirement to break the continuity of any of the conductors. Of course, that does not relieve the requirement to connect the box to an equipment grounding conductor as required by 314.4. However, if a box is connected to a metal raceway, there is no reason to interrupt the continuity of the unbroken conductors. In addition, there is no reason to break the continuity of any equipment grounding conductors associated with circuit conductors that are unbroken in a box, even if conductors on or associated with a different circuit are spliced or terminated with the box and therefore subject to the five rules that follow:

Part **(A)** requires that all connections and splices meet 110.14**(B)**, except that insulation is not required.

Part **(B)** requires that the grounding connections in a box be arranged so removing a device or other piece of equipment will not interrupt the continuity of the equipment grounding conductor to any other loads on the branch circuit. As a practical matter this means using pigtail connections so the grounding connection to any item can be released with the splice still intact.

Part **(C)** requires that for a metal box, a connection must be made between the one or more equipment grounding conductors that enter in association with conductors that are spliced or terminated (and that are subject to these five rules) and also a connection must be made between them

and the box itself, using a grounding screw that is used for no other purpose, or other equipment or device listed for grounding.

Part (D) requires that equipment grounding conductors entering a nonmetallic box be arranged so a grounding connection can be made to any item in the box that requires the use of a grounding connection.

Part (E) forbids the use of connections that depend solely on solder.

Many issues follow from Part (C) above, beginning with the fact that grounding conductors in any metal box (for which the associated ungrounded conductors are spliced or terminated) must be connected to each other and to the box itself. [Figure 250-111](#) shows a method of connecting ground wires in a box to satisfy the letter of 250.148(C). Note that the two ground wires are solidly connected to each other by means of a crimped-on spade-tongue terminal, with one of the ground wires (arrow) cut long enough so that it is bent back out of the crimp lug to provide connection to the green hex-head screw on a receptacle outlet (if required by 250.146). The spade lug is secured firmly under a screw head, bonding the lug to the box. Of course, the specific connections could be made in other ways. For instance, the ground wires could be connected to each other by twist-on splicing devices; and connection of the ground wires to the box could be made by simply wrapping a single wire under the screw head or by connecting a wire from the splice connector to an approved grounding clip on the edge of the box ([Fig. 250-112](#)).

Fig. 250-111. Both ground wires are solidly bonded together in the crimped barrel of the spade lug, which is screwed to the back of the metal box. (Sec. 250.148.) Note that length of the branch-circuit equipment grounding conductors in this photo are probably less than 6 in. long from cable sheath to

the lug. This would violate 300.14, which, contrary to widespread belief, applies to all conductors entering a box including equipment grounds.

In all the drawings here, connection to the box is made either by use of a screw in a threaded hole in the side or back of the box or by an approved ground clip device which tightly wedges a ground wire to the edge of the box wall, as shown in [Fig. 250-113](#). Preassembled pigtail wires with attached screws are available for connecting either a receptacle or the system ground wire to the box.

Approved grounding clip will satisfy bonding connections specified in 250.146 and 250.148

Approved grounding clip bonds grounding wire to box

Grounding wires spliced together w/approved connectors

Grounding wire bonded to box w/screw used solely for connecting such wire

NM cables w/gr. wire

250.146. Typical method of bonding at flush-type metal boxes used to support grounding-type recept.

Fig. 250-112. All these techniques bond the ground wires together and to the box. (Sec. 250.148.)

Installation of grounding clip.

Fig. 250-113. Ground clip is “identified” for use as called for by 110.14(B). (Sec. 250.148.) Note that the length of free equipment grounding conductor shown here is likely less than 150 mm (6 in.) and therefore in violation of 300.14. Contrary to widely held opinion, nothing in the wording of 300.14 limits it to current-carrying conductors; it applies equally to equipment grounding conductors.

Figure 250-114 shows connection of two cable ground wires by means of two grounding clips on the box edges (arrow). In the past, such use has been disallowed by some inspection authorities because the ground wires are not actually connected to each other but are connected only through the box. The text “... between the one or more... and a metal box by means of... equipment listed for grounding ...,” however, permits such practice as long as the clips are listed for grounding.

Fig. 250-114. Each ground wire is connected to the metal box by a ground clip (one on each side at arrows). The first sentence of 110.14(B) permits ground wires to be “spliced or joined” by use of ground clips or ground screw terminals in the box. (Sec. 250.148.)

Fig. 250-115. This clearly violates 250.148(C) because the screw is also used to anchor the cable clamp. (Sec. 250.148.)

Figure 250-115 shows another method that has been objected to as clear violation of **NEC** 250.148(C) which requires that a screw used for connection of grounding conductors to a box “shall be used for no other purpose.” Use of this screw, simultaneously, to hold the clamp is for “other purpose” than grounding. Objection is not generally made to use of the clamp screw for ground connection when, in cases where the clamp is not in use, the clamp is removed and the screw serves only the one purpose—to ground the grounding wires.

The exception to this rule eliminates the need for connecting an isolated grounding conductor to all other grounding conductors.

250.164. Point of Connection for Direct-Current Systems. On a 2- or a 3-wire dc distribution system, a neutral that is required to be grounded must be grounded at the supply station only.

As noted in part **(B)**, an on-site supply for a dc system must have a required grounding connection made at either the source of the dc supply or at the first disconnect or overcurrent device supplied. Because the basic rule says a dc source (from outside a premises) must have a required grounding connection made at “one or more supply stations” and *not* at “any point on premises wiring,” an on-site dc source would be prohibited from having a grounding connection that might be required. This rule resolves that basic problem by referring to a “dc system source ... located on the premises.”

250.166. Size of the Direct-Current Grounding Electrode Conductor. [Figure 250-116](#) is a diagram of a balancer set used with a 2-wire 230-V generator to supply a 3-wire system as referred to in 445.12(D) and covered by part **(A)** of this section. These rules require the grounding electrode conductor to be no smaller than the neutral if there is a balancer set or balancer winding and not smaller than 8 AWG copper or 6 AWG aluminum. Otherwise the grounding conductor must be as large as the largest conductor supplied by the system. This rule is applicable to solar photovoltaic sources among other places. The rules also incorporate the special electrode sizing applicable to the same specific electrodes called out in 250.66, and with the same wire sizes specified. The 2014 **NEC** further correlated these requirements and Table 250.66 by setting 3/0 copper or 250 kcmil aluminum as the largest grounding electrode conductors required for dc systems.

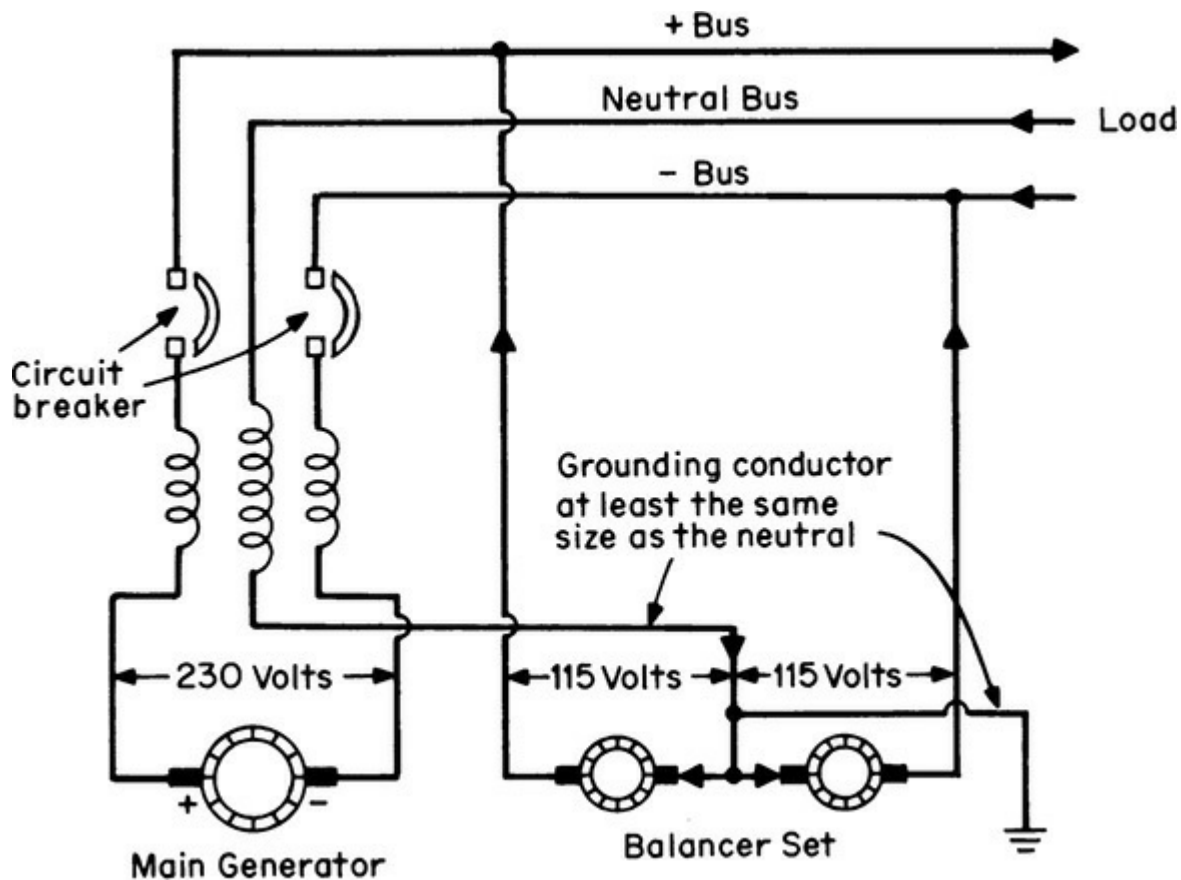

Fig. 250-116. Sizing a dc system grounding conductor. (Sec. 250.166.)

250.167. Direct-Current Ground-Fault Detection. This section is new as of the 2014 NEC. DC systems that are ungrounded must be equipped with ground-fault detection, and those that are grounded are permitted to use it. They must be marked at their source of first disconnecting means as to the type of grounding system that is applicable. An informational note points to the 2012 edition of NFPA 70E as a source of information about the four applicable grounding types.

The four grounding types listed in the Informational Note attached to Sec. 320.3(C)(2) in the 2012 edition of that standard are:

- (1) Type 1. Ungrounded dc usually equipped [and now NEC mandated] with ground detection alarms.
- (2) Type 2. Solidly grounded dc with either the most positive or most negative pole grounded; ground detection not typically deployed.
- (3) Type 3. Resistance grounded dc; a fault enables activation of an alarm and a second fault may result in a short circuit.
- (4) Type 4. Solidly grounded dc at a center point; a ground fault on either polarity can result in a short circuit, and ground-fault detection is not typically deployed.

250.184. Solidly Grounded Neutral Systems. Figure 250-117 shows the details of this set of rules. This section does permit a neutral conductor of a solidly grounded “Y” system to have insulation rated at only 600 V, instead of requiring insulation rated for the high voltage (over 1000 V). It also points out that a bare copper neutral may be used in such systems for service-entrance conductors or for direct buried feeders, and bare copper or copper-clad aluminum may be used for overhead sections of outdoor circuits.

Solidly grounded neutral conductor must have insulation rated for at least 600 volts, although a bare copper neutral may be used for SE conductors or for direct-buried feeders, and bare copper or aluminum may be used for overhead parts of outdoor circuits.

Fig. 250-117. Neutral of high-voltage system generally must be insulated for 600 V. (Sec. 250.184.)

250.186. Grounding Service-Supplied Alternating-Current Systems. This section is new as of the 2014 **NEC**. This section is a medium-voltage counterpart to Sec. 250.24(C) and is intended to assure a low impedance path, wherever this would be reasonably possible, for returning fault current by requiring that a grounded circuit conductor of some description [refer to the two possibilities covered in (A) and (B) below] is solidly connected at the service equipment. Part (A) covers distributions with a grounded conductor at the service point. In this case 250.184 will still apply, and in accordance with 250.184(A)(2) the minimum neutral ampacity will depend on the load profile but never less than one-third or one-fifth of the ampacity of the phase conductors, depending on engineering supervision. This new section sets a different floor based on fault return performance, one that can be higher but never less than the minimum size required to service the load. Both calculations will need to be completed, because the worst case will vary and is not obvious. For a single raceway or overhead run, this minimum sizing depends on whether the service is configured as a single run or in parallel. A single run follows the usual rules in 250.102(C)(1). If the service entrance wiring is made up in parallel, whether overhead or underground, the grounded conductor shall also run in parallel, with the size in each run also figured on the usual 250.102(C)(1) process, but based on associated ungrounded conductor sizes in that run, and never smaller than 1/0. As in the case of 250.24(C), an identically worded exception allows for multiple disconnecting means within an appropriately listed assembly. Rounding out the picture, a corner-grounded delta connected service mirrors 250.24(C)(3), with the grounded conductor at least equal in size to its ungrounded partners, and an impedance-grounded system neutral is sized, for medium voltage, in accordance with 250.187.

Part (B), covering distributions without a grounded conductor at the service point, does not have a direct 250.24(C) counterpart, and this makes it more interesting. Note, however, that even this part contains the wording “is grounded at any point” in its first sentence. Even the **NEC** Committee cannot make a completely ungrounded system grounded. The substantiation on this point concludes with the following sentence, that puts this in a reasonable perspective: “Where a utility does not provide a neutral conductor there is generally a static line or other ground fault return path where the supply side bonding jumper can be connected to, completing the return circuit.” That statement is

undoubtedly correct. The sizing and routing requirements for the grounding conductor installed under this part are completely identical to those in (A), the only difference being the identity of the wire. This conductor is not a grounded conductor, it is a supply-side bonding jumper. Left entirely unanswered in this new section is the insulation level to be applied to this wiring. Presumably the rules in 250.184(A)(1) would be the place to start.

250.187. Impedance Grounded Neutral Systems. Medium-voltage systems are often grounded using the neutral point of a wye connection and connecting it to a grounding electrode through an impedance. There are two general types of systems, generally described as either high or low impedance. The high impedance systems operate in a similar manner as those described at 250.36. The low impedance systems use a much lower impedance that is not intended to keep the system running, but instead allows for orderly and prompt operation of circuit protective devices while the destructive effects of the fault are greatly diminished, allowing for less extensive repairs. The neutrals on such systems are insulated based on the maximum neutral voltage that would be encountered, which is $\frac{1}{2}\sqrt{3}$ or 58% of the line-to-line voltage.

250.190. Grounding of Equipment. All noncurrent-carrying metal parts of equipment, housings, and enclosures must be grounded, including associated fences and supporting structures. The exception covers equipment isolated from ground and placed so it would be impossible for anyone in contact with the ground to touch such metal parts when the equipment is energized. This correlates with 250.110 Exception No. 2 that exempts wooden-pole-mounted distribution equipment that is over 2.5 m (8 ft) high from the usual equipment grounding requirements.

Part (B) requires that if a grounding electrode conductor is installed and connects noncurrent-carrying metal parts to ground, it must be sized in accordance with Table 250.66 as applies to such conductors generally. Enter the table using the size of the largest associated ungrounded conductor at that location, with a minimum size of 6 AWG (or 4 AWG for aluminum).

Part (C) covers equipment grounding conductors. The first paragraph requires that equipment grounding conductors that are not an integral part of a cable assembly must be no smaller than 6 AWG copper or 4 AWG aluminum. This requirement establishes the usual size of conductor that will be installed routinely in the field for transformer vaults, switchboards, and at other medium-voltage cable termination locations to make the required grounding connections to medium-voltage cable shielding.

The second paragraph covers shielded cables. Shielding is normally used to confine the voltage stresses to the insulation, thereby avoiding damage from corona discharge. However, limited permission is granted for the use of shielding to function as an equipment grounding conductor. A concentric neutral type of arrangement with the collective size of the concentric conductors, if collectively equalling or exceeding the sizing rule in the third paragraph, is generally acceptable. Only on systems that are grounded through an impedance, or ungrounded, metallic tape or drain wire insulation shields are permitted for equipment grounding, provided the shield is rated for the clearing time of the ground-fault current protective device.

The third paragraph incorporates the equipment grounding conductor sizing table in 250.122, but applies it to the current rating of the upstream fuse or the setting of the protective relay, as applicable. An informational note points out that medium-voltage circuit breakers use current transformers and a protective relay to actuate; combining the current pickup setting with the CT winding ratio determines the actual breaker current setting.

250.194. Grounding and Bonding of Fences and Other Metal Structures. This

section is new as of the 2014 **NEC**. It provides prescriptive requirements that will be extremely useful with respect to addressing a very common construction feature of outdoor medium-voltage substations, particularly those with “exposed electrical conductors and equipment.” These fences and other metal structures must be arranged so step, touch, and transfer voltages are limited. Refer to the coverage in this book of these voltages at Sec. 682.33. Transfer voltage is, in effect, a special case of touch voltage; it refers to instances where a metallic conductor entering or leaving a substation and connected to its grounding system sees the entire ground potential rise during a fault condition.

In all cases, the requirements reference, directly or indirectly, connects to “the grounding electrode system.” These systems depend on careful engineering because they must go far beyond any conventional prescriptive requirements in the **NEC** in order to address applicable voltages, soil resistivity, and potential influences of other conductive elements of the electrical distribution system. However, when that system is established, the requirements in this new section are comparatively easy to apply and inspect.

ARTICLE 280. SURGE ARRESTERS, OVER 1 KV

280.1. Scope. This article provides rules and regulations covering the application of “surge arresters” or, as they are more commonly known, “lightning arresters.” Here, as stated the Code provides general, installation, and connection requirements for lightning equipment and systems (Fig. 280-1). The major change as of the 2008 **NEC** is that this article now only applies to over 1 kV applications. All other applications at conventional utilization voltages have been transferred to Art. 285.

Fig. 280-1. Surge (lightning) arresters in an electric substation serving an industrial plant are

commonly used in areas where lightning is a problem. (Sec. 280.1.)

Figure 280-2 shows a lightning arrester used on one of several high-voltage circuits serving the heavy electrical needs of a modern sports stadium.

Fig. 280-2. Lightning arrester (arrow) is a typical “surge arrester” and, where used, one arrester must be connected to each ungrounded circuit conductor—such as shown here for a 2400-V grounded circuit supplying a transformer for stepping voltage down to supply lighting at this athletic stadium. (Sec. 280.3.)i

280.3. Number Required. A double-throw switch which disconnects the outside circuits from the station generator and connects these circuits to ground would satisfy the condition for a single set of arresters for a station bus, as covered in the second sentence of this section.

280.4. Surge Arrester Selection. Figure 280-3 shows the position of a choke coil where it is used as a lightning-protection accessory to an arrester.

Fig. 280-3. Using a choke coil as an accessory to an arrester. (Sec. 280.4.)

In 280.4(B), ratings of surge arresters are covered by the basic rule that applies to silicon-carbide-type surge arresters with an informational note pointing up the difference in voltage rating of metal-oxide-varistor-type arresters. This addresses the high-technology operating nature of the metal-oxide surge arrester as applied to premises wiring systems. The concern is to make an effective distinction between gapped silicon-carbide arresters, widely used in the past, and the newer metal-oxide block arresters. Manufacturers' application data on rating and other characteristics and the minimum duty-cycle voltage rating of an arrester for a particular method of system grounding must be observed carefully.

280.12. Uses Not Permitted. A surge arrester must only be installed in a location where the voltage rating of the arrester is at least equal to the maximum available continuous voltage to ground at the available frequency.

280.14. Routing of Surge Arrester Grounding Conductors. This rule is particularly important because bends and turns enormously increase the impedance to lightning discharges and therefore tend to nullify the effectiveness of a grounding conductor.

280.24. Interconnections. These rules are aimed at ensuring more effective lightning protection of transformers. Lightning protection of a transformer cannot be provided by a primary arrester that is connected only to a separate electrode. Common grounding of gaps or other devices must be used to limit voltage stresses between windings and from windings to case.

280.25. Grounding Electrode Conductor Connections and Enclosures. This section refers to Art. 250, which also covers connection of lightning arresters. The second sentence covers the need to keep grounding conductors electrically in parallel with their enclosing metal raceway. For instance, assume that a lightning arrester is installed at the service head on a conduit service riser, with the grounding conductor run inside the service conduit, bonded to the meter socket at the grounding lug, then run through a hole in the meter socket to the grounding electrode without a metal enclosure from the drilled hole to the electrode. In such a hookup, this rule requires the grounding conductor to be bonded to the conduit at the service head (Fig. 280-4). Ordinarily, the meter enclosure has a threaded hub, which would mean the conduit would be in good electrical contact with the meter enclosure and would be bonded at the meter socket end. However, 280.25 requires that the grounding conductor, if in a metallic enclosure, be bonded at both ends. Therefore, bonding at the service head is necessary.

Fig. 280-4. Arrester grounding conductor must be bonded to both ends of enclosing metal raceway (or other enclosure). (Sec. 280.25.) Since surge arresters now only apply to installations over 1 kV; this drawing probably shows a surge protective device covered in Art. 285, however, it correctly illustrates the concept of the rule.

The reason given for putting that rule in the **NEC** was explained as follows:

When conducting lightning currents, the impedance of a lightning arrester grounding conductor is materially increased if run through a metallic enclosure, especially if of magnetic material. The voltage drop in this impedance may be sufficient to cause arcing to the enclosure, and in any event it reduces the effectiveness of the lightning arrester. Bonding of the conductor to both ends of the enclosure is necessary to eliminate this detrimental effect where metallic enclosures are used.

ARTICLE 285. SURGE-PROTECTIVE DEVICES, 1 KV OR LESS

285.1. Scope. The term “surge-protective device” (SPDs) is now, as of the 2008 **NEC**, the term of art for devices that shunt voltage spikes to ground. At one time the term was “lightning arrester” but, effective with the 1981 **NEC**, the terminology changed to “surge arrester” in recognition that voltage surges had many origins in addition to lightning. The next step occurred in the 2002 **NEC**, when a new article recognized “transient voltage surge suppressors” in addition to surge arresters. These devices were normally located on the load side of the service equipment, but could be on the line side if special arrangements were made. This has now changed, and the terminology “surge arrester” is now reserved for medium-voltage (over 1 kV) applications exclusively. The term “surge protective device” covers the entire installation spectrum for 600 V and lower applications.

285.3. Uses Not Permitted. SPDs may not be used on circuits exceeding 600 V or ungrounded electrical systems unless specifically listed for these connections. That is, if the system in question does not have one of its circuit conductors intentionally connected to earth, such as with a 480-V, ungrounded delta system, then use of surge suppressors is prohibited unless specifically listed for ungrounded systems. The same limitation applies to the use of these devices on high-impedance grounded systems, or on corner-grounded delta systems. In addition, an SPD must never be applied at a point where its rating is less than the maximum continuous phase-to-ground voltage using the available power frequency at the point of application.

285.6. Listing. Surge protective devices must be listed products for **NEC** applications.

285.7. Short-Circuit Current Rating. Care must be taken when installing SPDs to ensure that the device, which is required to be listed by 285.5, has a listed fault-current rating that is at least equal to the fault current available at the point in the distribution system where it is installed. This rule doesn't apply to receptacles.

285.12. Routing of Connections. As in the case of surge arresters running over 1 kV, this rule is particularly important because bends and turns enormously increase the impedance to lightning discharges and therefore tend to nullify the effectiveness of a grounding conductor.

285.13. Type 4 and Other Component Type SPDs. This section, new as of the 2014 **NEC**, clarifies that Type 4 surge protective devices along with other component-type protection are not appropriate for field installation; they are to be installed by a manufacturer only as a component of some other product.

285.21. Connection. As given in Secs. 285.23, 285.24, and 285.25, which cover permitted application locations of specific SPDs, such devices may be installed on the load side of the service OC protection, the load side of the OC protection at a main building disconnect, or on the load side of the first OC device fed from a separately derived system. Take care to find and use appropriate termination methods for the conductors from these devices. Particular attention must be paid to the requirement in 110.14(A) that terminals for more than one conductor must be so identified. The frequent practice of shoving the leads from an SPD into the lugs of a main circuit breaker along with the principal circuit conductors will not comply with any known listing recognition for such a combination of conductors. Installation of such devices at other locations would constitute a violation of this rule.

The **NEC** recognizes three types of surge protective devices as suitable for field installations. Type 1 devices correspond to the old surge arresters and are suitable for installation on the line side of the service equipment. Type 2 devices can be installed at any point on the load side of a service disconnect. They are also permitted on the load side of the first overcurrent device in a building or other structure supplied by a feeder. When special arrangements are made for overcurrent protection, these devices can also go on the line side of the service. Type 3 devices, the least robust, are permitted only on the load side of branch circuit protective devices and with the further restriction that they are at least 30 ft, measured along the conductors, from the service or local feeder disconnect for the building. The 2008 **NEC** imposed this limitation generally. However, some manufacturers are testing them to Type 2 tolerances and the distance restriction need not apply. For the 2011 and subsequent editions of the **NEC**, if and only if the restriction does apply, then the installation instructions will contain this limitation.

Chapter Three

ARTICLE 300. GENERAL REQUIREMENTS FOR WIRING METHODS AND MATERIALS

300.1. Scope. Part (A) of this section indicates that the rules of Art. 300 apply to all installations of the wiring methods covered by this article and the remainder of [Chap. 3](#). As is generally the case, clearly not all the general requirements in Art. 300 apply to specialized installations, such as remote-control circuits, to signal circuits, to low-energy circuits, to fire-protective signaling circuits, and to communications systems. The wording “unless modified by other articles” is intended to convey that idea.

Part (B) establishes what amounts to the boundary line between the **NEC** and UL or other equipment testing labs, at least with respect to this article, which has no “construction” part. In fact, the **NEC** contains requirements throughout that are effectively aimed at the equipment manufacturers, in the process of setting policy around how products need to perform in order to be used safely, based on a consensus vote of a Code-making panel (CMP). For only one of countless examples, the reason there is foam-core (“nonhomogeneous”) PVC conduit available is that a Code-making panel voted it in [352.10(G)], but then (for one cycle) also limited its use to underground applications. The reason that UL, with well-earned pride, points to its representation on all the Code-making panels is that it is then in a position to make sure that its product standards correctly implement the policy decisions reached through the **NFPA** consensus process. This rule clearly states that there is no intent, or permission, to apply Code rules within Art. 300 to the interior wiring of equipment to be connected. That is the province of the testing labs. If a product is “listed,” it has been tested and found to be essentially free from hazards. Generally, the equipment is tested for use in accordance with the Code, which includes any Code-prescribed construction or performance requirements.

In part (C) of this section, a table is provided to allow proper selection of standard trade size raceways and tubing whether applying the Code in the United States or abroad. Simply determine the needed raceway size, in either system, and use Table 300.1(C) to establish the correct metric or English system size equivalent. The table also establishes that the dimensions are not real dimensions, but only to be used for identification purposes. Generally throughout this book, we are following the **NEC** style, and therefore if we are referring to what is known on the street as “3-in. conduit” we refer to it here, in the customary **NEC** practice of listing the metric size first and the English unit following in parentheses, as “metric designator 78 (trade size 3) conduit.”

300.3. Conductors. Part (A) requires that single conductors described in Table 310.104(A) must be used only as part of one of the wiring methods covered in [Chap. 3](#). This basically means that the various insulated conductors recognized in Table 310.104(A) may not simply be strung overhead, without benefit of being incorporated into a cable assembly or otherwise protected and supported by

conduit or tubing. The exception to part **(A)** recognizes the permission given in 225.6, where individual conductors *are* permitted to be run as “open conductors” in overhead feeders and branch circuits installed outdoors, as well as in festoon lighting.

Part **(B)** requires that all conductors of the same circuit—including the neutral and all equipment grounding conductors—must be run in the same raceway, cable tray, trench, cable, or cord. Part **(B)(1)** recognizes the use of separate raceways and cables, where circuits are made up of multiple (two or more) sets of conductors or cables in parallel. The exception that follows correlates with 300.5(I) Exception No. 2 for isolated phase installations. Part **(B)(2)** in that rule notes those very specific and unusual sections of the **NEC**, where an equipment grounding conductor may be run separately from the other conductors of the circuit such as for dc circuits and for retrofits under the provisions of 250.130(C).

Part **(B)(3)** requires taking steps to prevent induced currents where nonmetallic or nonmagnetic sheathed conductors are run through metallic enclosure walls with magnetic properties as covered in 300.20(B). The second sentence gives a similar warning for Type MI cables and references 332.31, which addresses the concern for induced currents. Both of those other rules discuss methods for preventing induced currents.

Part **(4)** of 300.3(B) permits limited use of a pull box equipped with a terminal block for the connection of the system neutral, as the point of origin for branch-circuit neutral conductors. That is, a properly sized neutral is run to the pull box—which is connected by an auxiliary gutter to a column-width panelboard—from the panelboard, and the individual branch-circuit neutrals may be run from the pull box and need not go back to the panelboard where the hot conductors originate. This saves space within the panelboard, but is only permitted for column-width panelboards connected by an auxiliary gutter to a pull box that is manufacturer-equipped with a neutral terminal block. Note that there is no inductive heating in this arrangement and it is arguably permitted even without this permission. Every ampere that comes up the auxiliary gutter from the panel on a branch-circuit conductor is equaled by an ampere of current moving down the same gutter space to the panel over one of the feeder conductors.

Part **(C)** covers system separations under ordinary conditions. The first topic is conductors operating on different voltages, but not over 1000 V. This rule clearly allows conductors of different voltage systems, and whether dc or ac, to occupy the same raceway, cable assembly, or enclosure. The only limitation here is that all the conductors must be insulated for the maximum voltage that will be present in the common location. For example, nonpower-limited 6-V circuit conductors running to a valve motor can run in the same raceway as 277-V circuit wiring to a duct heater, if both sets of conductors have 600-V (technically 277-V) insulation.

This brings up [Fig. 300-1](#). Whoever wired this furnace must have read this section, because when he wanted to get his 24-V thermostat circuit neatly down to the burner control, he carefully ran 600-V THHN down the EMT riser along with the 120-V circuit for the burner motor, making the transition to thermostat wire where the THHN poked out of the upper end of the riser. A nice neat job, and a serious Code violation. The thermostat circuit is a Class 2 power-limited circuit, covered under the enhanced system separation rule found in 725.136(A). This comes up so often that the **NEC** now has a note at this location. A Class 2 circuit is a *special condition*, covered in [Chap. 7](#) of the **NEC**. As such, the rules in [Chap. 7](#) automatically supersede or modify information in [Chaps. 1](#) through [4](#) of the **NEC**, as per 90.3. And for Class 2 wiring, it is forbidden to ever rely on insulation alone to define a

circuit separation. These systems are presumed to be incapable of fire and electrocution hazard by virtue of the limitations built into their power supplies and the only way to be really sure of this is to keep them out of common raceways and enclosures, except under extremely well-controlled situations. There is even a special exception to the rule forbidding cables to be attached to electrical raceways [300.11(B)(2)] that allows the Class 2 wiring to be attached to the outside of the raceway, and that would have been the way to wire the oil burner in [Fig. 300-1](#).

Fig. 300-1. The 14 AWG THHN leaving the box from the EMT riser and connected to 18-2 thermostat wire for a 24-V Class 2 circuit does comply with 300.3(C)(1), but violates 725.136(A).

The second informational note here reminds users that photovoltaic source and output circuits are prohibited by 690.4(B) from sharing enclosures or raceways unless they are contained within a separately partitioned area. There are other **NEC** rules that require circuit separation, notably including 700.10(B) for emergency circuits and 695.6(A)(2)(a) for fire pump supply conductors, so these two notes do not begin to cover the subject.

Part **(C)(2)** of 300.3 states that conductors operating at more than 1000 V must not occupy the same equipment wiring enclosure, cable, or raceway with conductors of 1000 V or less. There are four conditions where this can be relaxed; however, note that none of these involve a common raceway. Raceways remain fully segregated, but there are limited applications where having both systems in a common enclosure is essential. Part **(C)(2)(b)** is intended to apply to enclosures, not raceways, such as used for high-voltage motor starters, permitting the high-voltage conductors

operating at over 600 V to occupy the same controller housing as the control conductors operating at less than 600 V (Fig. 300-2).

300.3 (C) (2) PROHIBITS THIS —

BUT, SUBPART (4c) IN THAT RULE PERMITS THIS—

1. For any **individual** motor or starter—excitation, control, relay and/or ammeter conductors operating at 600 volts or less **may** occupy the same **starter or motor enclosure** as the conductors operating at over 600 volts.
2. Any **raceway** containing conductors operating at over 600 volts **may not** also contain **any** conductors operating at 600 volts or less.

Fig. 300-2. Control wires for high-voltage starters may be used in the starter enclosure, but not in *raceway* with power conductors. (Sec. 300.3.)

Note that the former 600-V parameter has been routinely changed to 1000 V as of the 2014 **NEC**. In large part, this change has been driven by increased voltages in photovoltaic systems, and the changes here follow the global revisions throughout [Chap. 3](#) (and the large majority of other **NEC** locations), as covered in 300.2(A). This paragraph [(C)(2)] is a case in point; it used to have five enumerated conditions, the first of which addressed 1000-V secondary wiring to electric discharge lamps. Since the voltage went up generally to 1000 V, that item became superfluous in this location and it was relocated as a second paragraph to (C)(1).

The last sentence in part (C)(2) is intended to prohibit unshielded conductors (now limited by 310.10(E) to 5 kV) from occupying the same enclosure, raceway, or cable, unless the actual voltage carried is the same. Now that the allowable voltage for unshielded conductors has been reduced from 8 kV, the application of this in new construction is limited, but there are a lot of higher voltage unshielded conductors still in use. Some feel that the normal voltage discharge and leakage current will be increased where a difference of potential exists between two unshielded conductors. It is theorized that the result of the increased discharge and leakage will be premature insulation failure. Although the assertion of premature failure has not been determined empirically, there is no data to suggest otherwise. Any problem can be avoided by simply complying with this requirement and using

separate raceway systems.

300.4. Protection Against Physical Damage. This rule presents a general requirement for ensuring that conductors, raceways, and cables are properly protected where “subject to physical damage.” Common sense must be applied and the normal operation of the facility in question must be considered. If it appears that, during normal operations, a given conductor or cable is likely to be damaged, then physical protection in the form of a raceway sleeve, an enclosure, kickplate, etc., must be provided. This requirement is a catchall. That is, the specific situations spelled out in the subsequent parts of 300.4 must be provided with the physical protection prescribed, under the circumstances described. But, in any other location where conductors or cables are exposed to damage, suitable remedies must be employed to satisfy this most basic requirement. The 2017 **NEC** added an informational note here advising that minor damage to cable sheaths is not necessarily a problem for the conductors within.

Part **(A)** gives the rules on protection required for cables and raceways run through wood framing members, as shown in [Fig. 300-3](#). Where the edge of a hole in a wood member is less than 1¼ in. (32 mm) from the nearest edge of the member, a 1/16 in. (1.6 mm) thick steel plate must be used to protect any cable or flexible conduit against driven nails or screws. The same protection is required for any cable or flexible conduit laid in a notch in the wood. But, as given in Exception No. 1, rigid metal conduit, electrical metallic tubing (EMT), intermediate metal conduit (IMC), and PVC conduits do not require such protection. And, Exception No. 2 allows for the use of steel plates that are less than 1/16-in. thick where the plate is “listed and marked” as providing “equal or better protection” from nails, etc.

If BX, NM cable, or raceway wiring (rigid conduit, EMT, etc.) is used through holes bored in joists, rafters or similar wood members. . .

. . . the holes should be (not a Code rule) at the approximate center of the face of the member

Cable (BX, NM, etc.) or flexible conduit may be run in notch in wood member, but a steel plate 1/16 in. thick must be used over notch to protect cable from nails, etc. But, a plate is not needed for rigid metal conduit, IMC, EMT, or PVC conduit.

For any raceway or cable wiring (BX, NM, etc.) through holes bored in studs, edge of bored hole must be not less than 1-1/4 in. from nearest edge of stud

. . . OR . . .

If hole is less than 1/4 in. from nearest edge, a steel plate 1/16 in. thick must be used to protect flexible conduit or cable against driven nails or screws . . . But a plate is not needed for rigid metal conduit, IMC, EMT, or PVC conduit.

Any cable and all raceways except IMC, rigid metal, rigid nonmetallic and EMT . . .

. . . must have minimum 1 1/4-in. clearance from both edges.

NOTE: If clearance is less than 1 1/4 in., a 1/16-in. thick steel plate or sleeve must be used to protect cable or raceway.

Wiring on structural members must have clearance for protection against nails.

Fig. 300-3. Holes in wood framing must not weaken structure or expose cable to nail puncture. (Sec. 300.4.)

Clearance must be provided from the edge of a hole in a wood member to the edge of the wood member. The **NEC** requires only 1¼ in. (32 mm). This permits realistic compliance when drilling holes in studs that are 3½ in. (89 mm) deep. It also was taken into consideration that the nails commonly used to attach wall surfaces to studs are of such length that the 1¼-in. (32-mm) clearance to the edge of the cable hole affords entirely adequate protection against possible penetration of the cable by the nail.

Figure 300-4 shows typical application of cable through drilled studs, with holes at centers and adequate clearance to the edge of the stud. Figure 300-5 shows an objectionable example of a drilled hole, violating the rule of part (2) of this section, which warns against “weakening the building structure.” Figure 300-6 shows an acceptable way of protecting cables run through holes in wood members.

Drilled holes at the center of the face of a joist do not reduce the structural strength of the joist.

Signal and alarm wiring is run through the same stud holes as the NM cables. The NEC does not prohibit use of more than one cable through a single hole.

Fig. 300-4. Holes or notches in joists and studs must not weaken the structure of a building. (Sec. 300.4.)

Fig. 300-5. Excessive drilling of structural wood members can result in dangerous notching (arrow) that weakens the structure, violating Sec. 300.4(A)(2). (Sec. 300.4.)

Fig. 300-6.. Steel plates are attached to wood structure member to protect cable from penetration by nail or screw driven into finished wall, where the edge of the cable hole is less than $\frac{1}{4}$ in. (31.8 mm) from the edge of the wooden member. (Sec. 300.4.)

In part **(B)**, the rules on installations through metal framing members apply to nonmetallic-sheathed cable and to electrical nonmetallic tubing (ENT). Part **(1)** of 300.4(B) applies to NM cable run through slots or holes in metal framing members and requires that such holes must always be provided with bushings or grommets installed in the openings before the cable is pulled. But that requirement on protection by bushings or grommets in the holes does not apply to ENT where run through holes in metal framing members. The grommet must encircle the entire hole; “V”-shaped grommets that are open at the top are not permitted for this purpose. The reason is that experience pulling cable into such holes has shown repeated instances where the cable rose up when under tension and the outer jacket was severely damaged.

Part **(2)** applies to both NM cable and ENT and requires that the cable or tubing be protected by a steel sleeve, a steel plate, or a clip when run through metal framing members in any case where nails or screws might be driven into the cable or tubing.

Part **(C)** requires cables and raceways above lift-out ceiling panels to be supported as they are required to be when installed in the open. They may not be treated as if they were being run through closed-in building spaces or fished through hollow spaces of masonry block.

Part **(D)** requires cables and raceways run along (parallel with) framing members (studs, joists, rafters), as well as furring strips, to have at least a $1\frac{1}{4}$ -in. (32-mm) clearance from the nearest edge of the member; otherwise, the cable or raceway must be protected against nail or screw penetrations by a steel plate or sleeve at least $\frac{1}{16}$ in. (1.6 mm) thick. The application of the 32 mm ($1\frac{1}{4}$ -in.) spacing rule to furring strips means that cables can be stapled across the lower edges of ceiling joists on a

furred ceiling, provided the cables are secured at least that distance away from the edges of the furring strips. In that way, an errant drywall screw won't bother the cable, as the rule intends. For conventional framing members, the distance applies from both the edges of the member, which makes a conventional 2 by 3 incapable of supporting a cable because at 2½ in. deep the prescribed distance from each face leaves no room for wiring. There are some products designed that stack cables at some distance from the framing, which may solve this problem.

Objections have been raised to this rule from the manufacturers of metal-clad cables (Types MC, AC, etc.) because actual tests have shown that these cables tend to roll out of the way of a screw, and are actually far more difficult to penetrate than rigid raceways. For similar reasons, proposals have also been made to relocate this rule into Art. 334 on nonmetallic sheathed cable, which is the wiring method most likely to be damaged. However, none of these attempts has succeeded over the years.

The rule applies in both exposed and concealed locations to most wiring methods, with two exceptions, with a third being the customary allowance for listed shielding plates to be of thinner steel than the default 1.6 mm ($\frac{1}{16}$ in.) thickness.

Exception No. 1 excludes IMC, rigid metal conduit, rigid nonmetallic conduit, and EMT from the rule. The rule will apply to Romex (Type NM), BX (Type AC), flexible metal conduit, ENT, Type MC cable, and all other cables and raceways, except those excluded by Exception No. 1. (see [Fig. 300-3](#), bottom). Exception No. 2 excludes from this rule concealed work in finished buildings and finished panels in prefab buildings, where cables may be fished.

Part (E), on wiring under roof decking, is new as of the 2008 **NEC** but was expanded and clarified in the 2011 **NEC**. It requires all wiring, whether cables or raceways (subject to an exception for rigid and for intermediate metal conduits) as well as boxes to be mounted far enough below "metal-corrugated sheet roof decking" so subsequent reroofing and repairs don't end up impaling the wiring with the long screws commonly used to hold down the new surface, as explained in the note. This change follows actual loss experience.

The text calls for 38 mm (1½ in.) spacing between the top of the wiring method (meaning nearest to the roof decking) and the "lowest" edge of the roofing (meaning nearest to an observer on the floor). This puts the wiring well below the lowest part of the corrugations, which is appropriate because subsequent roofing activities proceed blindly, with screws sized to penetrate to a bottom of a corrugation as easily as an upper portion. [Figure 300-7](#) shows how the clearances are to be measured. The 2011 **NEC** extended the coverage of this rule to include boxes, in addition to general wiring methods, and has also applied the prohibition to the concealed cavity between the decking and the roof membrane, as shown in [Fig. 300-7](#).

38 mm (1½ in.) required spacing applies to boxes as well as wiring methods, measured only from the lowest plane of the metal decking. NEC also prohibits concealed wiring above the decking.

Fig. 300-7.. This new (2008 **NEC**) rule to avoid damage from roof repair has been clarified and the clearance measurement is to be applied from the plane of the lowest surface of the roof decking. It also has been expanded to cover boxes and the concealed spaces above the decking. [Sec. 300.4(E).]

Although the exception waives the rule for installations using heavy-wall steel (rigid or intermediate) conduit, take care in using this exception. As previously noted, tests run by UL on a variety of wiring methods to determine their susceptibility to penetration under conditions covered by the related rules in 300.4(D) showed that even heavy wall conduits were no match for drill-point screws. Interestingly, only unrestrained steel-armored cables that could roll out of the way typically survived the testing, a result not reflected in the Code.

Part **(F)** presents protection requirements where cables are run in “shallow grooves.” This rule calls for the same $\frac{1}{16}$ in. (1.6 mm) thick steel kick plate, sleeving, or the equivalent. Alternately, one may locate the cable with at least $1\frac{1}{4}$ in. (32 mm) of “free space” for the cable’s entire concealed length. The “free space” is to be measured from the top of the groove to the top of the cable, not to the bottom of the groove. This rule is aimed at applications with exposed beam construction where grooves or channels are cut in the beams for supply conductors to lighting fixtures or ceiling fans.

Part **(G)** applies to all conductors of size No. 4 or larger entering a cabinet or box from rigid metal conduit, flexible metal conduit, electrical metallic tubing, and so forth. As indicated in 300.4(G), to protect the conductors from cutting or abrasion, a smoothly rounded insulating surface is required. While many fittings are provided with insulated sleeves or linings, it is also possible to use a separate insulating lining or sleeve to meet the requirements of the Code.

[Figure 300-8](#) shows use of a bushing with an insulated edge or a completely nonmetallic bushing to satisfy this rule. [Figure 300-9](#) shows an approved sleeve which may be used to separate the conductors from the raceway fitting, which may be installed after the conductors are already installed and connected.

Fig. 300-8.. An insulated-throat bushing or other protection must be used at enclosure openings. [Sec. 300.4(G).]

In the exception to 300.4(G), an insulated throat is not required for conductor protection on enclosure threaded hubs or bosses that have a rounded or flared entry surface. This is recognition of a long-standing reality—that there is no need for protective insulating material around the interior opening of integral hubs and bosses on equipment enclosures. Insulated-throat bushings and connectors are needed only for entries through KOs in sheet-metal enclosures.

The last paragraph of 300.4(G) prohibits use of a plastic or phenolic bushing (“wholly of insulating material”) as a device for securing conduit to an enclosure wall. On a KO, there must be a metal locknut outside and a metal locknut inside to provide tight clamping to the enclosure wall, with the nonmetallic bushing put on after the inside locknut. An EMT or conduit connector must also be secured in position by a metal locknut and not by a nonmetallic bushing. This paragraph also requires that any insulating bushing or insulating material used to protect conductors from abrasion must have a temperature rating at least equal to the temperature rating of the conductors.

It is important to remember that this is a rule that applies to wiring being pulled into raceways, and

therefore there is no requirement to put an insulating bushing on the end of an SE cable connector, for example. If an enclosure has a molded hub, it will be sufficiently rounded on the inside and no additional protection is required.

Part (H), new in the 2011 edition, requires the use of listed expansion or deflection fittings, or other approved methods, as required for the particular application when a raceway crosses a structural joint in a building or other structure that is intended to shift while in use. These joints are common in bridges and parking structures, where wide areas of concrete must be allowed to expand and contract due to temperature changes, and they are also applied in some designs to counteract the effects of earthquakes.

300.5. Underground Installations. This section is a comprehensive set of rules on installation of underground circuits for circuits up to 600 V. (Higher-voltage circuits must satisfy 300.50.) Table 300.5 in the Code book establishes minimum earth cover needed for specific conditions of use. [Figure 300-10](#) shows cover requirements for rigid metal conduit and IMC. [Figure 300-11](#) shows the basic depth requirements for the various wiring methods. In all instances, “cover” is *not the depth of the trench*. It is the depth of the trench plus the diameter of the wiring method, which equals *the amount of dirt on top of the wiring method* when the job is complete.

Fig. 300-9.. Slip-over nonmetallic sleeve may be used to cover metal bushing throat. [Sec. 300.4(G).]

Fig. 300-10. These are the details involved with the use of rigid metal conduit and IMC underground.

DIRECT-BURIED CABLES

RIGID METAL CONDUIT

INTERMEDIATE METAL CONDUIT

ELECTRICAL METALLIC TUBING (EMT)

RIGID NONMETALLIC CONDUIT

Conduit approved for burial
without concrete encasement

Fig. 300-11. These are the *basic* burial depths, but variations are recognized in Table 300.5 for certain conditions. (Sec. 300.5.)

Because Table 300.5 does not specifically mention EMT, it could be taken to indicate that the **NEC** does not recognize EMT for underground use. But 358.10(B) does recognize EMT for direct earth burial if “protected by corrosion protection and judged suitable for the condition,” and so does UL, with this stipulation: “In general, electrical metallic tubing in contact with soil requires supplementary corrosion protection.” Note that such protection is not literally mandatory in all instances, but it is close. The UL note means to indicate that EMT might be buried without a protective coating (like asphalt paint) where local experience verifies that soil conditions do not attack and corrode the EMT. On the other hand, UL does not evaluate supplementary corrosion protection on this product with respect to the corrosive influences of soils, so the inspector is on his own in choosing to permit this. Supplementary corrosion protection must always be applied unless there is a solid local record of positive experience, which is very unusual. On balance, EMT should not be used for direct burial. Refer to the more extensive discussion at 358.10 in this book for additional information on this point.

Figure 300-12 shows modifications of basic cover requirements. If a 2 in. (50 mm) thick or thicker concrete pad is used in the trench over an underground circuit other than rigid metal conduit or IMC, the basic burial depth in Table 300.5 may be reduced by 6 in. (150 mm). It should be noted that the intent here is for the concrete pad to be in the trench, right over the cable or raceway. The wording must be taken to mean that it may not be a walk or other concrete at grade level. And the burial depth may not be reduced by more than 6 in. (150 mm) no matter how thick the concrete pad is. This rule is at odds with Note 3 to Table 300.50, where burial depth for high-voltage circuits may be reduced “6 in. (150 mm) for each 2 in. (50 mm) of concrete” or equivalent protection in the trench over the wiring method (other than rigid metal or IMC). Remember this when installing underground runs of conductors and cables that are rated over 600 V. For those installations, compliance with 300.50, not 300.5, must be ensured.

Fig. 300-12. Concrete pad “in trench” permits what amounts to a 6-in. (150-mm) reduction of burial depth for circuits up to 600 V for other than RMC, IMC, and applications covered in column 5. (Sec. 300.5.)

Note that in Table 300.5, rigid metal conduit or IMC that is buried in the ground must have at least a 6 in. (150 mm) thick cover of earth or earth plus concrete—even if it has a 2 in. (50 mm) thick concrete pad over it. But rigid metal conduit, IMC, or other raceways may be installed directly under a 4 in. or thicker exterior slab that is not subject to vehicle traffic, without any need for earth cover. Given the fact that rigid metal conduit or IMC may be laid directly on the ground (which supports it for its entire length) and would not necessarily require any concrete cover, there is no reason why it cannot be laid on the ground or flush with the ground and covered with at least 4 in. (102 mm) of concrete. (See Fig. 300-10.)

Section 300.5 only applies to “underground installations” and is not applicable if the conduit is laid directly on the ground. No Code rule prohibits conduit laid on the ground, provided the conduit is “securely fastened in place” (300.13) and is not exposed to physical damage such as vehicular traffic, and many such installations have been made for years. But, when conduit is installed in the ground, there is serious concern about damage due to digging in the ground, which Sec. 300.5 addresses.

As shown in Fig. 300-13, Table 300.5 recognizes that raceways run under concrete slabs at least 4 in. (102 mm) thick or under buildings have sufficient protection against digging and are not required to be subject to the burial-depth requirements given in the top line of Table 300.5. Where raceways are so installed, the rule requires that the slab extend at least 6 in. (150 mm) beyond the underground raceway, as follows:

Fig. 300-13. Table 300.5 eliminates burial-depth requirements for direct buried raceways under

specified conditions. (Sec. 300.5.)

1. Any direct burial cable run under a building must be installed in a raceway, as required by 300.5(C), and the raceway may be installed in the earth, immediately under the bottom of the building, without any earth cover. Some cables, as covered in exceptions to 300.5(C), are now permitted for direct burial under buildings.
2. Any direct buried cable under a slab at least 4 in. (102 mm) thick and not subject to vehicles is subject to the 18-in. (450-mm) minimum burial-depth requirement of Table 300-5. The reason for the equivalence in cover between the 2-in. (50-mm) concrete-in-trench rule and the 4-in. (102-mm) concrete slab rule is that when the concrete is buried in the trench an excavator will recognize it as a protective structure. The surface slab may not be easily recognized as performing an additional protective function.

Figure 300-14 shows the mandatory 24 in. (600 mm) of earth cover given in Table 300.5 for any wiring methods buried under public or private roads, alleys, driveways, parking lots, or other areas subject to car and truck traffic. A minimum earth cover of 24 in. (600 mm) is required for any underground cable or raceway wiring that is installed under vehicle traffic, regardless of concrete encasement or any other protective measure. This requires the minimum 2 ft (600 mm) earth cover for wiring under the designated areas, including driveways and parking areas of private multifamily residences. The minimum earth cover for cables and raceways under driveways and parking areas for one- and two-family dwellings is only 18 in. (450 mm).

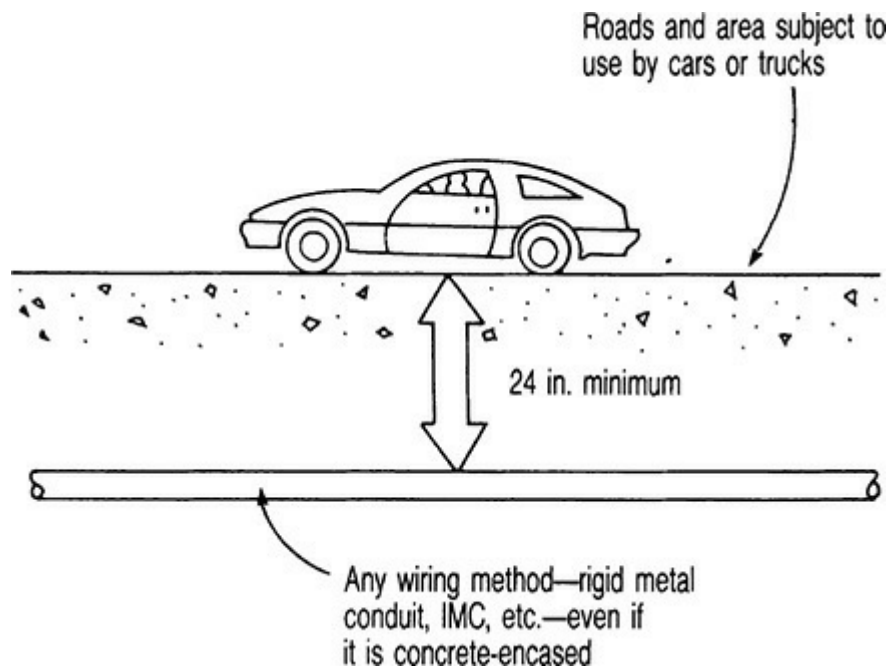

Fig. 300-14. All wiring methods must be at least 2 ft (600 mm) under vehicular traffic. (Sec. 300.5.)

Table 300.5 (second vertical column from right) gives limited use of lesser burial depth for the residential circuits described, as shown in Fig. 300-15. Any GFCI-protected residential “branch circuit” not over 120 V and protected at 20 A or less may be buried only 12 in. (300 mm) below grade, instead of, say, 24 in. (600 mm), as required for Type UF cable for any nonresidential use or for a residential “feeder.”

Fig. 300-15. This is OK only for a residential branch circuit rated not over 20 A and protected by a GFCI circuit breaker. (Sec. 300.5.)

Figure 300-16 shows three other special conditions for burial depth. Table 300.5 (vertical column at right) recognizes reduced burial depth for low-voltage landscape lighting circuits and supply circuits to lawn sprinkler and irrigation valves, as shown in Fig. 300-17. This recognizes the reduced hazards and safety considerations for circuits operating at not more than 30 V. However, such systems must be supplied by Type UF cable or other “identified” cable or raceway. Such identification is generally required to be marked by the manufacturer. On the cables and conductor, the marking should include a “W” indicating suitability for use in a “wet location” to ensure compliance with part (B). The 2017 **NEC** added recognition, in terms of two table footnotes, of listed low-voltage landscape lighting systems. In general, such wiring can use even lesser cover in accordance with the product instructions. In addition, for use around swimming pools and if run in nonmetallic raceway and not operating over 30 volts, such systems can be used with a 6-in. burial depth.

Of course, lesser depths than shown in Table 300.5 are permitted where cable or conductors in raceway come up to terminations or splices in boxes or equipment. NOTE 3.

Any cables or raceways may be buried not less than 18 in. deep under airport runways and adjacent defined areas where trespass is prohibited.

Duct and raceway installed in solid rock may be buried if concrete at least 2 in. thick covers the raceway and extends down to the rock surface.

Fig. 300-16. These applications are also covered in the table burial depths. (Sec. 300.5.)

Fig. 300-17. Reduced burial depth for low-voltage landscape lighting and lawn-sprinkler controls. (Sec. 300.5.)

Part (B) of 300.5 requires all electrical cables and conductors to be listed for use in “wet locations” where installed underground, even if they are contained within a raceway or other enclosure (Fig. 300-18). This effectively applies to all raceways, cables, boxes, enclosures, etc., covered by Chap. 3.

Fig. 300-18. Conductors run underground must be listed for “wet locations.” (Sec. 300.5.)

Figure 300-19 shows the rule of part (C). Note that this rule has been clarified to avoid the former implication that the raceway always had to exit beyond the building perimeter. It is now clear that a raceway can go from one point to another below the floor grade of a building without needing to pass beyond the wall line. However, the requirement for all cables under a building to be in raceway still applies.

Fig. 300-19. Burial of most cables in earth is not permitted under a building. Exceptions include some MI and MC cables. (Sec. 300.5.)

Two exceptions to this general prohibition against running cables under buildings without raceway protection were added in the 2011 **NEC**. Type MI cable is permitted if suitably protected against damage and corrosion, and Type MC cable is permitted if identified for direct burial and it meets the construction requirements for wet locations. Note that the first, fourth, and fifth columns in Table 300.5 have been changed to reflect these new exceptions. These applications presumably meet minimum safety requirements, but the design implications of putting any direct burial wiring method under a building need careful consideration. If the wiring fails it may not be repairable as a practical matter.

As shown at the top of [Fig. 300-20](#), direct buried conductors or cables coming up a pole or on a building from underground installation must be protected from the minimum required burial distance below grade (from Table 300.5, but never required to be more than 18 in. [450 mm] into the ground) to at least 8 ft (2.5 m) above grade, as required by part **(D)** of this section. Where exposed to physical damage, raceways on buildings and raceways on poles must be rigid conduit, IMC, RTRC-XW or PVC Schedule 80, or equivalent, and the raceway or other enclosure for underground conductors must extend from below the ground line up to 8 ft (2.5 m) above the finished grade. The 2017 **NEC** added EMT to this list; note, however, that 358.12(1) would prohibit it if exposed to severe physical damage. If a raceway on a building or on a pole is not subject to physical damage, EMT or Schedule 40 PVC may be used instead of other raceways.

Fig. 300-20. Conductors from underground must be protected. (Sec. 300.5.)

Figure 300-21 shows the service lateral protection ribbon rule from 300.5(D)(3), along with other requirements including the ground movement accommodation rule in 300.5(J) and a warning on an important limitation on straight underground USE cable not colisted with a building wire designation.

Fig. 300-21. Underground installations must accommodate ground movement. [Sec. 300.5(J).] Note that the bell end on the bottom end of the PVC ell (could also have been a bushing) meets the provisions of part (H).

Although always intended to apply to buried PVC (or RTRC) raceways containing service conductors, the literal text of the parent language may limit the reach of this requirement to direct

burial conductors and cables. The 18-in. parameter in this rule (as opposed to the 24-in. specification for direct-burial cables) was chosen to reflect the usual minimum burial depth for nonmetallic raceways. Attempts to fix this problem in the 2014 and 2017 **NEC** cycles failed, so it is still addressed incorrectly. Another attempt will be made in the 2020 **NEC** cycle.

Figures 300-22 and 300-23 show other rules of 300.5. Part **(E)** covers direct burial splices, which do not require boxes but do need to comply with 110.14(B), which requires the splicing method to be listed for this application. There are twist-on wire connectors listed for direct burial, and they are an appropriate solution for single-conductor type USE; however, do not use these connectors for conventional Type UF cable. The direct-burial listing on Type UF cable applies to the entire cable assembly and not to the individual conductors within the jacket. Therefore, if a splice is made with the jacket stripped back and these connectors made up, the resulting exposure of individual conductors within the UF cable assembly to direct soil burial violates the UF cable listing. The splicing method must provide an outer surface that is continuous from cable jacket to cable jacket.

Part (E)

Splices or taps are permitted in trench without a box—but only if listed methods and materials are used.

Part (F)

Backfill of heavy rocks or sharp or corrosive materials must not be used if it may cause damage or prevent adequate compaction of ground.

Part (G)

Conduits or other raceways must be sealed or plugged at either or both ends if moisture could contact live parts

Part (H)

Bushing must be used on any conduit end where direct-burial cables leave conduit. Or, a seal that gives the same protection may be used instead of a bushing.

Fig. 300-22. Underground wiring must satisfy these requirements. Part G requires the sealing material to be identified as suitable for the wiring in the raceway. The sealing rule also applies to

spare raceways. (Sec. 300.5.)

Fig. 300-23. For direct burial underground conductors, a box must be used at splice points, with conductors brought up in sweep ells and the box properly grounded—*unless* listed materials are used to make directly buried splices in the conductors in accordance with Sec. 110.14(B). (Sec. 300.5.)

Note that part **(F)** specifically requires that backfilled trenches must contain any necessary protection for raceways or cables buried in the trench. It specifies that sand or suitable running boards of wood or concrete or other protection must be afforded in those cases where backfill consists of heavy stones or sharp objects that otherwise would present the possibility of damage to the cable or raceway. Refer to the discussion at 310.10(F) for additional information on this topic.

Part **(I)** of this section requires that an underground circuit made up of single-conductor cables for direct burial must have all conductors of the circuit run in the same trench. That rule raises the question: When an underground direct burial circuit is made up of conductors in multiple, must all the conductors be installed in the same trench? And if they are, is derating required for more than three current-carrying conductors in a trench, just as it would be for more than three conductors in a single raceway? The answer to both questions is yes.

The wording of the rule in part **(I)** clearly indicates that all the conductors making up a direct burial circuit of single conductors in parallel must be run in the same trench and must be “in close proximity.” The wording of 300.5(I) also requires that all conductors of a circuit be run in the same raceway if a raceway is used (with building wire suitable for wet locations, such as THW or THWN). But Exception No. 1 permits parallel conductor makeup in multiple raceways, with each raceway containing all hot, grounded, and (if used) grounding conductors of the circuit. And Exception No. 2 to 300.5(I) recognizes the use of “isolated phase” installations, provided the rules for paralleling conductors—given in 310.4—and the rules for reducing the effects of inductive heating in adjacent metallic materials—as given in 300.20—are satisfied.

When multiple-conductor makeup of a circuit is installed with all the parallel-circuit conductors in

the same trench, it is necessary to observe the rule of 310.15(B)(3) of the **NEC**, which states:

Where single conductors ... are installed without maintaining spacing for a continuous length longer than 24 in. (600 mm) and are not installed in raceways, the allowable ampacity of each conductor *shall* be reduced as shown ...

This means that the same deratings must be made as when more than three conductors are used in a single conduit, as explained in 310.15(B)(3)(a). Certainly, direct burial single conductors are covered by that requirement because Table 310.15(B)(16) specifically covers direct burial conductors.

These Code rules often make for tricky and troublesome applications. For instance, as shown in [Fig. 300-24](#), an underground circuit of Type USE insulated aluminum conductors might be used for a 3-wire, single-phase service to a multifamily dwelling. Because that is a residential service, 310.15(B)(7) might be considered to gain a higher-than-normal ampacity for the conductors; however, the rule has been rewritten to exclude multifamily applications and it only applies to applications where the conductors only supply a one-family dwelling unit. Assuming that a 400-A conductor ampacity is indicated by the calculated demand load from Art. 220, each phase leg of the service feeder must have an ampacity of 400 A. Refer to the 75°C column in Table 310.15(B)(16): A 250 kcmil THW aluminum has an ampacity of 205 A. Two such conductors per hot leg and two for the neutral would give the required 400-A capacity for the service. But how should the parallel circuit be run? All the circuit conductors must be run in close proximity in the same trench, as required by 300.5(I). At first blush that would mean that all six USE conductors are in the same trench; and, because the neutrals do not count as current-carrying conductors, the derating of these conductors run without spacing must be to 80 percent of the 200-A ampacity, as required for four conductors in the table of Table 310.15(B)(3). With each 250 kcmil THW aluminum now derated to 161 A (0.8×205), the ampacity of each hot leg would only be 322 A (2×161).

BECAUSE THIS IS LITERALLY PROHIBITED FOR SINGLE CONDUCTORS, BUT NOT FOR RACEWAYS OR CABLES . . .

. . . THIS LARGER CIRCUIT WAS REQUIRED BECAUSE EXCEPTION NO. 1 DOES NOT APPLY.

Fig. 300-24. Literal application of Code rules often imposes stiff requirements. (Sec. 300.5.) The rewording of Exception No. 1 for the 2011 **NEC** made it possible to run two trenches and avoid this outcome.

In referring to Table 310.15(B)(16), it would therefore seem necessary to pick a larger size of THW aluminum, such that, when derated to 80 percent of their Table 310.15(B)(16) value, the two of them will still provide the required 400-A rating. A 350-kcmil THW aluminum has a normal rating of

250 A. Derated to 80 percent (250×0.8), it has the needed ampacity of 200 A, so that two in parallel per hot leg and neutral will have the ampacity of 400 A. Fortunately, Exception No. 1 was rewritten in the 2011 cycle to avoid this result. In addition to directly buried multiconductor cables and raceways, the exception now also applies to sets of directly buried conductors. As a result, two parallel trenches can be run, in this case with a set of 250 kcmil THW aluminum conductors in each, each running at their normal ampacity value of 205 A. If the two parallel sets of conductors could have been run in separate trenches, the 250 kcmil THW aluminum conductors would have met the need in terms of ampacity. Obviously, the conductors selected for actual direct burial must be Type USE, or combine that rating with THW (or RHW).

Exception No. 1 of part (I) permits an underground circuit to be made up in parallel in two or more raceways, without need for derating. But, in such cases, each raceway must contain one of each of the phase legs, a neutral (if used), and an equipment grounding conductor (if used). With “A-B-C-N” in each raceway of a multiple group, that would be the same type of multiple-conduit-parallel-conductor makeup as required and commonly used for aboveground circuits.

One question that often arises when designing this work is how much distance to allow between parallel trenches before heat generated in one trench begins to affect the other. The NEC does not answer this directly for 600 V and below applications. However, running each set of cables in parallel trenches would generally line up with Detail 8 in Fig. 310.60(C)(3), which shows a spacing of 24 in. in order to still allow the application of the related medium-voltage ampacity tables. This distance is probably somewhat conservative for utilization voltages, so it should be more than sufficient. Closer spacings could be applied if justified by engineering support.

Exception No. 2 permits “isolated-phase” makeup of underground circuits in multiple conduits—all phase A conductors in one conduit, all phase B conductors in a second conduit, all phase C conductors in a third conduit, all neutrals in a fourth conduit—with an equipment grounding conductor (or conductors, if needed) installed in a fifth conduit or installed in each of the three conduits carrying the phase conductors. However, that makeup is permitted only where the conduits are nonmetallic and are “in close proximity” to each other. (See 300.20.) Remember that the raceways must terminate in a manner that avoids inductive heating using methods in 300.20(B), such as entering below an open-bottom switchboard, or through a nonferrous window.

Isolated phase installations on ac systems inherently increase the circuit impedance because the magnetic fields surrounding each phase conductor do not cancel. This means the impedance (and therefore voltage-drop) increase with the distance between conductor groups; on the other hand, some engineers employ this technique to reduce the available fault current at the end of the run.

Warning! Because of difficulties that can be encountered with pulling lines sawing through the inner radii of nonmetallic sweeps, some wiring designs show PVC everywhere except at both ends of an underground installation, where steel sweeps are specified. In Art. 250, 250.102(E)(2) Exception, 250.80 exception, and 250.86 Exception No. 3 all facilitate this practice. Never use this wiring procedure on an isolated phase installation covered here. The failure to comply with 300.20(A) in such instances will result, especially for the large current installations for which this procedure was designed, in significant inductive heating within the steel sweeps. A leading cable engineer described to the author actual field instances where the conductor insulation within the steel sweeps had completely melted. Aluminum sweeps with supplemental corrosion protection would be one option, and another is staying with PVC and switching to a polyester pulling line, as covered in the wire pulling analysis offered in our sister publication, the *American Electricians' Handbook*.

Part **(J)** makes it mandatory that frost heave and settling be accommodated. In those areas of the country that experience cyclical freezes and thaws, concern about frost damage to buried raceways and cables has generally been addressed either by installation below the frost line or by the use of expansion fittings and direct buried cables with slack. This is done to ensure that the raceway remains intact and its contained circuits remain operational. The Code now mandates the implementation of those materials and methods that will ensure the underground raceways and cables are not damaged by frost heave. The informational note immediately following part **(J)** identifies methods to accomplish the desired effect.

Figure 300-21 shows the rules in action. Note that this rule applies regardless of whether the run from grade to termination is enough to raise a concern about thermal expansion and contraction [300.7(B)]. It also applies regardless of the thermal expansion coefficient of the wiring method, because it is the ground that is moving, not the raceway changing length, and therefore it applies equally to metallic and nonmetallic raceways alike. There is considerable loss experience associated with steel raceways being forced vertically upward through concentric knockouts until the raceway shorted against a line bus.

In addition, do not make the mistake of assuming that this rule only applies in areas subject to frost. It applies to “earth movement.” This includes settling conditions that tend to drag raceways downward to the point of exposing the service conductors within to touch, or pulling downward on intact locknut connections to the point where enclosures are removed from a wall or severely deformed to the point that the covers no longer work properly. The usual way to address this rule is through the use of expansion fittings, which are certainly acceptable, but expensive in the case of metallic models. In some cases other approaches have worked, such as an elliptical hole where a conduit body entered a building on a small branch circuit.

This author once reviewed a medium-voltage application where the feeder emerged from grade and went up the side of a new industrial occupancy to the roof. The engineers were so concerned about the likelihood of settlement that they specified a special pull box with telescoping sides that would allow for the conductors to gently sweep up out of the ground, crest, and go downward almost to grade, and then rise again and enter the vertical raceways up the side of the building. The arrangement was designed to allow the grade to settle several feet without compromising the required bend radius on the Type MV cables.

In part **(K)** the Code mandates that underground cables and raceways installed using “direct boring equipment” must be “approved” for such installation. “Approved” means acceptable to the inspector. In this case, wording in the manufacturer’s instructions indicating that such installation is permitted will generally satisfy the local inspector.

300.6. Protection Against Corrosion and Deterioration. This section provides some specific wording with regard to what must be provided to achieve compliance with the rule here. Ferrous-metal equipment is covered in part **(A)**. An exception exempts stainless steel from the necessity to have protective coatings.

The 2014 **NEC** has added a new informational note explaining what a field-cut thread is. This was necessary because it was suggested that a thread applied in a mechanic’s shop or anywhere else beside the field location where the conduit would be installed was not field cut. It is now clear that any thread not applied by the manufacturer is a field-cut thread for these purposes, and if corrosion protection is necessary, the threads must be coated with a compound that is both corrosion resistant and conductive, as approved by the inspector.

Part (A)(1) limits the use of ferrous-metal equipment protected solely by enamel to damp and dry indoor locations. Part (A)(2) allows organic coatings to be applied to metallic boxes or cabinets to prevent corrosion when used outdoors, in lieu of the standard “4-dip” zinc galvanizing method. And part (A)(3) addresses the use of ferrous metal equipment in concrete, earth, or other hostile environments, provided either the material or the corrosion protection is approved for the location.

Part (B) covers aluminum raceways, enclosures, etc. All such equipment must be provided with supplemental where in concrete or the earth. In a previous cycle, this part referred to nonferrous metal, which was an error because red brass is not subject to this limitation. Part (C) covers nonmetallic equipment, which must be suitable for use in direct sunlight and impervious to other environmental hazards based on its chemical makeup.

Figure 300-25 shows the right and wrong ways of installing equipment in indoor wet locations, as covered in part (D) of this section. Note that the exception that allows nonmetallic products to avoid the 6-mm ($\frac{1}{4}$ -in.) air space rule is limited to surfaces that are impervious to moisture, such as tile or concrete.

Fig. 300-25. Water or moisture must not be trapped in contact with metal. (Sec. 300.6.)

300.7. Raceways Exposed to Different Temperatures. Part (A) requires protection against moisture accumulation. If air is allowed to circulate from the warmer to the colder section of the raceway, moisture in the warm air will condense in the cold section of the raceway. This can usually be eliminated by sealing the raceway just outside the cold rooms so as to prevent the circulation of air. Sealing may be accomplished by stuffing a suitable compound in the end of the pipe (Fig. 300.26). Note that this rule has been expanded in recent years, and now expressly includes a passage from inside to outside a building (presumably only where there is a known issue, as with conditioned air). The former limitation to refrigerated rooms, as suggested in the sketch, is not the only mandatory application of this sealing rule.

Fig. 300-26. Sealing protects against moisture accumulation in raceway. (Sec. 300.7.)

The rule of part **(B)** makes it mandatory to ensure that expansion fittings are used where raceways are exposed to different temperatures to ensure that the raceways, fittings, and enclosures are not damaged and compromised by the inherent expansion and contraction that results from thermal cycling. The informational note directs the reader to data regarding the use of expansion fittings for PVC conduit and provides guidance and data that applies to the expansion characteristics of IMC, EMT, and rigid steel conduit. Do not confuse this with ground movement as covered in 300.5(J). They are two different rules and different conditions mandate their application, although the usual solution for both problems is an expansion fitting. In some cases thermal action results in deflection rather than simple expansion or contraction. There are also fittings to address this issue, and some are evaluated for both deflection and expansion/contraction.

300.8. Installation of Conductors with Other Systems. Any raceway or cable tray that contains electric conductors must not contain “any pipe, tube, or equal for steam, water, air, gas, drainage, or any service other than electrical.”

300.9. Raceways in Wet Locations Above Grade. This new (2008 NEC) rule clarifies once and for all that the inside of a raceway in a wet location is presumed to be wet, and the enclosed wiring must be suitable for wet locations.

300.10. Electrical Continuity of Metal Raceways and Enclosures. This is the basic rule requiring a permanent and continuous bonding together (i.e., connecting together) of all noncurrent-carrying metal parts of equipment enclosures—conduit, boxes, cabinets, enclosures, housings, frames of motors, and lighting fixtures—and connection of this interconnected system of enclosures to the system grounding electrode at the service or transformer ([Fig. 300.27](#)). The interconnection of all metal enclosures must be made to connect all metal to the grounding electrode and to provide a low-impedance path for fault-current flow along the enclosures to ensure operation of overcurrent devices that will open a circuit in the event of a fault. By opening a faulted circuit, the system prevents dangerous voltages from being present on equipment enclosures that could be touched by personnel, with consequent electric shock to such personnel.

Fig. 300-27. All metal enclosures must be interconnected to form “a continuous electric conductor.” (Sec. 300.10.)

Simply stated, this interconnection of all metal enclosures of electric wires and equipment prevents any potential aboveground on the enclosures. Such bonding together and grounding of all metal enclosures are required for both grounded electrical systems (those systems in which one of the circuit conductors is intentionally grounded) and ungrounded electrical systems (systems with none of the circuit wires intentionally grounded).

Exception No. 1 to this rule recognizes the specific permission given in Art. 250 to depart from the requirement for “electrical continuity,” where an isolated metallic elbow is used underground. As indicated in 250.86, Exception No. 2, short sections of metallic piping used for providing physical protection for cables are not subject to the basic requirement that such metallic raceways, cable jackets, etc., all be electrically continuous. But effective equipment interconnection and grounding are extremely important for grounded electrical systems to provide the automatic fault-clearing that is one of the important advantages of grounded electrical systems. A low-impedance path for fault current is necessary to permit enough current to flow to operate the fuses or CB protecting the circuit.

Exception No. 2 recognizes the permission given in 250.96(B) to interrupt the electrical continuity of a raceway containing a so-called isolated ground circuit. But, such installation must fully comply with all requirements given in 250.96(B) to ensure a modicum of safety.

300.11. Securing and Supporting. The basic rule in part (A) requires all raceways, cables, boxes, and so on to be “securely fastened in place.” That wording effectively prohibits simply laying raceways, cables, boxes, and so on on the floor, on piping, on ceiling tiles, or anywhere. Although such installation may provide “support,” the basic rule calls for fastening, not just support. Regardless of where raceways, cables, boxes, and the like are installed, they must be fastened in place using a recognized method. Generally speaking, the rule in part (B) permits the use of “ceiling support” wires to secure wiring methods and equipment; however, they must be “in addition to the ceiling grid support wires.” That is, the ceiling will have a designed pattern of support wires, and tie wires for electrical equipment are to be in addition to the ones required to hold up the ceiling. This is accomplished by using appropriate commercially available fasteners. Note that where ceiling support wires are used, they must be secured at both ends. The last sentence simply reiterates a long-held interpretation that asserts that unfastened cables and raceways are prohibited, and that if tied to a support grid the adjacent ceiling panel will be very difficult or impossible to remove. Note that 300.23 specifically requires that any wiring above such panels be arranged so the panels can be removed and equipment accessed above the ceiling.

In part (B)(1), the Code calls for an independent means of support for wiring methods within the cavity above a suspended ceiling that is an integral part of fire-rated floor-ceiling or roof-ceiling assembly. This rule covers those installations where the fire rating of the hung ceiling is being used to establish the fire separation rating—typically specified by local building codes—for the space above and beneath the ceiling. Such installations are covered by (B)(1). Nonfire-rated hung-ceiling assemblies are covered under part (B)(2).

A true (B)(1) application is somewhat unusual, and it is important to know exactly what it is and why the rules make the distinctions they do. Building codes typically establish required fire separation ratings between floors of major buildings. Usually, the building is simply designed with enough concrete so the structural ceiling possesses the required fire separation by itself. In these cases the integrity of the suspended ceiling has no bearing on how much time it would take for a fire on one floor to compromise the next higher floor. These ceilings are covered in (B)(2).

However, there are other ways to achieve a particular floor/ceiling separation. Some ceilings are designed with a thinner slab than one that would establish the required fire separation on its own. In this case, the suspended ceiling is an integral part of the overall fire rating. Qualified testing laboratories have evaluated many such designs, using specified ceiling panel materials. These tests involve actually constructing such a room and ceiling inside a giant furnace, so they are extremely expensive to run. Invariably, the designs specify, in precise detail, exactly how many support wires must be used, how thick they must be, how and where they must be attached, how fixtures are to be supported, how air ducts must be constructed and run, etc.

In making these tests, the testing laboratories do not assume any additional weight loads on these support wires, nor do they (or could they) evaluate how such a ceiling might deform under fire conditions with such loading. In these cases, the wiring methods must be supported securely and independently of the support wires. The only exception allows for the remote possibility that someone might rerun a ceiling assembly test with specified wiring attached to specified supports. The fact that the rated designs specify the support wire locations makes it essential that both electrical and

building inspectors be able to know which support wires were placed in addition to the essential elements of the ceiling construction.

Therefore, no raceways or cables may be supported by the wires installed to support the ceiling. But, if additional wires are installed, such wires may be used to “securely support” the raceways or cables within the ceiling. And because of the critical nature and precise construction detail that goes into such a ceiling design, where additional ceiling support wires are used as the support for wiring methods within a hung ceiling, such wires must be identified via marking, tagging, painting, or virtually any method that will permit the ceiling support wires to be readily distinguished from the electrical system support wires.

In part **(B)(2)** the Code addresses the same consideration for wiring method support within nonfire-rated hung ceilings. In the case of nonfire-rated applications, you have to add wires to those required for ceiling support, and due to a change in the 2011 **NEC** they must be identifiable in the same way as those used for fire-rated assemblies in 300.11(B)(1). The language in this paragraph talks of an “independent means of secure support” which has led some to conclude that all support wires were off limits. That has never been the case and the issue was clarified in the 2008 **NEC** which added the phrase “and shall be permitted to be attached to the assembly.” Thus, as in the case of the **(B)(1)** applications, you can’t use the ceiling design wires but you can add to them, provided they are attached at both ends so as to “provide secure support” as covered in the parent language in 300.11(A). The extension of the identification rule makes this easy to police.

Both **(B)(1)** and **(B)(2)** have rather impractical exceptions that recognize the use of the ceiling design wires if the design includes the wiring. The **(B)(1)** exception would require the entire ceiling system to go back in for testing, which is so costly as to be unimaginable. Remember, the exact location of the wiring would need to be specified, and that is something that changes with every installation. The **(B)(2)** exception is predicated on the ceiling manufacturer choosing to recognize wiring on his specified ceiling support protocol. Frankly the likelihood of that happening is only slightly better than infinitesimal, but the exception is probably harmless as long as no one expects to use it.

In part **(C)**, raceways are prohibited from being used as a means of support for cables or nonelectrical equipment. Telephone or other communication, signal, or control cables must not be fastened to electrical conduits, such as by plastic straps or any other means. Although raceways must not be used as a means of support for other raceways, cables, or nonelectric equipment, part **(C)(1)** might permit large conduits with hanger bars or fittings intended to support smaller raceways, but this application would have to be called out on some manufacturer’s literature, as provided in the definition of “identified.” Part **(C)(2)** permits such applications as tying Class 2 thermostat cable to a conduit carrying power-supply conductors for electrically controlled heating and air-conditioning equipment that is controlled by the Class 2 wires. Part **(C)(3)** applies to those instances where raceways are permitted to support boxes or conduit bodies (314.23) or luminaires [410.36(E)].

In part **(D)**, the Code also prohibits the use of cable assemblies as a means of support for any equipment, such as other power cables, raceways, boxes, cable TV, or phone lines. In short, nothing may be supported by any of the cable assemblies recognized as wiring methods by the **NEC**. Two cables tie-wrapped together are a support for neither. The reason for the cable-on-other-wiring prohibitions is that the ampacity calculation procedures in the **NEC** presume that wiring methods are free to radiate heat. Adding a blanket of cables can lead to overheated wiring.

300.13. Mechanical and Electrical Continuity—Conductors. The general rule of part (A) is: Where conductors are spliced, a box is needed. The second sentence then identifies those limited number of cases where the Code does allow a splice without a box.

Part (B) prohibits dependency upon device terminals (such as internally connected screw terminals of duplex receptacles) for the splicing of neutral conductors in multiwire (3-wire or 4-wire) circuits. Grounded neutral wires must not depend on device connection (such as the break-off tab between duplex receptacle screw terminals) for continuity. White wires can be spliced together with a pigtail to the neutral terminal on the receptacle. If the receptacle is removed, the neutral will not be opened (Fig. 300.28).

Fig. 300-28. Neutrals of multiwire circuit must *not* be spliced at receptacle terminals. (Sec. 300.13.)

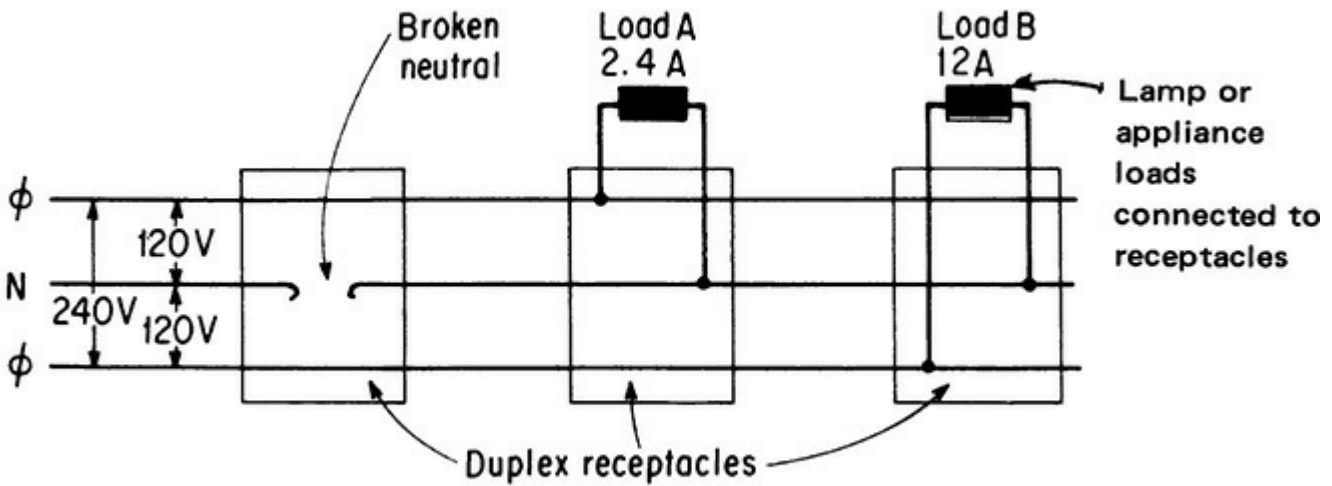

This rule is intended to prevent the establishment of unbalanced voltages should a neutral conductor be opened first when a receptacle or similar device is replaced on energized circuits. In

such cases, the line-to-neutral connections downstream from this point (farther from the point of supply) could result in a considerably higher-than-normal voltage on one part of a multiwire circuit and damage to equipment, because of the “open” neutral, if the downstream line-to-neutral loads are appreciably unbalanced.

Note that this paragraph does not apply to 2-wire circuits or circuits that do not have a grounded conductor. This rule applies only where multiwire circuits feed receptacles or lampholders. This would most commonly be a 3-wire 240/120-V or a 3- or 4-wire 208/120-V or even a 480/277-V branch circuit.

The reason for the pigtail requirement is to prevent the neutral conductor from being broken and creating downstream hazards. The problem lies in the inclination of electricians to work on hot circuits. Assume that a duplex receptacle on a 240/120-V 3-wire circuit becomes defective, and the first thing the electrician does, working hot, is to disconnect the neutral wires from the receptacle. Downstream, 2.4- and 12-A loads have been operating (plugged into additional receptacles on the multiwire circuit), each connected to a different hot leg. When the neutral is broken by the electrician upstream, normal operation of the loads reverts to the condition shown in [Fig. 300-29](#). The two loads are now in series across 240 V. As shown, load A now has 200 V impressed across it. It could run extremely hot and burn out. Load B now has only 40 V across it; if it is a motor-operated device, the low voltage could cause the motor to burn up. Both could cause injuries. Also, in disconnecting the neutral, the electrician could get a 120-V shock if both the disconnected neutral conductor going downstream and the box were touched—not unlikely, since the neutral is usually considered to be dead—that is, at ground potential.

An open neutral like this...

... puts 200 volts across a 120-volt load

EQUIVALENT CIRCUIT

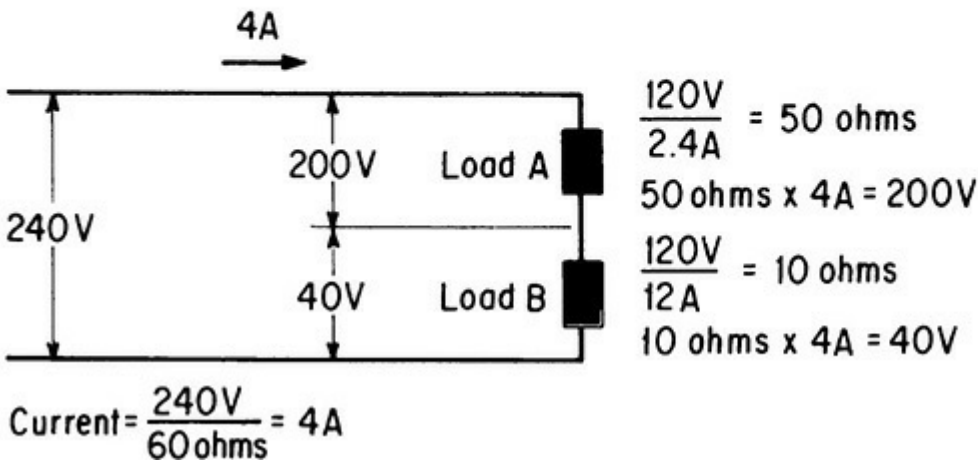

Fig. 300-29. Splicing neutrals on receptacle screws causes “open” in neutral if receptacle is removed. (Sec. 300.13.)

300.14. Length of Free Conductors at Outlets, Junctions, and Switch

Points. The rule here applies only to the length of the conductor at its end. The exception covers wires running through the box. Wires looping through the box and intended for connection to outlets at the box need have only sufficient slack that any connections can be made easily. Generally, at least 150 mm (6 in.) of slack must be provided. This dimension is measured from the point the conductor emerges from its raceway or cable sheath. In addition, for smaller boxes (i.e., those smaller than 200 mm [8 in.] in any dimension), the minimum length of slack is based on the amount of conductor that extends outside the box—presumably when held at a 90° angle to its entry. For these smaller boxes, the conductor must be long enough so that at least 75 mm (3 in.) of conductor can extend from the box opening. This recognizes that boxes with small openings prevent a person from getting two hands into the box for the purpose of connecting devices, etc. Therefore, the Code mandates the conductors

extend beyond the face of the box for not less than 75 mm (3 in.) where the box has an opening that is less than 200 mm (8 in.) in width or height.

Note the “emerges from its ... cable sheath” provision. Those who don’t remove cable jackets prior to the walls being closed, and strip the jackets only at the finish wiring stage at the point where the cable assembly comes out of the wall may want to reconsider this practice. The 150-mm (6-in.) dimension would then start at the wall, resulting in excessive box fill. Although 314.16 has no prescriptive volume rule to cover this, it does require “free space for all enclosed conductors.” One of the reasons for specifying the point of emergence on cable assemblies as being the end of the jacket was to discourage this practice.

300.15. Boxes, Conduit Bodies, or Fittings—Where Required. The basic rule requires either a “box” or a “conduit body” to be used at splice points or connection points in cable and raceway systems. [Figure 300-30](#) covers the basic principles. In addition, concealed knob-and-tube wiring must have a box at outlet and switch points. This sets the default stance of the **NEC**. The lettered paragraphs that follow, (A) through (L), set forth the only circumstances under which wiring methods can have any form of termination, pull, or outlet point without a box or conduit body.

Fig. 300-30. Raceways and cables may use boxes or conduit bodies at conductor splice points. (Sec. 300.15.) Note that based on current typical conduit body volumes, splices such as those shown are problematic because they usually will not meet the volume requirements in 314.16.

The second sentence in 300.15, also part of the default stance, was included to address the almost universal misuse of Type NM (Romex) connectors with other cables and even cords. The wording as it appears in the Code, however, requires that *any* fitting or connector be “designed and listed” for the wiring method used. Be aware that, while it will be up to the manufacturers of this equipment to obtain the listing for these products, it is the designer-installer’s responsibility to specify or use only those fittings and connectors specifically listed for the application. Connectors for Type MC cable are another source of abuse; many listed connectors for Type AC cable are misapplied on aluminum armored MC cable. The permitted cable types, including the allowable cable diameters and whether the cable is listed for smooth or corrugated or interlocking-armor cable or some combination of the three, will be listed on the smallest shipping unit carton.

In part **(A)** the Code eliminates the need for a box or conduit body where certain enclosures that have removable covers are used. And part **(B)** recognizes equipment that is provided with adequately sized junction boxes or wiring compartments, such as motor terminal housings, or wiring compartments in HID and other luminaires that are arranged for a direct wiring entry.

Part **(C)** calls for abrasion protection for cables where they enter/exit a conduit or tubing. This ensures that rough or sharp edges on the conduit or tubing will not damage the cable. This applies to kick pipes and also to short risers from outlet and switch points on unfinished basement walls. Part **(D)** exempts a specific Type MI splice, but only where the actual splice is accessible.

Part **(E)** of this section recognizes the use of wiring devices that have “integral enclosures.” These are the so-called boxless devices made and acceptable for use in nonmetallic sheathed cable systems (Type NM). Such listed devices [see 334.30(C) for the rules on these devices] do not require a separate box at each outlet because the construction of the device forms an integral box in itself. These devices are flush, modern versions of the old surface-mounted devices covered in **(H)**. The devices in this latter paragraph are primarily used for surface installations of Type NM cable as covered in 334.40(B), although fished-in applications are recognized as well.

Part **(F)** recognizes transition from Type AC or MC cable to raceway without the need for a box, provided that no splice or termination is made in the conductors. This permits the common practice of changing from, say, AC to EMT for a run down a wall, with the armor stripped from a long length of the AC and the exposed wires run in the EMT. A suitable fitting made for connecting AC to EMT must be used ([Fig. 300.31](#)).

Fig. 300-31. This type of no-box connection for cable-to-raceway change is permitted by part (F). [Sec. 300.15(F).]

Part (G) correlates with the rules of 300.5(E) and 110.14(B), which permit splicing of underground direct burial cables and conductors using listed splice kits without a box.

Part (I) covers terminations and pull points in large accessible enclosures much larger than the wiring methods, where a box would serve no purpose. Examples include switchboards, motor control centers, and cabinets and cutout boxes generally.

Part (J) permits splices to be made within luminaire wiring compartments where the branch-circuit wires are spliced to fixture or ballast wires and the wiring compartment qualifies for consideration as a raceway under one of the three conditions provided in 410.64.

Part (K) correlates with provisions for radiant electric heating cable connections that are done with the connections embedded with the cables.

Part (L) covers handholes and manholes unless there is an actual connection to electrical equipment contained in the handhole or manhole, as opposed to a simple conductor or cable splice.

300.16. Raceway or Cable to Open or Concealed Wiring. Where the wires are run in conduit, tubing, metal raceway, or armored cable and are brought out for connection to open wiring or concealed knob-and-tube work, a fitting such as that shown in Fig. 300-32 may be used. Where the terminal fitting is an accessible outlet box, the installation may be made as shown in Fig. 300-32.

A terminal fitting satisfies the rule on transition from raceway to knob and tube.

An outlet box may be used where raceway connects to open wiring or concealed knob and tube.

Fig. 300-32. These are techniques for connecting conduit to open wiring. (Sec. 300.16.)

300.17. Number and Size of Conductors in Raceway. This section contains the general principle that raceway installations must permit the ready installation and withdrawal of the enclosed conductors. The various raceway articles have rules that generally limit the number of bends in

tubular raceways between pull points, all as part of carrying out the general objectives of this rule. Note, however, that no individual raceway article can impose a bend limit on two different raceways joined together with a changeover fitting and no pull point at the transition. On the literal text of those articles, it would be possible to have 360° in bends in a run of intermediate metal conduit connected to a run of EMT, also with 360° of bends. This section can and should be applied to challenge that practice. It frequently arises with respect to transitions to flexible wiring methods at the end of a run.

300.18. Raceway Installations. This section presents a general Code concept requiring raceways to be installed as a complete system, with associated boxes and other enclosures, before pulling conductors into the raceway and box system. This rule is in the **NEC** because of reports of damage to conductors being pulled into incomplete raceway systems. There is another, more fundamental reason for this rule. Any raceway system is supposed to be capable of having its enclosed conductors withdrawn and replaced without damage (see 300.17). On very long runs, the frictional forces can overcome the tensile strength of the conductors and the ability of the insulation to stand up to the sidewall bearing pressures that will develop on difficult pulls. To avoid these problems, some contractors have pulled wire in segments, adding raceway lengths as they go forward, eventually resulting in a raceway that might as well be classified as a cable because there will be no possibility that the wires could ever be withdrawn. This section provides a partial defense against this by assuring that, at least, someone actually pulled the wires in through all the bends, from access point to access point.

The last sentence of (A) does recognize prewired assemblies, but only where the raceway article specifically permits this to occur. An example is 362.10(8) for ENT. The rule also intends to permit wiring of motors and fixture whips after the basic raceway system has been wired, as well as covering prewired assemblies. [Figure 300-33](#) shows wires pulled into an incomplete raceway system. That used to be a Code violation, but the rule prohibiting it was removed as long as the raceways are complete between pull points. The raceway to the right is still OK because it has no wires in it. The exception recognizes the permission given in 250.86 Exception No. 2. Part **(B)** prohibits welds made to raceways unless they were specifically designed for this purpose, or some Code provision specifically allows it.

Fig. 300-33. Conductors shown here have been pulled into the conduit before boxes and continuation of the raceway system were installed to supply underground circuits to outdoor building lighting. Under previous Code editions, this was a violation of Sec. 300.18. That section and its rules were removed after the 1981 **NEC**, but restored six years later.

300.19. Supporting Conductors in Vertical Raceways. Long vertical runs of conductors should not be supported by the terminal to which they are connected. Supports, as shown in [Fig. 300-34](#), may be used to comply with 300.19(A), as may the other support methods recognized by part (C). (See also [Figs. 300-35](#) and [300-36](#).) Note that support intervals for fire-rated applications, as covered generically in part (B), may and frequently do differ substantially from the normal requirements for the wiring method. For example, the normal interval for Type MI cable is 1.8 m (6 ft), but if the cable is employed as a component of an electrical circuit protective system the support interval decreases significantly. The exact spacing is specified for each system employed, along with the support method (generally involving steel components, etc.) that will withstand both the heating tests for the time duration associated with the rating, as well as a hose stream test designed to simulate fire suppression activity afterwards.

Conductor-support bushing screwed on end of conduit at a cabinet, pull box, or conductor-support box. (*Russell & Stoll.*)

Conductor-support box with single-wire cleats to clamp conductors.

Fig. 300-34. Some type of support must carry the weight of conductors in long risers. (Sec. 300.19.)

Fig. 300-35. Bore-hole cable, with steel wire armor, is permitted by the exception to be supported only at the top of very high risers because the steel armor supports the length of the cable when the steel wires are properly clamped in the support ring of the type of fitting shown here. (Sec. 300.19.)

Fig. 300-36. Separate strands of cable armor are snubbed between flanges of support fitting at top of run. Partitioned enclosure protects unarmored sections of cable. (Sec. 300.19.)

300.20. Induced Currents in Ferrous Metal Enclosures or Ferrous Metal

Raceways. When all conductors of an ac circuit are kept close together—in a raceway or a box or other enclosure—the magnetic fields around the conductors tend to oppose or cancel each other, thereby minimizing the inductive reactance of the circuit and also minimizing the amount of magnetic flux that can cause heat due to hysteresis loss (magnetic friction) in steel or iron and due to the I^2R losses of currents that are induced in adjacent metal. The rule of this section calls for always running a neutral conductor with the phase legs of an ac circuit to minimize such induction heating. The equipment grounding conductor must also be run close to the circuit conductors to achieve the reduction in inductive reactance and minimize the impedance of the fault-current return path when a fault does occur, thereby assuring the fastest possible operation of the protective device (fuse or CB) in the circuit. The reference to “all” grounding conductors in the basic rule is aimed at the so-called isolated grounding conductors, which must also be run with the circuit conductors from the outlet to the panel where that circuit originates. Where the isolated ground continues through that panel, it should be run with the feeder that supplies that panel, although that is not entirely clear (Fig. 300.37).

In a typical 3-phase circuit —

the magnetic fields around the conductors have the phase displacements of the currents...

... therefore, the magnetic fields tend to cancel each other (like the neutral current becomes zero under balanced loading) if the conductors are close together

Fig. 300-37. Close placement of ac conductors minimizes magnetic fields and induction. (Sec. 300.20.)

When an ac circuit is arranged in such a way that the individual conductors are not physically close for mutual cancellation of their field flux, it is particularly important to take precautions where a single conductor passes through a hole in any magnetic material, such as a steel enclosure surface. The presence of the magnetic material forms a closed (circular) magnetic core that raises the flux density of the magnetic field around the conductor (i.e., it greatly strengthens the magnetic field). Under such conditions, there can be substantial heating in the enclosure due to hysteresis (friction produced by the alternating reversals of the magnetic domains in the steel) and due to currents induced in the steel by the strong magnetic field. To minimize those effects, the second paragraph of Sec. 300.20 requires special treatment, such as that shown in [Fig. 300-38](#). Or a rigid, nonmetallic board (fiberglass, plastic, etc.) should be used for the enclosure wall that the conductors pass through.

Fig. 300-38. Induction heating is reduced by opening the magnetic core. (Sec. 300.20.)

300.21. Spread of Fire or Products of Combustion. Application of this section to all kinds of building constructions is a very broad and expanding controversy in modern electrical work, in particular because of the phrase *substantially increased*. The rule here requires that electrical installations shall be made to substantially protect the integrity of rated fire walls, fire-resistant or fire-stopped walls, partitions, ceilings, and floors. Electrical installations must be so made that the possible spread of fire through hollow spaces, vertical shafts, and ventilating or air-handling ducts will be reduced to a minimum. These rules require close cooperation with building officials to avoid destruction of fire ratings when electrical installations extend through such areas.

Floor Penetrations

Certainly, poke-through wiring—that technique in which floor outlets in commercial buildings are wired through holes in concrete slab floors—is an acceptable wiring method if use is made of UL-listed poke-through fittings that have been tested and found to preserve the fire rating of the concrete floor. Throughout the country, poke-through wiring continues to be a popular and very effective method of wiring floor outlets in office areas and other commercial and industrial locations. Holes are cut or drilled in concrete floors at the desired locations of floor outlets, and floor box assemblies are installed and wired from the ceiling space of the floor below. The method permits installation of every floor box at the precise location that best serves the layout of desks and other office equipment.

The wiring of each floor outlet at a poke-through location may be done basically in either of two ways—by some job-fabricated assembly of pipe nipples and boxes or by means of a manufactured through-floor assembly (Fig. 300.39) made expressly for the purpose and tested and listed by a nationally recognized testing lab, such as UL.

Numbered components include (1) combination floor service box, (2) fire-rated center coupling, (3) concrete slab, (4) barred extension, and (5) barred junction box.

UL-listed assembly is fire-rated for thickest concrete slab.

Bottom end of UL-listed poke-through fitting consists of a partitioned box for 120-V circuit and telephone circuit run through vertical channels of fitting into dual-service floor outlet box on top of slab.

Fig. 300-39. Several manufacturers make UL-listed poke-through assemblies. (Sec. 300.21.)

May either of the methods be used? A clear regulation of the Occupational Safety and Health Administration (OSHA) appears to rule decisively on this question. OSHA clearly and flatly

demands that an installation or equipment determined to be safe by a nationally recognized testing lab must always be used in preference to any equipment not certified by a testing lab. Thus, if a UL-listed poke-through fitting is available, then the use of any nonlisted, homemade assembly that has not been determined to be safe appears to be clearly not acceptable to OSHA.

300.21 also applies to cable and/or conduit penetrations of fire-rated walls, floors, or ceilings without altering the fire rating of the structural surface (Figs. 300-40 and 300-41).

Fig. 300-40. Fire-stop fitting for passing cables or conduit through a fire-rated wall, floor slab, or similar concrete surface, without altering the fire rating of the surface. (Sec. 300.21.)

Fig. 300-41. Another type of device to provide for passing cable and/or conduit through fire-rated building surfaces without altering the conditions of fire resistance. (Sec. 300.21.)

Ceiling Penetrations

Another similar concern covered by this section is the installation of lay-in lighting fixtures in a fire-rated suspended ceiling. Suspended ceilings are usually evaluated only for their esthetic and acoustic value, but they also serve as fire-protective membranes for the floor above. Although concrete floor structures have various fire-resistance ratings by themselves (depending on the concrete thickness and aggregate used), some assemblies require some type of protective cover. When this is the case, the ceiling is tested in combination with the floor-slab structure for which the rating is desired. Such a ceiling properly serves its function of fire protection until an installer cuts holes in it, such as for recessed lighting fixtures or for air diffusers or grilles. Because of that, the acceptability of the overall ceiling system must be carefully determined. Refer to the discussion at 300.11(A)(1) for more information on this part of the process.

The informational note following the basic rule provides some guidance, but the following presents a comprehensive step-by-step procedure for using the publications vaguely referenced in the note. First, check the Underwriters Laboratories' Guide Card information [see discussion at 110.3(B) for details], which notes that recessed fixtures that have been shown to provide a degree of fire resistance with the floor, roof, or ceiling assemblies with which they have been tested are labeled as follows: "Recessed-type electric fixture classified for fire resistance; fire-resistance classification floor and ceiling Design No. — —." Next, find the design referred to in the *UL Fire Resistance Index*. This booklet follows the format to that used with UL Guide Card information. Refer to a design of the required fire rating and be sure that the fixtures are listed for use with that design.

Designers must specify the particular UL design that suits their requirement, note this in the specifications, and be certain that the lighting fixtures are fire-rated in accordance. But it is advisable for the electrical contractor to investigate the ceiling design for possible fire rating in all cases and to receive from the designer written confirmation of the exact nature and value of the rating, if one exists.

In the *UL Building Materials Directory*, various fire-rated assemblies are listed by design number and by rating time. A companion publication, the *Fire Resistance Index*, contains detailed cross-sectional drawings of the assemblies, with all critical dimensions shown. Each pertinent element is usually flagged with an identifying number. Keyed to the number are clarifying statements listing additional critical limitations (such as the size and number of penetrations in the ceiling).

The top installation in Fig. 300-42 was tested and given a 1½-h rating. No protective material was used between the fixture and the floor slab above. A somewhat better rating could have been obtained had protection been provided over the fixture.

Recessed fixture without protective covering (1½-hr rating)

Recessed fixture with box board shell (2-hr rating)

Fig. 300-42. The complete assembly of concrete slab plus fixture and ceiling gets a fire rating. (Sec. 300.21.)

At the bottom of Fig. 300-42 is a fixture with protection. When this construction was tested, failure occurred after 2 h 48 min, and it received a 2-h time rating. Even with this type of protection, the UL listing will limit the area occupied by fixtures to 25 percent of the total ceiling area. (But a coffered ceiling may contain 100 percent lighted vaulted modules.)

Other Penetrations

Plasterboard (gypsum board) panels used so commonly for interior wall construction in modern buildings are fire-rated. UL and other labs make tests and assign fire ratings (in hours) to wall assemblies or constructions that make use of plasterboard. For instance, a wall made up of wood or metal studs with a single course of $\frac{5}{8}$ -in. (15.9-mm) plasterboard on each side of the studs would be assigned a 1-h fire rating. A wall with two courses of $\frac{1}{2}$ - or $\frac{5}{8}$ -in. (12.7- or 15.9-mm) plasterboard on each side of the studs would be a 2-h wall (Fig. 300.43). The assigned fire ratings are based on the thickness and number of courses of plasterboard. And the fire rating is for the wall assembly *without any penetrations into the wall*.

Note: These are only typical assemblies. Carefully determine fire-rating time for specific walls.

Fig. 300-43. Wall assemblies using plasterboard are fire-rated by UL and others. (Sec. 300.21.)

Because of the fire rating assigned to the assembly, any wall so constructed is fire-rated. The wall may be between rooms or between a room and a corridor or stairwell. No distinction is made between an interior wall of an apartment and a wall that separates one apartment from another. All wall assemblies using plasterboard are fire-rated and immediately raise concern over violation of

300.21 if any electrical equipment is recessed in the wall. However, this is one area where an intelligent use of the phrase “substantially increased” may be useful. If the building code considers both sides of a given wall, such as the one between a dwelling unit bedroom and the hallway leading to it, as being in the same smoke compartment and not deserving of any particular fire rating by code, then it is difficult to imagine how using fire-rated electrical penetrations accomplishes any improvement in safety.

Building inspectors and electrical inspectors have generally permitted installation of wall switches, thermostats, dimmers, and receptacles in boxes recessed in plasterboard walls. In single-family houses, the entire interior is not considered to be compartmented. It is assumed that individual rooms or areas are not normally closed off from each other and that fire or smoke spread would not be affected at all by those penetrations. The consensus has been that such small openings cut in the plasterboard do not violate the letter or intent of 300.21.

In apartment houses, office buildings, and other multioccupancy buildings, however, inspectors could logically question use of wiring devices installed in common walls between apartments or between an apartment and a corridor or stairwell. Such walls are assumed to be between interior spaces that are normally closed off from each other by the main doors to the individual apartments. Fire and/or smoke spread, which are normally restricted by the closed doors, might be considered substantially increased by any penetrations of those fire-rated walls (Fig. 300.44). Although switch and receptacle boxes are usually accepted, use of a panelboard in a common wall has been rejected.

Fig. 300-44. Walls separating closed-off spaces must have maintained fire rating. (Sec. 300.21.)

Another issue frequently arises in mirror image construction in apartment houses, where one kitchen will back up to the kitchen in the next unit to save on plumbing costs. The default separation rule on boxes is 600 mm (24 in.) of horizontal separation, and that dimension applies even if framing members intervene. With boxes required every few feet in kitchen counters, these rules need careful

attention. There are now listed nonmetallic boxes that do not require the full horizontal separation. In addition, there are now listed “putty pads” that can be used to wrap around metal boxes that also dramatically reduce the required separation.

For larger electrical equipment, such as panelboards, the same general analysis would apply. For interior walls of private houses or individual unit occupancies in apartment houses, hotels, dormitories, office buildings, and the like, a panel installed in a wall between two rooms or spaces that are normally not closed off from each other cannot “substantially” contribute to greater fire and/or smoke spread. However, panelboards and similar large equipment should normally not be installed in fire-rated walls between spaces that are closed off from each other by doors that are normally closed.

When it is necessary to install a panelboard or other large equipment in a wall between areas that are normally closed off from each other, a boxed recess in the wall should be constructed of the fire-rated plasterboard to maintain the fire rating of the wall (Fig. 300.45). This is also a common practice for installing recessed enclosures for fire extinguishers in corridor walls and medicine cabinets mounted in walls between apartment units.

Fig. 300-45. Boxing of large-area penetrations has been required in fire walls. (Sec. 300.21.)

Another technique that has been used to maintain fire rating where a panelboard is installed in a wall between individual apartments is to glue pieces of plasterboard to the top, bottom, sides, and back of the recessed panel. In one particular job, this was done as a corrective measure where panelboards had first been installed in such walls without attention to maintaining the fire rating of the wall. But the use of plasterboard directly affixed to the panelboard surfaces could be considered an unauthorized modification of the panel that voids UL listing because of improper application.

There are now fire protection materials that are designed to be applied to panelboards that allow the preservation of up to a 2-hour fire separation, and they have the listings to support those claims. Typically they come with specifications as to the numbers and sizes of steel raceways that can enter which walls of the enclosure. If it is necessary to vary from the anticipated limits, the manufacturer will accept requests for variances and will quickly provide engineered analyses to back up such variances if appropriate. The author recently used this process to retrofit a panel into a 2-hour wall.

300.22. Wiring in Ducts Not Used for Air Handling, Fabricated Ducts for Environmental Air, and Other Spaces for Environmental Air (Plenums). Part (A) of this section applies only to wiring in the types of ducts described, which can contain no wiring systems of any type. Part (B) covers use of wiring methods and equipment within “ducts or plenums,” which are channels or chambers intended, specifically fabricated, and used only for supply or return of conditioned air. Such ducts or plenums are sheet metal or other types of enclosures that are provided expressly for air handling and must be distinguished from “Other Space Used for Environmental Air”—such as the space between a suspended ceiling and the floor slab above it. Space of that type is covered by part (C) of this section. The space between a raised floor ([Fig. 300.46](#)) and the slab below the raised floor is also covered by part (C), unless the air-handling raised floor is within a computer room. If the raised floor is in a computer room, as defined in Art. 645, part (D) states that such an air-handling raised floor used for data-processing circuits must comply with Art. 645.

Fig. 300-46. Space under a raised floor, which is commonly used for circuits to data-processing equipment and provides for passage of conditioned air to the room and to the equipment is covered in part (D). (Sec. 300.22.)

Part (B) addresses actual duct systems with air movement and excludes all wiring with any nonmetallic coverings and with pervious enclosures. Thus, Type MC cable is acceptable, but only in its corrugated or smooth forms, and never with a nonmetallic jacket. Type MI cable is acceptable as well. Flexible metallic tubing, rigid and intermediate metal conduit, and electrical metallic tubing are permitted for the same reasons. Greenfield is permitted, but only where absolutely needed to repositionable equipment required to be there and never in lengths over 1.2 m (4 ft). A new 2017 **NEC** exception based on correlation with the NFPA 90A standard effectively permits comparable lengths (up to 4 ft) of other wiring suitable for Part (C) (plenum) applications to be used under similar conditions as the principal rule here (direct action on the air stream). Enclosed and gasketed luminaires are also permitted in association with other necessary equipment.

Part (C) covers other spaces used for environmental air movement, particularly plenum cavity ceiling spaces, where the space above a hung ceiling point is used as a central collection point for return air to a central air handler. These spaces are now formally considered to be, in accordance with the subsection title, actual plenums. In effect, now the word “plenums” freely substitutes for the former phrasing “other air handling spaces.” Prior to the 2011 **NEC** a plenum was specifically fabricated for air transport; its use now stands that concept on its head, and plenum cavity ceilings are now plenums. This new usage is consistent with mechanical codes and also the way the **NFPA** air conditioning and ventilation standard uses the word. Refer also to the commentary in this book on the Art. 100 definition.

These spaces present a less intensive, but comparable concern as actual ductwork carrying the same air, and the **NEC** rules are also comparable, but slightly less intense as well. There is an important exception at this point, generally used for Type NM cable, that excludes joist or stud cavities used for return air movement, as shown in [Fig. 300-47](#). This exception, however, has two very specific limitations. First, it only applies to dwelling units. Second, it only applies if the wiring involved passes straight across the short dimension. That means no turns, no device boxes, etc.; just straight across.

Fig. 300-47. A joist space through which Type NM cable passes “perpendicular to the long dimension” of the space may be closed in to form a duct-like space for the cold-air return of a hot-air heating system—but only in a “dwelling unit.”

This part permits use of totally enclosed, nonventilated, insulated busway in an air-handling ceiling space, provided it is a non-plug-in-type busway that cannot accommodate plug-in switches or breakers. This one specific busway wiring method was added for hung-ceiling space used for environmental air. The methods in part B can be used, except that interlocking-armor Type MC cable can be used as well (but still no nonmetallic covering is allowed). Surface metal raceway or wireway with metal covers or solid-bottom metal cable tray with solid metal covers may be used in air-handling ceiling space, provided that the raceway is accessible, such as above lift-out panels. Other factory-assembled cable assemblies (without nonmetallic jackets) for use with Art. 604 manufactured wiring systems are allowable as well. (See [Fig. 300-48](#).) The 2014 **NEC** has added a further limitation at this point, disallowing any nonmetallic cable ties or “nonmetallic cable accessories” unless they are listed as having “low smoke and heat release properties.” This requirement also correlates with work done in **NFPA 90A**. The air-handling space under a raised floor in a data-processing location is covered by Art. 645 on information technology equipment.

Figure 300-49 shows wiring methods for use in an air-handling ceiling space. Note that acceptable cable tray applications now appear in their own numbered paragraph (2). Cable trays must be constructed of metal, and if they contain wiring methods other than those normally permitted in these spaces, they must be the functional equivalent of metal wireways, with solid metal bottoms, sides, and covers.

Fig. 300-48. Modular wiring systems, as recognized by Art. 604, are permitted to be used in air-handling ceiling spaces.

Fig. 300-49. Any wiring method other than these is a violation in air-handling space. (Sec. 300.22.)

The Code panel has made it clear that they generally oppose nonmetallic wiring methods in ducts and plenums and in air-handling ceilings, except for nonmetallic cable assemblies that are specifically listed for such use. It is also the intent of the Code that cables with an outer overall nonmetallic jacket should not be permitted in ducts or plenums. Although the jacket material—usually PVC—would not propagate a fire, it would contribute to the smoke and provide additional flammable material in the air duct. The last sentence in the opening language of part (C) is intended to exclude from the requirements those areas that may be occupied by people. Hallways and habitable rooms are being used today as portions of air-return systems, and while they have air of a heating or cooling system passing through them, the prime purpose of these spaces is obviously not air handling.

Part (C)(2) splits off cable tray applications from the general wiring method coverage in (C)(1). Metal cable trays can always be used provided they only support cabled wiring methods that are allowable in such spaces anyway, such as Type MC cables without plastic coverings. In addition, other wiring methods are permitted in cable tray types that are the functional equivalent of a metal wireway, with solid bottoms, sides, and covers.

Part (C)(3) permits use of nonmetallic equipment enclosures and wiring that are specifically UL-listed or classified for use in air-handling ceiling spaces. The basic condition that must be satisfied is that the wiring materials and other construction of the equipment must be suitable for the expected ambient temperature to which they will be subjected, and constructed of materials tested in terms of minimal degrees of both heat release and smoke production.

In effect, the rules in parts (B) and (C) exclude from use in all air-handling spaces any wiring that

is not metal-jacketed or metal-enclosed, to minimize the creation of toxic fumes due to burning plastic under fire conditions. 800.113(C), and similar rules in Art. 810, 820, and 830 covering radio, cable TV, and power broadband networks, basically require telephone, intercom, and other communications circuits to be wired with Type CMP cable or other identified types installed in compliance with 300.22 when such circuits are used in ducts or plenums or air-handling ceilings. Wiring in air-handling space under raised floors in computer centers must use the wiring methods described in 645.5(E). Ventilation in the raised-floor space must be used only for the data-processing area and the data-processing equipment.

Application of that Code permission on use of equipment calls for substantial interpretation. The designer and/or installer must check carefully with equipment manufacturers and with inspection agencies to determine what is acceptable in the air-handling space above a suspended ceiling. Practice in the field varies widely on this rule, and Code interpretation has proved difficult.

The exception to part (C)(3) recognizes the installation of integral fan systems where such equipment has been specifically approved for the purpose. Equipment of this type is UL-listed and may be found in the *Guide Card information* under the heading “Heating and Ventilating Equipment.”

300.34. Conductor Bending Radius. This section covers the acceptable final bending radius of medium-voltage conductors in enclosures. This section is important because it is referenced in other locations in the **NEC**. For example, if a medium-voltage cable enters the back of a pull box opposite to a removable cover, this section sets the minimum depth allowed for the pull box. The dimensions are based on the diameters of the cables being installed. Great care must be used at medium-voltage cable terminations in enclosures, which may only be wide enough for straight-in terminations. Many failures have occurred after cables were bent into loops prior to landing in enclosures not wide enough to allow such loops to be formed without overstressing the shielding.

300.35. Protection Against Inductive Heating. This rule echoes 300.20, but it is worth noting that the higher power and voltages involved in these applications have produced dramatic failures in comparatively short order, as in within days of becoming energized.

300.37. Aboveground Wiring Methods. Conductors aboveground must be in rigid metal conduit, in intermediate metal conduit (IMC), in electrical metallic tubing, in auxiliary gutters, in cable trays, in a cable bus, in busways, in other identified raceways, or as open runs of metal-clad cable suitable for the use and purpose ([Fig. 300.50](#)). Rigid nonmetallic conduit has been added to the list of raceways acceptable for running medium-voltage circuits aboveground—and the PVC (and RTRC) conduit does not have to be encased in concrete. The phrase “other identified raceways” includes wireways; auxiliary gutters are specifically added because they are not raceways but should be permissible in this context. Refer to the discussion in Art. 100 on the raceway definition on this point.

Fig. 300-50. A variety of wiring methods may be used for aboveground high-voltage circuits. (Sec. 300.37.)

In locations accessible to qualified persons only, open runs of Type MV cable, bare conductors, and bare busbars may be used. The 2017 **NEC** additionally recognized medium-voltage airfield lighting series circuits for exposed applications in restricted access lighting vaults.

300.38. Raceways in Wet Locations Above Grade. This was a new section as of the 2014 **NEC** and it carries the existing rule in 300.9 for work below 1000 V to Part II for higher voltages.

300.40. Insulation Shielding. One of the basic decisions to make in selecting medium-voltage conductors is whether or not electrostatic insulation shielding is required on the cable. The basic requirements on electrostatic shielding of medium-voltage conductors are presented later in this chapter in the coverage of 310.10(E).

This section sets forth very general rules on terminating shielded medium-voltage conductors. The metallic shielding or any other conducting or semiconducting static shielding components on shielded cable must be stripped back to a safe distance according to the circuit voltage, at all terminations of the shielding. At such points, stress reduction must be provided by such methods as the use of potheads, terminators, stress cones, or similar devices. The wording of this regulation makes it clear that the need for shield termination using stress cones or similar terminating devices applies to semiconducting insulation shielding as well as to metallic-wire insulation shielding systems.

A stress cone is a field-installed device or a field-assembled buildup of insulating tape and

shielding braid that must be made at a terminal of medium-voltage shielded cable, whether a pothead is used or not. A stress-relief cone is required to relieve the electrical stress concentration in cable insulation directly under the end of cable shielding. Some cable constructions contain stress-control components that afford the cable sufficient stress relief without the need for stress-relief cones. If a cable contains inherent stress-relief components in its construction, that would satisfy 300.40 as doing the work of a stress cone. As a result, separate stress cones would not have to be installed at the ends of such cable. Or, heat-shrinkable tubing terminations may be used with stress-control material that provides the needed relief of electrostatic stress.

At a cable terminal, the shielding must be cut back some distance from the end of the conductor to prevent any arcing over from the hot conductor to the grounded shield. When the shield is cut back, a stress is produced in the insulation. Providing a flare-out of the shield, that is, extending the shield a short distance in the shape of a cone, relieves the stress, as shown in Fig. 300-51.

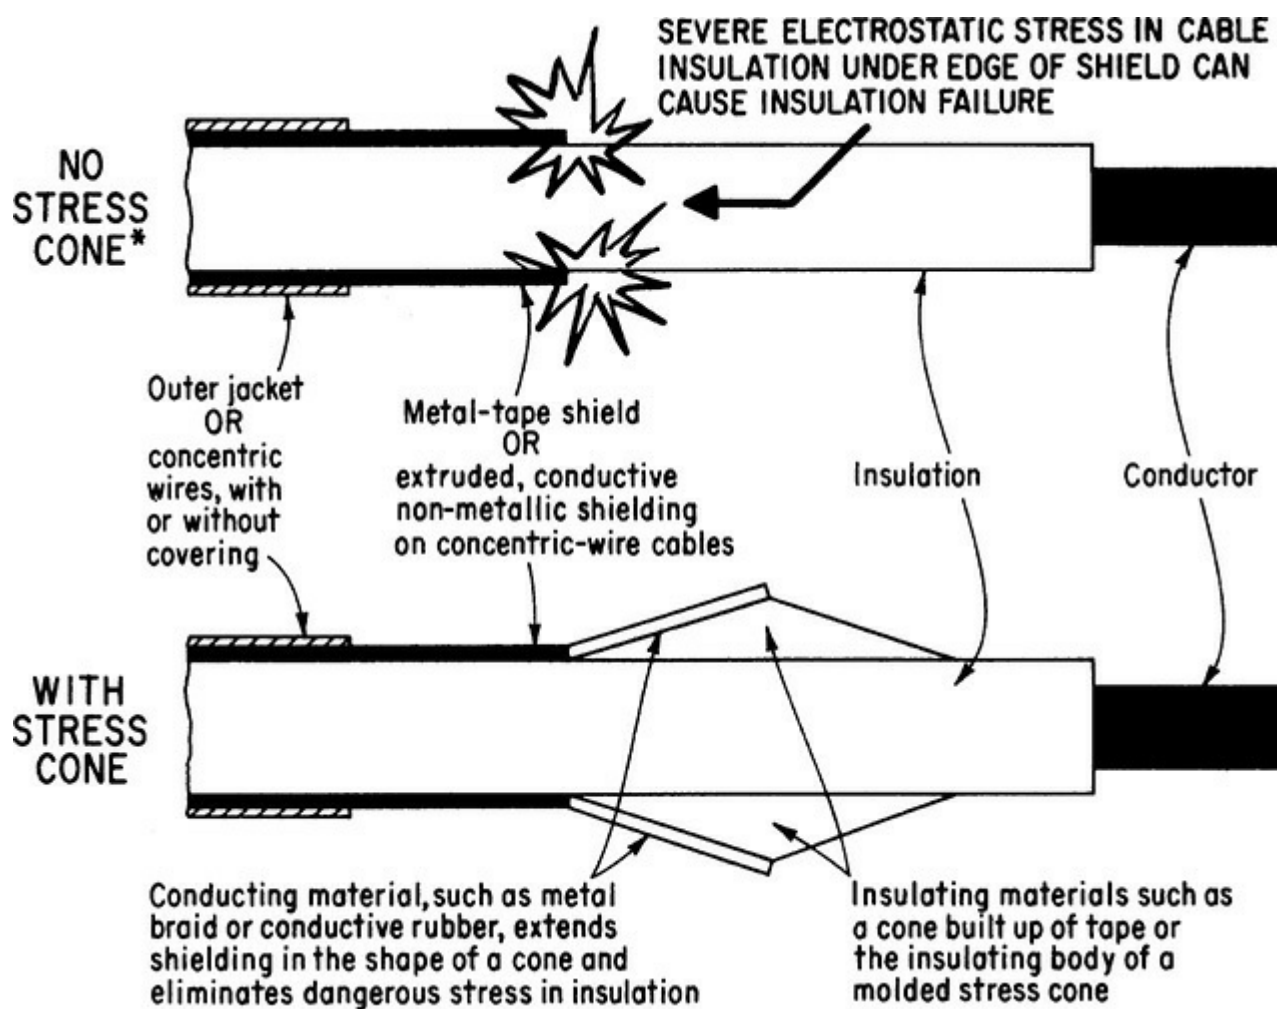

Fig. 300-51. Here is how a stress cone protects insulation at cable ends. (Sec. 300.40.)

Stress cones provide that protection against insulation failure at the terminals of shielded medium-voltage cables. Manufacturers provide special preformed stress cones (Fig. 300.52) and kits for preparing cable terminals with stress cones for cables operating at specified levels of medium voltage (Fig. 300.53). A wide assortment of stress-relief terminators are made for all the medium-voltage cable assemblies used today.

APPLICATION:

Cable shield is cut back about 12 in. Then, using silicone lubricant, the cable insulation surface and the inner bore of the stress cone are lubricated. The stress cone is simply pushed down over the cable end until it bottoms on the cable shield. After cable is prepared, termination takes about 30 seconds.

REFER TO DIAGRAM:

1. Cable insulation with shielding cut back
2. Tight fit between insulation and bore of stress cone
3. Insulating rubber
4. Stress relief provided by conductive rubber flaring away from insulation along bond between insulating rubber and conductive rubber
5. Conductive rubber of cone tightly fit to conductive cable shield

Fig. 300-52. Typical preformed stress cone is readily applied on cables up to 35 kV indoors. (Sec. 300.40.)

THIS IS CABLE PREPARED FOR PENNANT STRESS CONE

STEP 1— Wrap the cone build-up around the insulation at a given place

STEP 2— Cone assembly with preshaped wrap finished

STEP 3— Semi-conducting tape contacts semi-conducting cable jacket and extends up to peak of cone

STEP 4— Entire stress-cone assembly is then wrapped with insulating tape

STEP 5— Insulate terminal fitting area at end of cable and (for outdoor use) cover entire assembly with silicone tape or use potheads.

Fig. 300-53. “Pennant” method is one of a variety of job-site termination buildups. (Sec. 300.40.)

Metallic shielding tape must be grounded, as required by 300.40 and 300.5(B), which refer to “metallic sheathing,” as in [Fig. 300-54](#). The shield on shielded cables must be grounded at one end at least. It is better to ground the shield at two or more points. Grounding of the shield at all terminals and splices will keep the entire length of the shield at about ground potential for the safest, most effective operation of the cable. Cable with improperly or ineffectively grounded shielding can present more hazards than unshielded cable.

Metal conduit and metal sheath or electrostatic shielding must be effectively grounded at terminations by connection to grounded metal enclosure, by bonding jumper, etc., to limit voltage to ground and facilitate operation of overcurrent protective devices.

Fig. 300-54. Metallic shielding must be grounded for all high-voltage conductors—under- or aboveground. (Sec. 300.40.)

In addition to the requirements at terminations that apply to shielding, there is a related topic, that of the actual connector at the end, such as a lug. It should be designed to be compatible with medium-voltage applications. Its external surfaces should be well rounded to minimize the production of corona discharge. These lugs are available as listed items.

300.42. Moisture or Mechanical Protection for Metal-Sheathed Cables. A pothead is one specific form of stress-reduction means referred to in 300.40 and has long been a common means of protecting insulation against moisture or mechanical injury where conductors emerge from a metal sheath (Fig. 300.55). Such protection for metal-sheathed cables (such as lead-covered, paper-insulated cables) is required by this section. A *pothead* is a cable terminal that provides sealing to the sheath of the cable for making a moisture-proof connection between the wires within the cable and those outside.

Fig. 300-55. Typical single-conductor pothead protects metallic- or nonmetallic-jacketed cable. (Sec. 300.42.)

When metal-jacketed medium-voltage cables are terminated outdoors exposed to the weather, a pothead is commonly used to protect the insulation of conductors against moisture or mechanical injury where conductors emerge from a metal sheath, as shown in [Fig. 300-56](#).

Fig. 300-56. A pothead is used on the end of each paper-insulated, lead-covered cable to protect against entry of moisture, with a wiped lead joint at the terminal. (Sec. 300.42.)

On use of potheads:

1. Paper-insulated cables must be terminated in potheads. This requirement also extends to such cables operated at under 600 V.
2. Varnished-cambric-insulated cables should be terminated in potheads but may be terminated with taped connections in dry locations.
3. Rubber-insulated cables are commonly terminated in potheads in locations where moisture protection is critical but may be terminated without potheads in accordance with manufacturer's instructions.
4. Although many modern medium-voltage cables can be terminated without potheads, many engineers consider potheads the best terminations for medium-voltage cable.
5. The use of potheads offers a number of advantages:
 - a. Seals cable ends against moisture that would damage the insulation
 - b. Provides a compartment for surrounding the termination with insulating compound to increase the strength of electrical insulation
 - c. Seals cable ends against loss of insulating oils
 - d. Provides engineered support of connections

In the past, medium-voltage circuits used for commercial and industrial feeders, both outdoors and indoors, were covered in Art. 710. The 1999 Code eliminated Art. 710 and dispersed the rules formerly given in that article throughout the Code. Rules on wiring method are now contained in Part II of Art. 300. Although voltages up to 15,000 V (15 kV) are most commonly used for these circuits

today, higher voltages (26 and 35 kV) are often used because they can offer economy for extremely large installations. Typical circuits today operate at 4160/2400 and 13,800/8000 V—both 3-phase, 4-wire wye hookups.

Modern medium-voltage circuits for buildings include overhead bare or covered conductors installed with space between the conductors, which are supported by insulators at the top of wood poles or metal tower structures; overhead aerial cable assemblies of insulated conductors entwined together, supported on building walls or on poles or metal structures; insulated conductors installed in metal or nonmetallic conduits or ducts run underground, either directly buried in the earth or encased in a concrete envelope under the ground; insulated conductors in conduit run within buildings; and multiple-conductor cable assemblies (such as nonmetallic jacketed cables, lead-sheathed cable, or interlocked armor cable) installed in conduit or on cable racks or trays or other types of supports. Another wiring method gaining wide acceptance consists of plastic conduit containing factory-installed conductors, affording a readily used direct earth burial cable assembly for underground circuits but still permitting removal of the cable for repair or replacement.

300.45. Warning Signs. This is a general duty to warn relative to elevated voltages at points of medium-voltage conductor access within conduit and cable wiring systems. Although 314.72(E) for boxes and 490.53 for mobile equipment and 392.18(H) for cable trays have this requirement, there are many other comparable locations such as wireways that do not. This rule was revised in the 2014 **NEC** and relocated from Art. 225.

300.50. Underground Installations. Directly buried nonmetallic conduit-carrying medium-voltage conductors do not have to be concrete-encased they are is a type approved for use without concrete encasement. If concrete encasement is required, it will be indicated on the UL label and in the listing. 300.50 permits direct burial rigid nonmetallic conduit (without concrete encasement) for medium-voltage circuits. Part **(B)** extends to medium-voltage installations, the long-existing concept (see 300.9 for applications at 600 V and below) that the insides of raceways placed in wet locations are to be considered wet locations.

Part **(C)** requires protection of conductors where they emerge from underground ([Fig. 300.57](#)).

CONDUCTORS EMERGING FROM GROUND MUST BE IN APPROVED RACEWAY

Raceways on poles must be rigid conduit, PVC Schedule 80 or equivalent, and the raceway or other enclosure for underground conductors must extend from below the ground line up to 8 ft above finished grade.

Underground circuit to a building must be protected by an approved enclosure or raceway from below the ground line to the point of entrance.

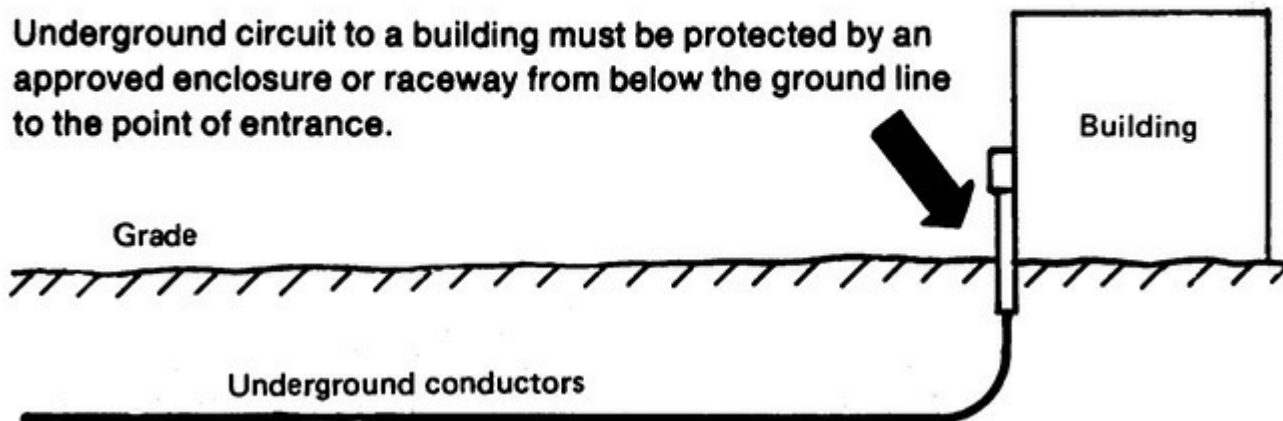

Fig. 300-57. Direct burial cables must be protected aboveground. (Sec. 300.50.)

300.50 makes it clear that underground circuits may be installed in rigid metal conduit, in intermediate metal conduit, or in rigid nonmetallic conduit. Rigid metal conduit or IMC does not have to be concrete-encased, but it may be, of course. Direct burial nonmetallic conduit must be an approved (UL-listed and labeled) type specifically recognized for use without concrete encasement. If rigid nonmetallic conduit is approved for use only with concrete encasement, at least 2 in. (50 mm) of concrete must enclose the conduit. All applications of the various types of nonmetallic conduit must conform to the data made available by UL in the applicable Guide Card information.

Specific footnote c to column 4 of Table 300.50 eliminates the need for any burial depth in earth for conduits or other raceways that are run under a building or exterior concrete slab not less than 4 in. (100 mm) thick and extending at least 6 in. (150 mm) “beyond the underground installation”—that is, overlapping the raceway by 6 in. (150 mm) on each side. Note that the 4 in. (100 mm) thick concrete may be up at grade level in the form of a slab or patio or similar concrete area not subject to vehicular traffic. [Figure 300-58](#) covers burial of underground medium-voltage circuits.

DIRECT-BURIED CABLES

Direct-buried cables must be concentric-neutral or drain-wire shielded type or with a conducting sheath of equivalent ampacity

NOTE: Unshielded cables are not acceptable directly buried!

IN RIGID METAL CONDUIT OR INTERMEDIATE METAL CONDUIT (IMC)

IN RIGID NONMETALLIC CONDUIT

Rigid nonmetallic conduit approved for direct burial—i.e., listed by UL or other nationally recognized testing agency

Rigid nonmetallic conduit requiring concrete encasement must have at least 2 in. of concrete (or equivalent) above conduit, and the conduit itself must be at the depths shown.

Fig. 300-58. Direct burial high-voltage cables must be of correct type, at specified depth. (Sec. 300.50.)

Part (A)(2) is new as of the 2014 **NEC** and covers the use of unshielded 2000-V conductors in qualified industrial locations where the conductors are directly buried, with the appropriate listing. The principal use of this provision is likely to be for PV farms on industrial property.

Part (A)(3) in 300.50 notes that other unshielded cable (i.e., cable without electrostatic shielding on the insulation)—other than within a metallic-sheathed cable assembly—must be installed in rigid metal conduit, in IMC, or in rigid nonmetallic conduit encased in not less than 3 in. (75 mm) of concrete. The effect of this rule is that unshielded, or nonshielded, cables may not be used directly buried in the earth. By reference to 310.10(F), nonshielded cables may be directly buried up to a rating of 2000 V, except that metal-encased, nonshielded conductors (as in Type MC or lead-jacketed cables) may be used in ratings up to 2400 V (other unshielded cables allowed up to 5000 V for series lighting at airfields). But all direct burial cables must be identified for such use. As indicated above, when nonshielded cable (of the nonmetallic-jacket type) is used underground in rigid nonmetallic conduit, the conduit must have a 3 in. (75 mm) thick concrete encasement. But if the same nonshielded cable is used in rigid nonmetallic conduit aboveground, concrete encasement is not required.

Figure 300-58 demonstrates uses of direct burial medium-voltage cables in relation to the Code rules. Figure 300-59 covers underground medium-voltage circuits in raceways. Figure 300-60 covers the basic rules of Table 300.50, subject to the considerations noted in the rules and exceptions, as follows:

VIOLATION—Under areas subject to heavy vehicular traffic, minimum burial depth must be 24 in. for any kind of circuit.

Fig. 300-59. Underground raceway circuits may vary widely in acceptable conditions of use. (Sec. 300.50.)

O.K.—Minimum 24-in. depth is required under areas of heavy traffic (even if conduit is concrete-encased).

? EMT is O.K. for direct earth burial and may satisfy 300.50 as a "raceway approved for the purpose." But Table 300.50 does not mention use of EMT.

? This is O.K. if rigid nonmetallic conduit is used in the concrete and the 18-in. burial depth from Table 300.50 is used. **BUT**—use of EMT in the concrete in this manner is not covered by the *NE Code*

VIOLATION—At this voltage, minimum burial depth for nonmetallic conduit must be 24 in. from Table 300.50.

Fig. 300-60. Underground high-voltage circuits must observe burial depths. (Sec. 300.50.) EMT, for the reasons given in the discussion at 300.5, is not a good choice for direct burial.

1. Where run under a building or slab that is at least 4 in. (102 mm) thick and that extends 6 in. (150 mm) in each direction beyond the cable or raceway.
2. Areas of heavy traffic (public roads, commercial parking areas, etc.) must have minimum burial depth of 24 in. (600 mm) for any wiring method.
3. In industrial locations only, with qualified maintenance and supervision, the minimum cover requirements for other than steel conduits can be reduced by 150 mm (6 in.) for each 50 mm (2

in.) of concrete or equivalent placed entirely within the trench over the underground installation. This applies to the general condition columns (1), (2), and (3). It does not modify the specific condition columns, which apply if applicable.

4. Lesser depths are permitted where wiring rises for termination.
5. Airport runways may have cables buried not less than 18 in. (450 mm) deep, without raceway or concrete encasement.
6. Conduits installed in solid rock may be buried at lesser depths than shown in diagrams when covered by at least 2 in. (50 mm) of concrete that extends to the rock surface.

Item 3 directly corresponds to Table 300.5, row 2 (for 600 V and below), with two differences. First, Table 300.50 allows the 50 mm (2 in.) provision to be duplicated, with successive reductions in burial for each thickness of concrete applied. This is appropriate because Table 300.50 has some required burial depths that are much lower than Table 300.5. In addition, Table 300.50 limits the permission to industrial occupancies, which is not done in Table 300.5. This permission (for medium voltage) had been in the **NEC** since 1968 but it dropped out when the table format was created in the 2005 **NEC**, without substantiation. It has now returned, but with the industrial limitation, a limitation that was never included in any prior version. This may be problematic in the many institutional occupancies that operate medium-voltage systems in campus layouts with similar qualified staffing.

As of the 2008 **NEC** there is now a warning tape requirement comparable to the one for underground service conductors in 300.5(D)(3), but with one significant difference. This rule appears as a footnote “d” to the first column of Table 300.50, and therefore only applies to direct-burial cable work, and not underground raceways whether steel or nonmetallic. The other provisions [“in the trench,” at least 300 mm (12 in.) above the underground installation, and applies only if no concrete protection or encasement] match up to the service protection rules generally. Refer to the discussion at 300.5(D)(3) for more information.

As noted in part **(D)**, splices or taps are permitted in a trench without a box, but only if approved methods and materials are used—that is, listed splice kits. Taps and splices must be watertight and protected from mechanical injury. For shielded cables, the shielding must be continuous across the splice or tap. There is an exception to this continuity rule for engineered systems using direct-buried single-conductor cables with maintained spacing between phases. Under these conditions, the shielding is permitted to be made discontinuous, provided the severed ends of the shielding are overlapped at the point of discontinuity. Each shielded section is then separately grounded at a single point for each end. This interrupts the circulating currents from capacitive charging that become significant on long runs under these conditions. The currents can be high enough such that the shield heating seriously degrades the cable ampacity.

[Figure 300-61](#) shows a permanent straight splice for joining one end of a cable off a reel to the start of a cable off another reel, or for repairing a cable that is cut through accidentally by a backhoe or other tool digging into the ground. T and Y splices are made with similar techniques. Disconnectable splice devices provide watertight plug-and-receptacle assembly for all types of shielded cables and are fully submersible.

Fig. 300-61. Splice may be made in direct burial cable if suitable materials are used. (Sec. 300.50.)

Figure 300-62 covers the rules of parts (D) and (E).

BACKFILL MUST NOT DAMAGE DUCTS, CABLES OR RACEWAYS

Backfill of heavy rocks or sharp or corrosive materials must not be used if it may cause damage or prevent adequate compaction of ground.

Protection shall be provided to prevent physical damage to the raceway or cable in the form of granular or selected material or suitable sleeves.

RACEWAYS MUST BE SEALED

Where raceway enters from an underground system, the end in the building must be sealed with suitable compound to prevent entry of moisture or gases; or it must be arranged to prevent moisture from contacting live parts.

Fig. 300-62. Circuits must be protected and sealed where they enter equipment. (Sec. 300.50.)

ARTICLE 310. CONDUCTORS FOR GENERAL WIRING

310.2. Definitions. The definitions are those for electrical ducts and thermal resistivity that appeared in Codes prior to the 2011 edition adjacent to the medium-voltage ampacity tables. They have been relocated here (and edited to be pure definitions that do not state requirements) because Sec. 2 is the section designated in the *NEC Style Manual* for this material.

310.10. Uses Permitted. In order to make this section look like wiring method sections (which is not required since this is not a wiring method article, but that is another story), as of the 2011 *NEC* former secs. 4, 6, 7, 8, and 9 have been combined here. There is no “Uses Not Permitted” section, so each of the relocated sections are pretty much the same, stating both what is and what is

not permitted, except they have been demoted to lettered subsections.

310.10(A), (B), (C), and (D). Locations. Part (A) on dry locations simply says to use wires as specified in the Code. Part (B) on dry and damp locations lists insulation types that generally, but not always, have a “W” in their insulation designation. Part (C) covers wet locations. Any conductor used in a “wet location” (refer to the definition under “location” in Art. 100) must be one of the designated types—each of which has the letter W in its marking to indicate suitability to wet locations. Any conduit run underground is assumed to be subject to water infiltration and is, therefore, a wet location, requiring use of only the listed conductor types within the raceway. In addition, “moisture-impervious metal-sheathed” cables and conductors can be used; until the 1999 **NEC** this was a permission to use lead-covered wire; the reason for making the change in terminology was never documented although it presumably had to do with the market unacceptability of lead for environmental reasons. Finally, any type listed for use in wet locations, even if not on the specific insulation list, can be used as well.

Part (D) covers locations exposed to direct sunlight, and requires that wiring directly exposed to the sun to have been evaluated for that exposure, or be protected by tape or sleeving that has been so evaluated. UL does those tests as part of its listing evaluations for Type SE cable, so there isn’t a problem there. Incidentally, Type SE cable is an example of wiring that is listed sunlight resistant but the individual wires are not marked accordingly. If they were, then by Code usage of the cable would be “listed and marked”; instead it qualifies as “listed.”

Either one is OK. However, on conduit services this whole requirement has been controversial, since almost every drip loop ever installed before there even was an **NEC** (1897) has used whatever building wire was on hand, provided it was good for wet locations. There have been a number of proposals to exempt drip loops, which emerge from separately bushed holes in the weatherhead, to no avail. Listed coverings are beginning to find their way to market, as are conductors. One major manufacturer is now selling all of its RHH/RHW-2/USE-2 as sunlight resistant, plus its XHHW-2 and its THHN/THWN-2 in all sizes of 2 AWG and larger as having been listed and marked as sunlight resistant.

310.10(E). Shielding. The default effect of this Code rule is to require all open conductors operating over 2 kV to be shielded, unless the conductor is UL-listed for operation unshielded at voltages above 2 kV. However, metal-clad cables, Type MC, using an unshielded cable makeup, are now permitted for use up to 5 kV in industrial establishments with qualified maintenance and supervision. This expands the permitted voltage range of the unshielded product from the 2.4 kV limit in the 2008 **NEC**, and will accommodate the many 4160 distributions still in use. The **NEC** permitted even higher voltages for approximately 60 years prior to the 2005 edition. At that time the limit dropped to 2.4 from 8 kV where it had stood since 1975. It stood from 3 to 6 kV, depending on distribution characteristics (2 kV, rising to 3 kV in 1959, for wet or damp locations), but without a listing requirement since 1947. There is a very large installed base of industrial equipment that lacks the terminating enclosure sizing to accommodate the stress cones associated with shielded cables. This is one of two provisions that provides some relief in this cycle, trading off the higher voltage for the requirement to use a metal-clad construction.

Exception No. 2 is the other provision in this cycle that addresses the installed base of medium-voltage equipment. If the connected equipment is *existing*, listed nonshielded cable can be used for replacement purposes provided it carries the appropriate listing and there is qualified maintenance and supervision. The exception provisions are essentially identical to the ones that applied to

comparable voltage cables prior to the 2005 **NEC**. An informational note following this exception cautions that replaced or relocated equipment may not qualify as “existing” as it is being used in the exception. The provisions that formerly allowed unshielded cables up to 8 kV have been deleted, replaced only by the 2400-V limit. Because 2300-V delta (which is over 2 kV) is the lowest general-purpose, medium-voltage circuit in use today, unlisted conductors must be shielded for such circuits. *But note this:* UL does list 2.4-kV unshielded conductors for use in accordance with Sec. 310.15(10) (E), Table 310.104(D), and other Code rules ([Fig. 310.1](#)). Exception No. 1 allows those cables to be generally used.

Fig. 310-1. A nonshielded conductor (arrow) is permitted for use on a 2300-V circuit (phase-to-neutral), as shown here, *only* if the conductor is listed by UL or another national test lab and approved for use without electrostatic shielding. [Sec. 310.10(E).]

UL also lists shielded conductors up to 35 kV. And, in accordance with **NEC** Table 310.104(B), UL has been listing Type RHH insulated conductors (rubber or cross-linked polyethylene insulation) with electrostatic shielding for operation up to 2 kV.

In addition to applicable **NEC**, Insulated Power Cable Engineers Association (IPCEA), and UL data on use of cable shielding, manufacturers’ data should be consulted to determine the need for shielding on the various types and constructions of available cables.

Shielding of medium-voltage cables protects the conductor assembly against surface discharge or burning (due to corona discharge in ionized air), which can be destructive to the insulation and jacketing. It does this by confining and distributing stress in the insulation and eliminating charging

current drain to intermittent grounds. It also prevents ionization of any tiny air spaces at the surface of the insulation by confining electrical stress to the insulation. Shielding, which is required by this Code rule to be effectively grounded, increases safety by eliminating the shock hazard presented by the external surface of unshielded cables. By preventing electrical discharges from cable surfaces to ground, shielding also reduces fire or explosive hazards and minimizes any radio interference medium-voltage circuits might cause.

Electrostatic shielding of cables makes use of both nonmetallic and metallic materials. As shown in accompanying sketches of typical cable assemblies, semiconductive tapes or extruded coverings of semiconductive materials are combined with metal shielding to perform the shielding function.

Metallic shielding may be done with:

1. A copper shielding tape wrapped over a semiconducting shielding of nonmetallic tape that is applied over the conductor insulation (Fig. 310.2)

Fig. 310-2. A flat copper tape spiraled over the insulation is an electrostatic shield. [Sec. 310.10(E).]

2. A concentric wrapping of bare wires over a semiconducting, nonmetallic jacket over the conductor insulation (Fig. 310.3)

Fig. 310-3. Wires, instead of metal tape, are also used for electrostatic shielding (URD and UD type). [Sec. 310.10(E).]

3. Bare wires embedded in the semiconducting nonmetallic jacket that is applied over the insulation (Fig. 310.4)

Fig. 310-4. Wires embedded in semiconducting jacket form another type of shielding. [Sec. 310.10(E).]

4. A metal sheath over the conductor insulation, as with lead-jacketed cable

For many years, medium-voltage shielded power cables for indoor distribution circuits rated from 5 to 15 kV were of the type using copper tape shielding and an outer overall jacket. But in recent years, cables shielded by concentric-wrapped bare wires have also come into widespread use, particularly for underground outdoor systems up to 15 kV. These latter cables are the ones commonly used for underground residential distribution (called URD). Such a conductor is shown in Fig. 310-3.

In addition to use for URD (directly buried with the concentric-wire shield serving as the neutral or second conductor of the circuit), concentric-wire-shielded cables are also available for indoor

power circuits, such as in conduit, with a nonmetallic outer jacket over the concentric wires. Such cable assemblies are commonly called *drain-wire-shielded* cable rather than *concentric-neutral* cable because the bare wires are used only as part of the electrostatic shielding and not also as a neutral. Smaller-gauge wires are used where they serve only for shielding and not as a neutral.

Figure 310-4 shows drain-wire-shielded medium-voltage cable with electrostatic shielding by means of drain wires embedded in a semiconducting jacket over the conductor insulation. This type of drain-wire-shielded conductor is designed to be used for medium-voltage circuits in conduit or duct for commercial and industrial distribution as an alternative to tape-shielded cables. For the same conductor size, this type of embedded drain-wire-shielded cable has a smaller outside diameter and lighter weight than a conventional tape-shielded cable. For the drain-wire cable the assembly difference reduces installation labor, permits reduced bending radius for tight conditions and easier pulling in conduit, and affords faster terminations (with stress cones) and splices. An extremely important result of the smaller overall cross-sectional area (csa) of the drain-wire-shielded cable is the chance to use smaller conduits—with lower material and labor costs—when conduit is filled to 40 percent of its csa based on the actual cable csa, as covered by Note 5 to the tables in Chap. 9 of the **NEC**.

Another consideration in conductor assemblies is that of strand shielding. As shown in Fig. 310-5, a semiconducting material is tape-wrapped or extruded onto the conductor strands and prevents voids between the insulation and the strands, thereby reducing possibilities of corona cutting on the inside of the insulation.

Fig. 310-5. Strand shielding is part of the overall electrostatic shielding system on the conductor. [Sec. 310.10(E).]

Refer to 300.40 on terminating and grounding shielded conductors. Refer to 250.190(C)(2) for equipment grounding considerations on shielded cables.

310.10(F). Direct Burial Conductors. The first sentence of this section applies to conductors rated for 600 V and lower systems as well as medium-voltage systems, and as noted, it requires conductors used for direct burial applications to be identified for this purpose. The remainder of the Code rules on underground use of conductors rated up to 600 V are covered in the following paragraphs.

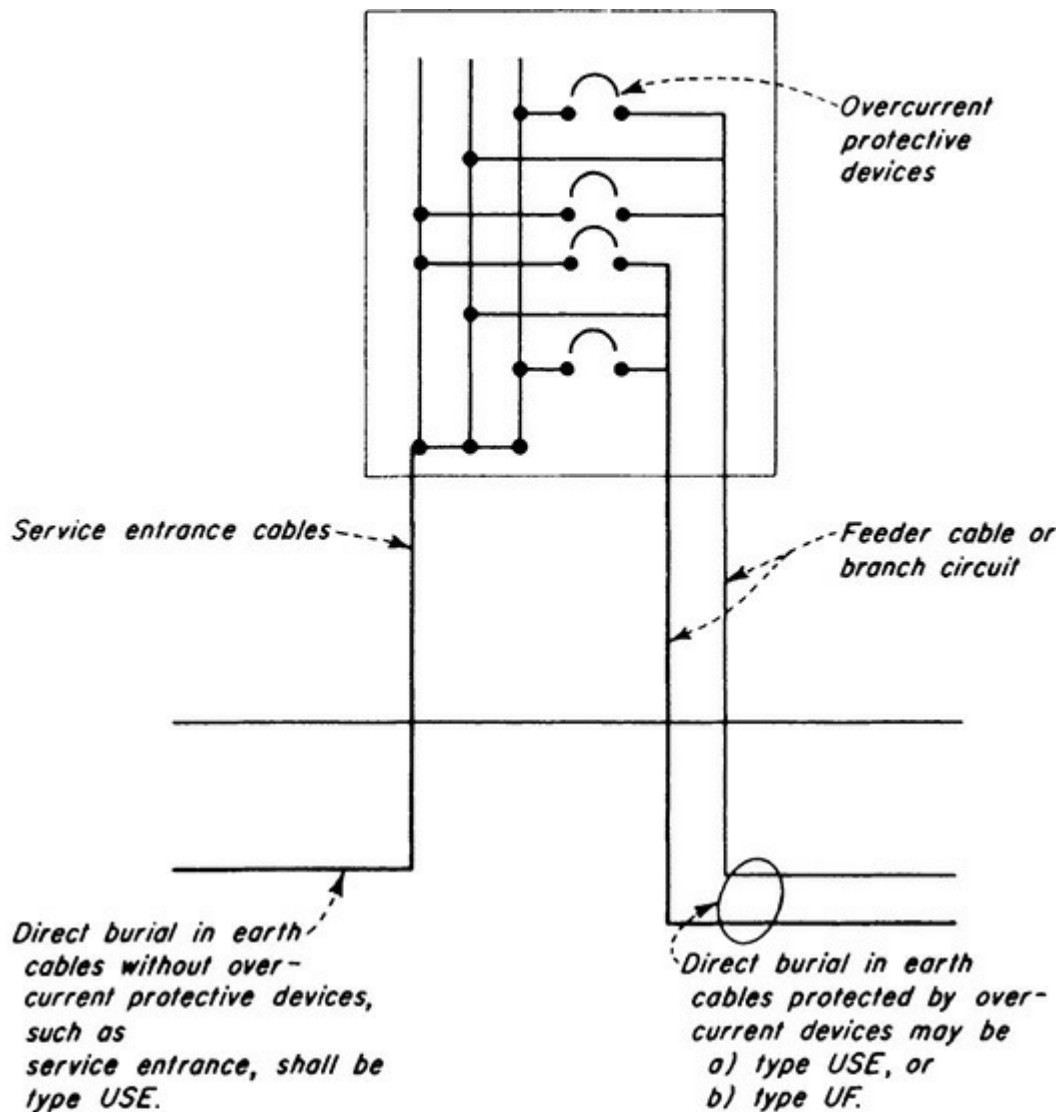

Figure 310-6 shows a clear violation of 310.10(F). In the photo, conductors marked RHW are run

from the junction box below the magnetic contactor, directly buried in the ground. Although Type RHW is suitable for wet locations, it is not approved for direct burial. If, however, the conductors were of the type that is marked RHW-USE—that is, it is listed and recognized as both a single-conductor RHW and a single-conductor Type USE (underground service entrance) cable—then such conductors would satisfy this section.

Fig. 310-6. Bundle of conductors (arrow) is Type RHW individual building conductors that would be suitable for installation in conduit underground but are not marked “USE”; and their use here, run directly buried to outdoor lighting poles, constitutes a violation of the last sentence of Sec. 310.10(F), first paragraph.

Type UF cable is acceptable for direct earth burial. Section 338.10(B)(4)(b) says USE cable used for branch circuits and feeders is to be installed in accordance with Part II of Art. 340 on Type UF cable, and 340.10(A) specifically says the cable is acceptable for direct burial, so that concludes the issue. In addition, the *UL Guide Card information* [see discussion at 110.3(B) for details] notes that listed USE cable is recognized for burial directly in the earth ([Fig. 310.7](#)).

Cables of one or more conductors for direct burial in the earth shall be type USE or type UF.

Fig. 310-7. Types USE and UF cables are designated by the letter U for underground use. [Sec. 310.10(F) first paragraph.]

Besides UF and USE, then, what other cables can be directly buried? 330.10(A)(5) does recognize

MC cable for direct burial “where identified for such use.” 332.10(10) recognizes MI cable for direct burial. Note that 332.10(6) permits MI in “fill” below grade, and 332.10(10) permits it for underground runs with suitable damage and corrosion protection.

For burial-depth requirements on directly buried cables, refer to 300.5 and Table 300.5. Cables approved for direct earth burial must be installed a minimum of 24 in. (600 mm) below grade, as given in Table 300.5, or at least 30 in. (750 mm) below grade for medium-voltage cables as covered in Table 300.50 with its footnotes.

Direct burial conductors should be trench-laid without crossovers; should be slightly “snaked” to allow for possible earth settlement, movement, or heaving due to frost action; and should have cushions and covers of sand or screened fill to protect conductors against sharp objects in trenches or backfill. [Figure 310-8](#) shows some recommended details on installing direct burial cables. Moreover, when conductors are routed beneath roadways or railroads, they should be additionally protected by conduits. To guard against damage that might occur during future digging, conductors in soft fill should be covered by concrete slabs or treated planks.

A—Soft bed of sand or screened fill.

B—Blanket of sand or screened fill 6 in. to 8 in. above top of cable.

C—Cable “snaked” slightly in trench for slack when earth settles. Keep single-conductor cables uniformly apart about 6 in. in trench. Avoid cable crossovers. Keep cable below frost line.

D—Add protective slab (creosoted plank, etc.) on sand fill in areas where future digging might occur. Enclose cable in pipe or conduit under highways or rail tracks.

E—Normal backfill.

Fig. 310-8. This satisfies the intent of Sec. 300.5(F); note that cover requirements, where given in the Code for minimum burial depths, are taken from the top of the electrical conductor, cable, or raceway. The minimum trench depth is, therefore, the cover dimension plus the diameter of the wiring method. If the wiring is not below the frost line, or in ground subject to settlement, requirements in 300.5(J) must be met as well. [Sec. 310.10(F).]

Where prewired cable-in-conduit (Art. 354) is being buried, it also should be slightly snaked, although it is unnecessary to provide sand beds or screen the backfill. Inasmuch as these complete conductor-raceway assemblies can be delivered on reels in specified factory-cut lengths, installation is simplified and expedited.

The second sentence in this section is a standalone paragraph reading “Cables rated above 2000 V shall be shielded.” Therefore direct burial cables over 2 kV must be shielded (Fig. 310.9), with an exception for multiconductor cables up to 2.4 kV if the cable has an overall metallic sheath or armor. There is no **NEC** listing requirement for this cable, which is different from the aboveground requirement in 310.10(E). However, the section has generic language in its first sentence requiring any direct burial cables to be “identified for such use.” Review the discussion in this book at the definition of “identified” in Art. 100 for more information on this point. The metallic shielding must be connected to a grounding busbar or a grounding electrode. Sec. 250.190 still applies and addresses the issues comprehensively.

Fig. 310-9. This application is covered by both Secs. 310.10(F) second paragraph and 300.50. The 2.4 kV cable must be identified for the purpose and has an overall metallic sheath or armor. [Sec. 310.10(F) second paragraph.]

There is also an exception to retain the former allowance for unshielded 5-kV cabling for direct burial applications of series-connected airport runway lighting.

Series lighting is still used in some locations by utilities to provide street lighting, although it is disappearing. It is widely used, with FAA sanction, for airport runways, in applications that are squarely premises wiring and not protected by the utility exemption.

310.10(G). Corrosive Conditions. Figure 310-10 shows how conductors such as Type THHN-THWN are marked to indicate that they are gasoline- and oil-resistant, for use in gasoline

stations and similar places.

Fig. 310-10. Typical marking indicates suitability of conductors for use under unusual environmental conditions. [Sec. 310.10(G).]

310.10(H). Conductors in Parallel. The requirements of part (H) for conductors in parallel recognize copper, copper-clad aluminum, and aluminum conductors in sizes 1/0 AWG and larger. Also, this section makes it clear that the rules for paralleling conductors apply to grounding conductors (except for sizing, which is accomplished in accordance with 250.122) when they are used with conductors in multiple. Conductors that are permitted to be used in parallel (in multiple) include “phase” conductors, “polarity” conductors, “neutral” conductors, and “grounded circuit” conductors. In the places where this section describes parallel makeup of circuits, a grounded circuit conductor is identified along with phase, polarity, and neutral conductors to extend the same permission for paralleling to grounded legs of corner-grounded delta systems and also dc circuits.

This section recognizes the use of conductors in sizes 1/0 and larger for use in parallel under the conditions stated, to allow a practical means of installing large-capacity feeders and services. Paralleling of conductors relies on a number of factors to ensure equal division of current, and thus all these factors must be satisfied in order to ensure that none of the individual conductors will become overloaded.

When conductors are used in parallel, all the conductors making up each phase, polarity, neutral, or grounded circuit conductor must satisfy the five conditions of part (2) in this section. Those characteristics—same length, same conductor material (copper or aluminum), same size, same insulation, and same terminating device—apply only to the paralleled conductors making up each phase, polarity, or neutral of a parallel-makeup circuit. All the conductors of any phase, polarity, or the neutral must satisfy the rule, but phase A conductors (all of which must be the same length, same size, etc.) may be different in length, material, size, etc., from the conductors making up phase B or phase C or the neutral. All phase B conductors must be the same length, same size, and so on; phase C conductors must all be the same; and neutral conductors must all be alike (Fig. 310.11). It is not the intent of the Code rule to require that conductors of one phase be the same as those of another phase or of the neutral. Note that the word “polarity” expressly supports the application of these provisions to dc circuits, if applicable. The only concern for safe operation of a parallel-makeup circuit is that all the conductors in parallel per phase leg (or neutral or grounded conductor) will evenly divide the load current and thereby prevent overloading of any one of the conductors. Of course, the realities of material purchase and application and good design practice will dictate that all the conductors of all phases and neutral will use the same conductor material, will have the same insulation, will have as nearly the same length as possible to prevent voltage drop from causing objectionable voltage unbalance on the phases, and will be terminated in the same way. The size of conductors may vary from phase to phase or in the neutral, depending upon load currents.

Fig. 310-11. This is the basic rule on conductors used for parallel circuit makeup. [Sec. 310.10(H).]

Figure 310-12 shows two examples of parallel-conductor circuit makeup. The photo at bottom shows six conductors used per phase and neutral to obtain 2000-A capacity per phase, which simply could not be done without parallel conductors per phase leg. Note that a fusible limiter lug is used to terminate each individual conductor. Although limiter lugs are required by the **NEC** only as used in 450.6(A)(3), they may be used to protect each conductor of any parallel circuit against current in excess of the ampacity of the particular size of conductor. In addition to protecting against unequal division of current, limiters placed at both ends also increase overall reliability, because in the event

of a ground fault on one of the conductors, the limiters will immediately deenergize only the faulted cable, often allowing the circuit to remain energized at reduced load until a complete shutdown can be arranged. The CB or fuses on such circuits are rated much higher than the ampacity of each individual conductor.

Multiple conductors (two in parallel for each phase leg) are used for normal and emergency feeder through this automatic transfer switch.

Six conductors in parallel make up each phase leg and the neutral of this feeder. Fusible limiter lug on each conductor, although not required by **Code** on other than transformer tie circuits, is sized for the conductor to protect against division of current among the six conductors that would put excessive current on any conductor.

Fig. 310-12. These are examples of circuit makeup using conductors in parallel. [Sec. 310.10(H).]

Where large currents are involved, it is particularly important that the separate phase conductors be located close together to avoid excessive voltage drop and ensure equal division of current. It is also essential that each phase and the neutral, and grounding wires, if any, be run in each conduit even where the conduit is of nonmetallic material.

Part (3) of the section requires the use of the same type of raceway or enclosure for conductors in parallel. The impedance of the circuit in a nonferrous raceway will be different from the same circuit in a ferrous raceway or enclosure. (See 300.20.) In addition, each raceway must have the same number of conductors per phase. This is a recent addition to the **NEC**, after it was substantiated that someone actually ran three sets of parallel conductors through two raceways—two sets in one and one set in the other. Since the heat developed in the raceway with two sets of conductors will significantly differ from the other, and since the resistance of a conductor differs with temperature, the current will divide unequally.

From the Code tables of current-carrying capacities of various sizes of conductors, it can be seen that small conductor sizes carry more current per circular mil of cross section than do large conductors. This results from rating conductor capacity according to temperature rise. The larger a cable, the less the radiating surface per circular mil of cross section. Loss due to “skin effect” (apparent higher resistance of conductors to alternating current than to direct current) is also higher in the larger conductor sizes. And larger conductors cost more per ampere than smaller conductors.

All the foregoing factors point to the advisability of using a number of smaller conductors in multiple to get a particular carrying capacity, rather than using a single conductor of that capacity. In many cases, multiple conductors for feeders provide distinct operating advantages and are more economical than the equivalent-capacity single-conductor makeup of a feeder. However, it should be noted that the reduced overall cross section of conductor resulting from multiple conductors instead of a single conductor per leg produces higher resistance and greater voltage drop than the same length as a single conductor per leg. Voltage drop may be a limitation.

Figure 310-13 shows a typical application of copper conductors in multiple, with the advantages of such use. Where more than three conductors are installed in a single conduit, the ampacity of each conductor must be derated from the ampacity value shown in **NEC** Table 310.15(B)(16). The four circuit makeups show:

1.

A 3-phase circuit of three 2,000 kcmil type THW conductors in a 6-in. rigid metal conduit.
Current rating of each phase = 665 amps.
Cross-section area per phase = 2.9013 sq. in.

2.

A 3-phase circuit of six 400 kcmil type THW conductors (two per phase) in a 4-in. rigid metal conduit.
Current rating of each phase might appear to be = $2 \times 335 = 670$ amps. But, because of the 80% derating required by 310.15(B)(2):
Current rating of each phase = $670 \times 80\% = 536$ amps.
Cross-section area per phase = 1.3938 sq. in. (two conductors).

3.

A 3-phase circuit of three 1,000 kcmil type THW conductors in a 4-in. rigid metal conduit.
Current rating of each phase = 545 amps.
Cross-section area per phase = 1.5482 sq. in.

4.

A 3-phase circuit of six 600 kcmil type THW conductors in a 5-in. rigid metal conduit.
Current rating of each phase might appear to be = $2 \times 420 = 840$ amps. But 80% derating must be applied because of the number of conductors in the conduit:
Current rating of each phase = $840 \times 80\% = 672$ amps.
Cross-section area per phase = 2.0522 sq. in. (two conductors).

Fig. 310-13. These circuit makeups represent typical considerations in the application of multiple-conductor circuits. [Sec. 310.10(H).]

1. Without ampacity derating because there are more than three conductors in the conduit, circuit 2 would be equivalent to circuit 1.
2. A circuit of six 400 kcmil can be made equivalent in ampacity to a circuit of three 2000 kcmil by dividing the 400s between two conduits [3 conductors/3-in. (76-mm) rigid metal conduit]. If

three different phases are used in each of two 3-in. (76-mm) conduits for this circuit, the multiple circuit would not require ampacity derating to 80 percent, and its 670-A rating would exceed the 665-A rating of circuit 1.

3. Circuit 2 is almost equivalent to circuit 3 in ampacity.
4. Circuit 4 is equivalent to circuit 1 in ampacity, but uses less conductor copper and a smaller conduit. The advantages are obtained even with the ampacity derating for conduit fill.

Except where the conductor size is governed by conditions of voltage drop, it is seldom economical to use conductors of sizes larger than 1000 kcmil, because above this size the increase in ampacity is very small in proportion to the increase in the size of the conductor. Thus, for a 50 percent increase in the conductor size, that is, from 1,000,000 to 1,500,000 cmil, the ampacity of a Type THW conductor increases only 80 A, or less than 15 percent, and for an increase in size from 1,000,000 to 2,000,000 cmil, a 100 percent increase, the ampacity increases only 120 A, or about 20 percent. In any case where single conductors larger than 500,000 cmil would be required, it is worthwhile to compute the total installation cost using single conductors and the cost using two (or more) conductors in parallel.

Figure 310-14 shows an interesting application of parallel conductors. A 1200-A riser is made up of three conduits, each carrying three phases and a neutral. At the basement switchboard, the 1200-A circuit of three conductors per phase plus three conductors for the neutral originates in a bolted-pressure switch with a 1200-A fuse in each of the three-phase poles. Because the total of 12 conductors make up a single 3-phase, 4-wire circuit, a 400-A, 3-phase, 4-wire tap-off must tap all the conductors in the junction box at top. That is, the three-phase A legs (one from each conduit) must be skinned and bugged together and then the phase A tap made from that common point to one of the lugs on the 400-A CB. Phases B and C must be treated the same way—as well as the neutral. The method shown in the photo was selected by the installer on the basis that the conductors in the right-hand conduit are tapped on this floor, the center-conduit conductors are tapped to a 400-A CB on the floor above, and the left-conduit conductors are tapped to a 400-A CB on the floor above that. But such a hookup can produce excessive current on some of the 500 kcmil. Because it does not have the parallel conductors of equal length at points of load-tap, the currents will not divide equally, and this is a violation of the second paragraph of 310.4, which calls for parallel conductors to “be the same length.”

Fig. 310-14. A 1200-A circuit of three sets of four 500-kcmil conductors (top) is tapped by a single set of 500-kcmil to a 400-A CB (bottom) that feeds an adjacent meter center in an apartment house. This was ruled a violation because the tap must be made from all the conductors of the 1200-A circuit. (*Note:* The conduits feeding the splice box at top are behind the CB enclosure at bottom.) [Sec. 310.10(H).]

This arrangement is also an unauthorized tap, in violation of 240.21 because it amounts to creating a (in this case) one-third tap, and then (depending on conductor sizing) either using that tap at an excessive length, or tapping that tap, both of which violate the **NEC**. Review the discussion associated with Fig. 240-23 in [Chap. 2](#) for more discussion of this concept.

Exception No. 1 of 310.(H)(1) permits parallel-circuit makeup using conductors smaller than 1/0

AWG—but all the conditions given must be observed.

This exception permits use of smaller conductors in parallel for circuit applications where it is necessary to reduce conductor capacitance effect or to reduce voltage drop over long-circuit runs. It also recognizes the benefits in terms of lower reactance for high-frequency circuits (360 Hz and higher) as are commonly used in the aerospace industry. As it was argued in the proposal for this exception:

If a 14 AWG conductor, for example, is adequate to carry some load of not more than the 15-A rating of the wire, there can be no reduction in safety by using two 14 AWG wires per circuit leg to reduce voltage drop to acceptable limits—with a 15-A fuse or CB pole protecting each pair of 14 AWGs making up each leg of the circuit.

Where conductors are used in parallel in accordance with this exception, the rule requires that all the conductors be installed in the same raceway or cable.

And that will dictate application of the last sentence of 310.4: “Conductors installed in parallel shall comply with the provisions of 310.15(B)(3)a” which applies to wire of 0 to 2000 V. Thus a single-phase, 2-wire control circuit made up of two 14 AWGs for each of the two legs of the circuit would have to be considered as four conductors in a conduit, and the “ampacity” of each 14 AWG would be reduced to 80 percent of the value shown in Table 310.15(B)(16). If TW wires are used for the circuit described, the ampacity of each is no longer the value of 15 A, as shown in Table 310.15(B)(16). With four of them in a conduit, each would have an ampacity of 0.8×15 , or 12 A. Then using a 15-A fuse or CB pole for each pair of 14 AWGs would properly protect the conductors and would also comply with the 240.4(D)(3) which says that No. 14 must not have overcurrent protection greater than 15 A. (See Fig. 310-15.)

From Table 310.16, No. 14 TW copper has ampacity of 15.

“Ampacity reduction” from Table 310.15(B)(3)(a):
 $15 \text{ amps} \times 0.8 = 12 \text{ amps}.$

**15-AMP FUSES PROPERLY PROTECT THE NO. 14s
AND SATISFY THE RULE OF 240.4(D).**

Fig. 310-15. Overcurrent protection must be rated not in excess of the ampacity of one conductor

when conductors smaller than No. 1/0 are used in parallel. Fifteen amperes is the rating of the next higher standard size of overcurrent protection, and therefore does protect the 14 AWG conductors in accordance with 240.4(B). The permitted loads under this exception do not include multiple receptacle outlets. [Sec. 310.10(H)(1) Exception No. 1.]

Exception No. 2 now recognizes the use of parallel conductors in sizes down to No. 2 where used as a neutral, but only in an existing installation. This is a good idea where necessary to accommodate additive harmonics on the neutral of multiwire circuits. The use of two No. 2s provides about 25 percent less cross-sectional area while at the same time providing 25 percent more surface area than a 3/0. This serves to reduce the heating caused by skin effect because the “skin” area has been increased. This exception is limited to existing installations under engineering supervision.

Equipment grounding conductors are to be sized in accordance with 250.122, which means they are sized to the overcurrent device and need not comply with the 1/0 AWG minimum size limitation that applies to load-bearing circuit conductors as itemized in 310.10(H)(1). Equipment (and, by virtue of the 250.102 reference, supply-side) bonding jumpers are also governed by Art. 250 rules and not the 1/0 limit.

310.15. Ampacities for Conductors Rated 0 to 2000 Volts. 310.15 states that ampacities of conductors may be determined by either of the two methods. The first method is described in part (B) and is the old, tested, and familiar method of the **NEC**, based on Tables 310.16 through 310.21, as they were numbered prior to the 2011 **NEC** edition. The second permitted method is covered in part (C) of the **NEC** and is the complex, confusing, incomplete, and problematic procedure that was presented in the 1987 **NEC** as the basic method, based on an elaborate formula to be applied under very sophisticated engineering supervision, as stated there.

The **NEC** ampacity determination procedure using the formula is permitted as an optional alternative “under engineering supervision.” The formula is generally known as the “Neher-McGrath” formula after the authors of a seminal 1957 paper describing a more precise way to measure ampacities, particularly for underground wiring. It takes into account all the factors that impede heat loss from a loaded conductor, including the ability of a raceway wall and the surrounding soil to conduct heat away from the conductors. These topics are considerably complicated by the effect of airspaces within the wiring, hysteresis losses in magnetic conduits (if applicable), and skin effects (depending in part on conductor size). These and other effects become the subject of elaborate side calculations that eventually generate the terms that are included in the overall formula in 310.15(C). Therefore the elaborate formula in the Code is actually deceptively simple. A proper application of the Neher-McGrath formula requires an extremely experienced electrical engineer who has made these calculations a major part of his or her professional specialty. Such engineers are hard to find and generally employed by major high-voltage cable vendors.

All of the ampacity tables based on the formula are in Annex B in the back of the Code book, where information on the formula method and its related ampacity tables is introduced with the sentence, “This informative annex is **not** part of the requirements of this NFPA document but is included for informational purposes only.” Thus, the 1987 **NEC** ampacity method is given as a nonmandatory, optional alternative to the old standby method. The tables do, however, allow for a more accessible format because they present results instead of requiring use of the formula in the field. Also included in Annex B is the old Note 8 ampacity reduction factors [Table B-310.15(B)(3)]

(11)] for multiple conductors in a raceway.

The second paragraph of (A) conveys the basic “weak-link-in-the-chain” principle that says when multiple ampacities apply to a conductor over the course of its run, then the lowest calculated ampacity must be used to determine the characteristics of the circuit. The exception allows a waiver in instances where adjacent portions of the conductor are capable of functioning as a heat sink, allowing the short section with a low ampacity to be ignored.

The exception has been in the **NEC** since the 1990 edition, and until the 2017 edition only applied to adjacent portions of a circuit. For example, suppose a circuit went through a boiler room, with the ampacity diminished by ambient temperatures in that space, on its way to its ultimate destination through areas with normal temperatures. The exception recognized that, to a degree, the heating from the boiler room could be offset by the process of thermal conduction. The adjacent parts of the circuit, to a limited degree, could be relied on as a heat sink for the boiler room exposure. The limits placed in the exception, 10 ft or 10 percent of the adjacent part of the circuit, whichever was less, were the result of a conversation with a renowned electrical engineer then serving on the code panel, based on his personal experience in Texas. The 2017 edition has retained the parameters, but removed the requirement of proximity. The substantiation for this completely ignored the essential concept of thermal conduction that was the basis for the exception in the first place. Until this change is reversed, the inspection community should consider challenging installations making use of it by using the next numbered paragraph.

The third paragraph of (A) is titled: **Temperature Limitation of Conductors**. This used to be 310.10 until the 2011 cycle. This rule says that no matter how your theoretical calculations seem to come out, no matter what number an ampacity table might seem to say is justified, if at the end of the day a wire will be consistently operating at a temperature above the ultimate temperature rating of its insulation, its operating conditions must change accordingly. The factors that influence this are set out in the detailed note following the rule. This rule is seldom cited by electrical inspectors. Instead, it is usually cited indirectly, such as through enforcement of 310.15(B)(3)(a) around a failure to allow for mutual conductor heating (thereby implicitly applying list item 4 from the note), or the failure to account for an elevated ambient temperature derating factor when using the pertinent ampacity table through enforcement of 240.4 (thereby implicitly applying list item 1 from the note), or a failure to account for heating in a neutral in response to triplen harmonic loading through enforcement of 310.15(B)(5)(c) (thereby implicitly applying list item 2 from the note), etc.

However, there are circumstances where this rule must be cited directly, because no other rule in the **NEC** can be cited. What follows is a real-world example, together with the underlying research that made it come together. This author was called on to inspect a single-family whole-house renovation that included a feeder from the basement to a panel in a second-floor storage area. The feeder was protected with a 100 A circuit breaker, and was wired with 2/3 aluminum SER cable with a 4 AWG equipment grounding conductor. The feeder ran through an outside wall of the building, where it went up two stories before swinging over through the attic floor joists and down to the panel. The house had been completely gutted and entirely new insulation consisting of polyurethane foam had been sprayed into all outside wall and ceiling joist cavities, completely embedding this cable.

Now to begin with, since the feeder was not carrying the full load of this single-family house, the special procedure in 310.15(B)(7) does not apply, and therefore the normal values in Table 310.15(B)(16) apply, which in this case would be 90 A, because the 75°C column must be used per 110.14(C)(1)(b). There were no continuous loads on this feeder. However, reducing the feeder

protection to 90 A, although fixing the preceding violations, would still have completely failed to cure a blatant violation of 310.15(A)(3). The reasons for this make good reading.

When wiring is embedded in thermal insulation, the ampacity is significantly degraded, and foamed-in-place polyurethane foam has about the best “R” value of any commercially available thermal insulation. The results tend to get progressively worse for larger cable sizes, because larger cables are generally installed to meet an expectation of higher-current draw. The heat generated by a conductor is I^2R . Larger cables carrying larger currents reduce the heat by the first power due to larger radiating surface areas, and increase the heat by the square of the current increase. This means that large cables tend to be worse than smaller ones, because the latter increase in heat ($+\Delta I^2$) usually overwhelms the former decrease ($-\Delta R$).

In the 1987 **NEC** cycle, this was confirmed by actual NEMA testing, with dramatic results. The test used 2 AWG aluminum Type SE cable of the “SEU” style (two insulated conductors and the grounded conductor configured as a spirally wrapped conductor around the ungrounded conductors). This cable is used routinely for 100 A residential services. It was run through thermal insulation under controlled test conditions. Specifically, the cable was run embedded in cellulose insulation with 7 in. above it. Thermocouples were placed on the cable, and the various loads under test were maintained for long periods. This cable has a Table 310.15(B)(16) ampacity (terminations not considered for this purpose) of 100 A. When the cable was loaded to 100 A, the cable jacket was “completely charred” as well as adjacent “charred wood members,” all while the cable was operating within its table ampacity limitations. In fact, the testing showed (65 A caused 96°C operation) the cable exceeded its rated operating temperature at any time the continuous current exceeded about two-thirds of the table ampacity.

These results strongly demonstrate the fact that the ampacity of a conductor is not necessarily what a table may predict. The ampacity of a conductor is its ability to carry current continuously under the conditions of use. This is determined by thermodynamics, not Code tables. The ampacity of 2 AWG aluminum XHHW configured as 2/3 Al SEU cable and embedded in cellulose insulation is approximately 60 A. Actually, the ampacity corresponding to Table 310.15(B)(16) would be even less than that, because that table is structured around three current-carrying conductors and this testing only used two of the three conductors in the test circuit.

This testing focused on Type SE cable, but a test run using 6 AWG copper in metal conduit embedded in foam insulation overheated those conductors as well, although not as badly. Typical branch circuits do OK by starting in the usually mandated 60°C ampacity column. There is no ampacity table for thermal insulation, and it would be impossible to create one, because variations in R factors significantly change end results. However, it is fair to say, for example, that the ampacity of 4/0 Al SE cable (table ampacity of 205 A) embedded in thermal insulation is far less than even the 60°C table result of 150 A would predict, perhaps as low as 100 A. **NEC** 310.15(A)(3), now focusing on item 3 of its application note, is the only **NEC** rule that covers this point, and it is referenced in notes to a number of cable articles for this reason. To the extent practicable, good practice is to route larger circuits in such a way as to avoid contact with thermal insulation.

And so the citation was 310.15(A)(3), cured with a 60 A circuit breaker, whose terminals were fortunately large enough to accept the 2 AWG feeder conductors, that ran to a panel where, fortunately again, the load per Art. 220 was probably not over 35 A.

In part **(B)**, an informational note points out that “Tables 310.15(B)(16) through 310.15(B)(19) are application tables that are for use in determining conductor size on loads calculated in accordance

with Art. 220.” Inasmuch as the **NEC** itself requires that Art. 220 be used at all times in calculating loads, the ampacity-determination method of part **(B)** is completely adequate for all conductor sizing in accordance with all Code rules.

Correctly integrating load calculation results with ampacity table values, ambient temperature adjustment factors, mutual conductor heating derating factors, termination temperature limitations, etc., is quite possibly the most challenging task confronting electrical personnel today, and also one of the most necessary. After all, if we do nothing else in this trade, we select and install wires. Since there is now a comprehensive example that focuses on these issues at the end of the Code in Annex D [Example D3(a)], the place to integrate these rules is there. Refer to the comprehensive discussion of these issues in [Chap. 9](#) of this book. In addition, there is an analysis with step-by-step calculations on Table B-310.15(B)(3)(11) so you can see how to bring the old Note 8 back to life.

Subparts to 310.15(B) (not in order)

(B)(2) Instead of repeating the same temperature correction factors under all the ampacity tables, the information is now only given once, and the ampacity tables all have a footnote that points here. Note that there are two tables, the first (a) applying to a default temperature of 30°C and that therefore applies to the familiar Table 310.15(B)(16). The second (b) applies to a default temperature of 40°C and applies to all the rest except 310.15(B)(17). The material concludes with the mathematical formula that allows an ampacity adjustment for any temperature to be calculated exactly if necessary.

(B)(7) This rule used to feature a special ampacity table for residential services and main feeders. The 2014 **NEC** removed the table and completely reformatted the rule, but in a way that makes the conductors selected under its provisions identical to those selected under previous **NEC** editions. The 2017 **NEC** has resurrected the old table, and inserted it into the calculation example of this procedure that is in Annex D as Example D7. For qualifying applications, the procedure now is, as before, to begin with a load calculation rounded up to the next higher standard size overcurrent device that will protect the relevant service or principal feeder. Then, instead of taking that number into a special ampacity table, multiply that number by 0.83 instead. If adjustments are required for mutual conductor heating [310.15(B)(3)(a)] or ambient temperature [310.15(B)(2)(a or b)], apply them. Then take the resulting number into Table 310.15(B)(16) and select a conductor with an ampacity, usually in the 75°C column as required by 110.14(C)(1)(b), that equals or exceeds the resulting number. There is a new example (D7) at the end of the Code book that shows this at work for a 175-A service. The calculation gives a result of 145 A, which translates to a 1/0 copper (or 3/0 aluminum) conductor, exactly the same as many previous decades. Note that although this is now a calculation instead of a table, it is not open ended as to size. Both services and feeders are still subject to the 400-A limit of the previous table approach.

This rule has been in the **NEC** in some form for a long time and permits use of certain conductors at ampacity values higher than those shown for the conductors in Table 310.15(B)(16). For instance, a 2/0 AWG THW copper conductor may be used protected at 200 A instead of at 175 A, as shown in Table 310.15(B)(16). This permission has been given by the **NEC** in recognition of the reality that residential service conductors are supplying loads of great diversity and of short operating periods or cycles, so that the conductors almost never see full demand load approaching their ampacity and certainly not for continuous operation (3 h or more). There are crucial conditions that underlie the acceptability of this rule; if any of these conditions is not met, then the rule is invalid and cannot be

used.

1. The conductors are for an individual dwelling unit. They must not be for a collection of dwelling units such as an apartment dwelling, even though it might be argued that the entire load is residential in nature. The collective load of a multifamily dwelling will be calculated differently and may not have the diversity, after the applications of relevant Art. 220 demand factors, of an individual dwelling unit load. The rule has always been based on those individual applications and no technical substantiation has been presented over the years to support broadening the application.
2. The conductors must see the entire load of the dwelling unit, including loads such as outdoor air conditioning units and swimming pools, together with any outbuildings if provided with electric power. For example, removing an air conditioner from a load profile obviously reduces the load. It also increases the intensity of the load that remains on the feeder, and thereby works to undermine the validity of the ampacity values allowed in this section. The load that remains on those conductors will be the subject of a new load calculation reflecting the actual connected load that remains. This process of load shedding could continue until there was only a single load left, which might even run continuously.

The provisions of (4) of 310.15(B)(7) permit the neutral conductor of these 3-wire services and 3-wire feeders to be smaller than the hot conductors because the neutral carries only the unbalanced current of the hot legs and is not at all involved with 2-wire, 240-V loads. However, it must not be sized smaller than 215.2, 220.61, and 230.42 requirements.

Note, however, that this fourth paragraph allowance for reduced neutral sizing does not apply to circuits originating from two phase legs of a 208Y/120-V three-phase distribution.

This limitation on neutral size reductions is all that remains, as of the 2017 **NEC**, of the former blanket prohibition regarding the use of 310.15(B)(7) for dwelling units, typically in large apartment buildings, that were supplied by such distributions. The action to remove this prohibition is extremely controversial, because, quite frankly, it defies the laws of physics. One of the principal reasons the traditional allowance works is that on a single-phase distribution the worst-case heating occurs with two conductors loaded to their full ampacity. This occurs when the entire load is either line to neutral on one side only, or line to line. The heating declines in proportion to the square of any reductions in current as the load becomes more evenly distributed. Since ampacity tables are based on three conductors operating fully loaded, the result is a justified bonus allowance under conditions that guarantee only two-thirds of the calculated heating will be present.

The 2017 **NEC** applies this deserved bonus for single-phase distributions equally to a distribution where all three conductors will see essentially full-loading assuming complete line-to-neutral loading, the worst case. The lowest loading will occur when one line conductor is at 100 percent and the other at 50 percent, in which case the neutral current is reduced to 86 percent ($\frac{1}{2}\sqrt{3}$) of the higher loaded phase conductor. This is why 310.15(B)(5)(b) requires such neutrals to be taken at 100 percent, and, indeed, the **NEC** is not changing that rule in any way. The evident technical validity of that requirement disqualifies the technical validity of this **NEC** change.

The substantiation for this change made essentially two arguments, based on the experience in Canada. The Canadian Code (CEC) allows what is now allowed here, and has done so for some time, apparently with no loss experience to point to as an objection. What this more properly suggests is that the CEC, as is the case with the **NEC**, overstates the actual load on residential feeders. The

electric utilities have been telling us this for many decades. If you routinely overbuild a class of feeders, then you can tolerate a bogus allowance on how you figure ampacity. However, as Art. 220 becomes more genuine in this area, and it is gradually doing so, we will begin to have problems. Neither the CEC nor the **NEC** gets to ignore the laws of physics.

Part (B)(4) 310.15(B)(4) provides that if an uninsulated conductor is used with insulated conductors in a raceway or cable, its size shall be the size that would be required based on it being a conductor having the same insulation as the lowest insulation temperature rating of the adjacent insulated conductors. The point is to assure that its surface temperature will not exceed the temperature rating of any adjacent conductor insulation ([Fig. 310.17](#)).

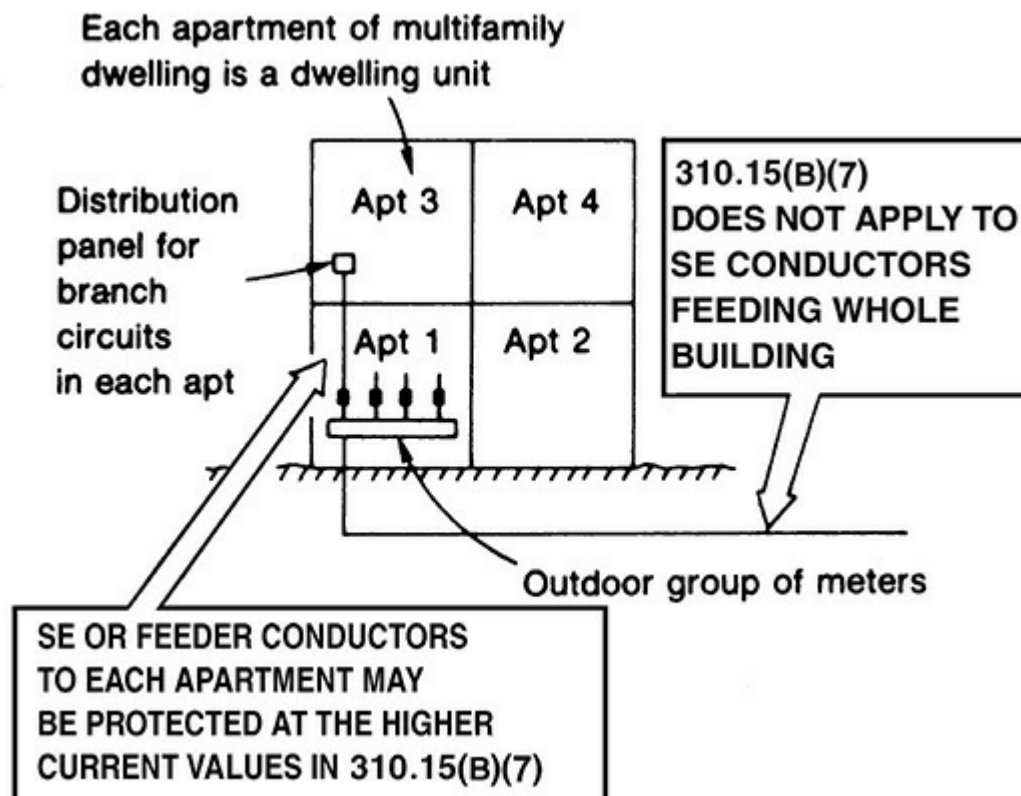

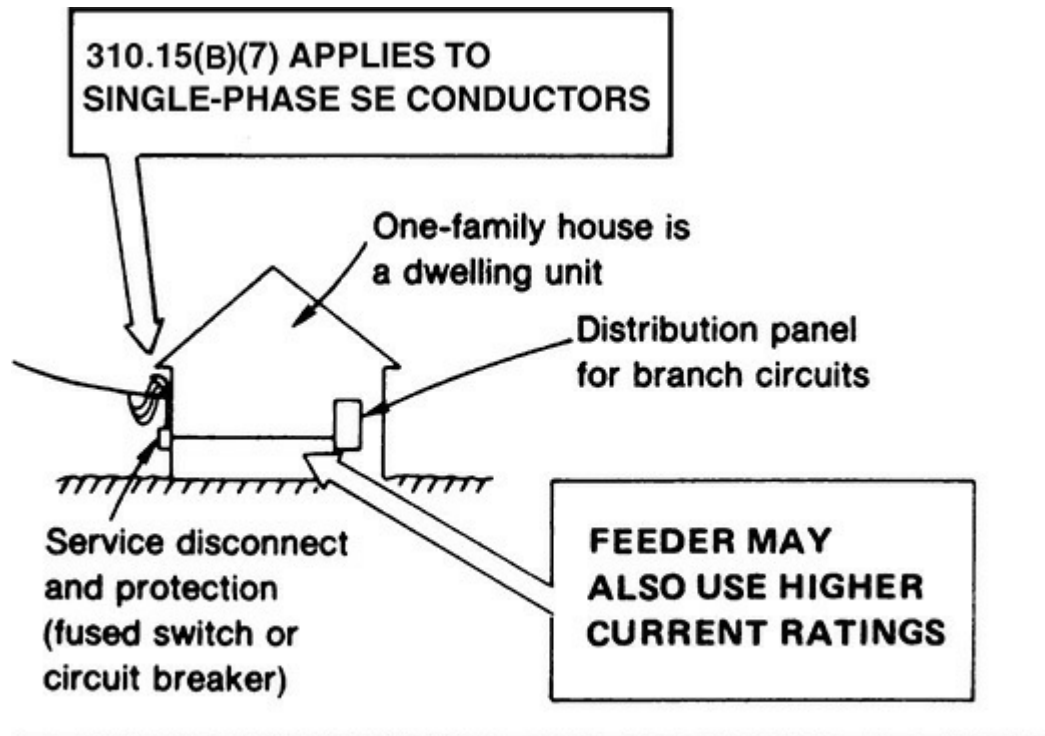

Fig. 310-16. Higher ratings of protective devices may be used for service conductors to “dwelling units.” [Sec. 310.15(B)(7).]

Fig. 310-17. How to figure ampacity of a bare conductor, where permitted. (Sec. 310.15.)

example Two 6 AWG Type THW conductors and one bare 6 AWG conductor in a raceway or cable. The ampacity of the bare conductor would be 65 A.

If the insulated conductor were Type TW, the ampacity of the bare conductor would be 55 A.

Part (B)(3) Where more than three current-carrying conductors are used in a raceway or cable, their current-carrying capacities must be reduced to compensate for the proximity heating effect and reduced heat dissipation due to reduced ventilation of the individual conductors that are bunched or form an enclosed group of closely placed conductors. Where the number of conductors in a raceway or cable exceeds three, the ampacity of each conductor shall be reduced as indicated in the table of part (B)(3).

If, for instance, four 8 AWG THW copper conductors are used in a conduit, the ampacity of each 8 AWG is reduced from the 50-A value shown in the table to 80 percent of that value. In such a case, each 8 AWG then has a new reduced ampacity of 0.8×50 A, or 40 A. And, from 240.4, “Conductors shall be protected in accordance with their ampacities.” Thus, 40-A-rated fuses or CB poles would be required for overcurrent protection as the general rule.

The application of those part (B)(3) conductors and their protection rating is based on the general concept behind the **NEC** tables of maximum allowable current-carrying capacities (called “ampacities”). The **NEC** tables of ampacities of insulated conductors installed in a raceway or cable have always set the maximum continuous current that a given size of conductor can carry continuously (for 3 h or longer) without exceeding the temperature limitation of the insulation on the conductor, that is, the current above which the insulation would be damaged. But, because the overcurrent devices were tested with conductors sized at 125 percent of the continuous current plus the noncontinuous, the conductor’s prederated ampacity must be increased where supplying a continuous load [see 210.19(A)].

This concept has always been verified in the informational note to 240.1, where the wording has been virtually identical for over 30 years and says, “Overcurrent protection for conductors and equipment is provided to open the circuit if the current reaches a value that will cause an excessive or dangerous temperature in conductors or conductor insulation.” To correspond with that objective, 240.4 says, “Conductors, other than flexible cords and fixture wires, shall be protected against overcurrent in accordance with their ampacities as specified in 310.15.”

Table 310.15(B)(16), for instance, gives ampacities under the conditions that the raceway or cable containing the conductors is operating in an ambient not over 30°C (86°F) and that there are not more than three current-carrying conductors in the raceway or cable. Under those conditions, the ampacities shown correspond to the thermal limit of the particular insulations. But if either of the two conditions is exceeded, allowable ampacities have to be reduced to keep heat from exceeding the temperature limits of the insulation:

1. If ambient is above 30°C, the ampacity must be reduced in accordance with the correction factors given in Table 310.15(B)(2)(a) [or (b) depending on the ampacity table under consideration].
2. If more than three current-carrying conductors are used in a single cable or raceway, the conductors tend to be bundled in such a way that their heat-dissipating capability is reduced and excessive heating would occur at the ampacities shown in the table. As a result, part **(B)(3)** requires reduction of ampacity, and conductors must be protected at the reduced ampacity.

(Note: It should be clearly understood that any reduced ampacity—required for higher ambient and/or conductor bundling—has the same meaning as the value shown in a table: Each represents a current value above which excessive heating would occur under the particular conditions. And if there are two conditions that reduce heat dissipation, then more reduction of current is required than for one condition of reduced dissipation.)

Part (B)(3) Requires Derating of Ampacity

Part **(B)(3)(a)** says, “Where the number of current-carrying conductors in a raceway or cable exceeds three ... the allowable ampacity of each conductor shall be reduced as shown in Table 310.15(B)(3) (a).” This table has a heading on the right to require that any ampacity adjustment for elevated ambient temperature must be made in addition to the one for number of conductors. If, for instance, four No. 8 THHN current-carrying copper conductors are used in a conduit, the ampacity of each No. 8 is reduced from the 55-A value shown in Table 310.15(B)(16) to 80 percent of that value. Each No. 8 then has a new (reduced) ampacity of 0.8×55 A, or 44 A. Then, if a derating factor must be applied because the conductors are in a conduit where the ambient temperature is, say, 40°C instead of 30°C, the factor of 0.91 (36°C to 40°C) from Table 310.15(B)(2)(a) must be applied to the 44-A current value to determine the final value of ampacity for the conductors ($44 \times 0.91 = 40$ A).

Moreover, 240.4 of the **NEC** states, “Conductors, other than flexible cords and fixture wires, shall be protected against overcurrent in accordance with their ampacities as specified in 310.15.” Thus, fuses or CB poles rated at 40 A would be required. The ampacity of the conductors is changed and the conductors must be protected in accordance with the derated ampacity value and not in accordance with the tabulated value.

Because conductor ampacity is reduced when more than three conductors are used in a conduit, the overcurrent protection for each phase leg of a parallel makeup in a single conduit would generally have to be rated at not more than the sum of the derated ampacities of the number of conductors used per phase leg. That would satisfy 240.4, which requires conductors to be protected at their ampacities. Because ampacity is reduced in accordance with the percentage factors given in part **(B)(3)** for more than three conductors in a single conduit, that derating dictates the use of multiple conduits for parallel-makeup circuits to avoid the penalty of loss of ampacity.

Figure 310-18 shows examples of circuit makeups based on the unsafe concept of load limitation

instead of ampacity derating, as applied to overcurrent rating and conductor ampacity—which is a Code violation, because the conductors are not protected in accordance with their ampacities.

Part (B)(2) max. conductor ampacity per phase
= $0.7 \times 600 = 420 \text{ A}$

Possible current in excess of conductor thermal limit
= $600 - 420 = 180 \text{ A}$

Part (B)(2), max. conductor ampacity per phase
= $0.8 \times 760 = 608 \text{ A}$

Possible current in excess of conductor thermal limit
= $800 - 608 = 192 \text{ A}$

Fig. 310-18. Parallel-conductor makeup must not be used in single conduits without ampacity reduction, even if load current is limited to the conductor ampacity as shown here.

Although part (B)(5) exempts only neutral conductors from those conductors that must be counted in determining load-limiting factors for more than three conductors in a raceway or cable [per part (B)(3)], similar exemption is, as of the 2014 NEC, allowed for one of the “travelers” in a three-way (or three- and four-way) switch circuit. As shown in Fig. 310-19, only one of the two conductors is a current-carrying conductor at any one time; therefore, the other should not be counted for load limitation purposes where such switch legs are run in conduit or EMT along with other circuit conductors. No change in Code language is needed to accomplish this; when one of two wires in a conduit necessarily carries zero amperes at all times, even if the wire at zero switches its identity

from time to time, the number of current-carrying conductors countable in that group of two is—exactly one.

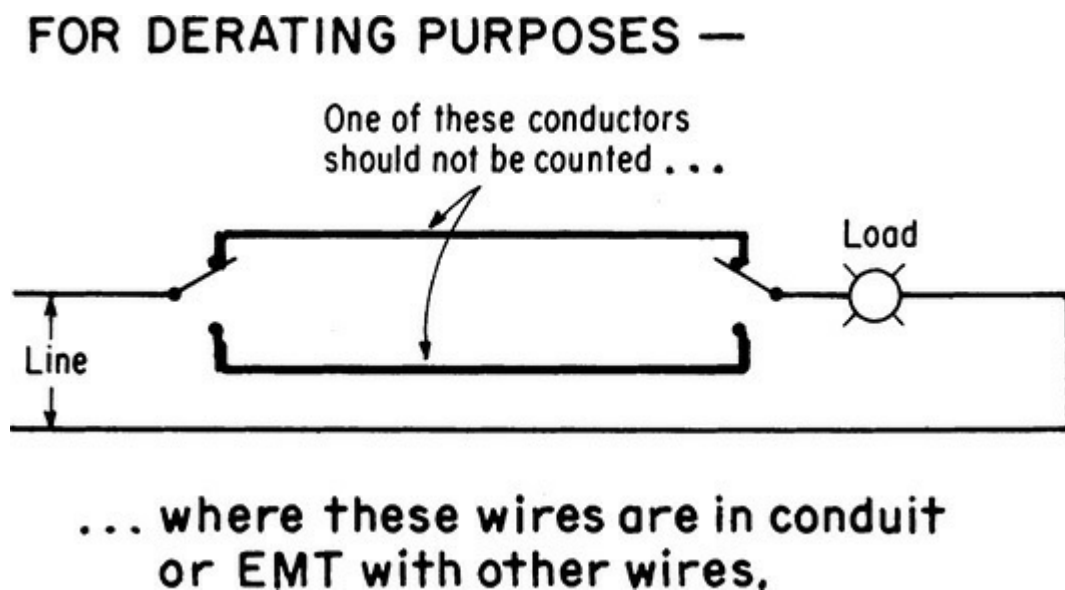

Fig. 310-19. The three-wire run in conduit between three-way switches contains only two current-carrying conductors. Whether both travelers (resulting in a total of three wires) must be counted depends on how the inspector applies the wording in the parent section (“current-carrying conductors”) to the table column heading (“conductors”). The same issue applies to any instance where multiple sets of conductors serving noncoincident loads run together. (Sec. 310.15.)

The reason the 2011 **NEC** dropped the term “current-carrying” from the table heading was because of concerns that spare conductors could be too easily brought into service without benefit of inspection. Therefore, spare conductors are now counted for ampacity adjustment purposes. The “current-carrying” limitation originated in the 1993 **NEC**, and the 2011 **NEC** position stands the 1993 substantiation on its head, which noted that spare conductors are a heat sink and improve the thermal performance of the assembly.

The 2014 **NEC** has split the difference in the process of revising the table note. Spare wires are now, unambiguously, counted in the wire fill, but wires subject to noncoincident loading are not. Although the three-way switch travelers are viewed by some as trivial, they can make a difference that is technically unjustified. There are other cases, particularly in industrial applications, where this issue is extremely serious. One instance wired by the author concerned two large, identical 3-phase motors fed through a common raceway that were wired, to save money, to a single-variable frequency drive through an interlocking contactor assembly that precluded simultaneous operation. The nature of the process involved made this practical because there were two sewage lines for which the plumbing arrangements precluded simultaneous operation. Literal enforcement of the prior table note would have caused an increase in wire size that in turn would have required an increase in raceway size.

Figure 310-20 shows a condition of bunched or bundled (now clarified as “installed without maintaining spacing for a continuous length”) Type NM cables where they come together at a panelboard location. A better example would be the common practice of running an entire group of cables across a basement ceiling through a single set of holes through adjacent joists. It looks very workmanlike but it will compromise ampacity, especially if there are enough conductors represented

to drop the ampacity to a lower standard size overcurrent device rating. This is a particular problem for receptacle circuits, because 240.4(B)(1) will not allow the next higher standard size device to protect such conductors. The rule of 310.15(B)(3)(a) requires conductors in bundled cables to have their load currents reduced from the ampacity values shown in Table 310.15(B)(16). The ampacity derating is required for conductor stacks or bundles that are longer than 2 ft (24 in. or 600 mm). For shorter bundles, derating is not required in general; however, note that Type NM cable has an effective length of not much more than zero if multiple cables run through draft- or fire-stopped holes in framing members. Item No. (2) excludes the need for derating groups of four or more conductors installed in nipples not over 24-in. (600 mm) long.

Fig. 310-20. If a large number of multiconductor cables are bundled together in a stud space, capacity derating in accordance with part **(B)(3)** would be required. If the individual cables are spaced apart and stapled, then the conductors in the cables may be loaded up to their rated ampacity values from Table 310.15(B)(16). (Sec. 310.15.)

Item No. (3) in 310.15(B)(3)(a) says that underground conductors that are brought up aboveground in a protective raceway [300.5(D)(1)] do not require derating if not more than four conductors are

used and if the protective conduit has a length not over 10 ft (3.0 m) “above grade.” The total length of raceway may exceed 10 ft (3.0 m). The phrase *above grade* clearly limits the length of protective conduit that may contain conductors without derating in accordance with Table 310.15(B)(3)(a). The 10-ft (3.0-m) length covers the length of 8 ft (2.5 m) above grade but not the 1½ ft (450 mm) into the earth given by 300.5(D)(1) on conductors emerging from underground.

310.15(B)(3) does not apply to conductors in metal wireways and auxiliary gutters, as covered in 366.23 and 376.22. Metal wireways or auxiliary gutters may contain up to 30 current-carrying conductors at any cross section [excluding signal circuits and control conductors used for starting duty only between a motor and its starter in auxiliary gutters, 366.22(A)] before limitations for mutual conductor heating take effect. Load-limiting factors for more than three conductors do not apply to a metal wireway, the way they do to wires in conduit. However, if the derating factors from Table 310.15(B)(3)(a) are used, there is no limit to the number of wires permitted in a wireway or an auxiliary gutter. However, the sum of the cross-sectional areas of all contained conductors at any cross section of the wireway must never exceed 20 percent of the cross-sectional area of the wireway or auxiliary gutter. More than 30 conductors may be used under those conditions.

Part **(B)(3)(b)** says that spacing between “conduits, tubing, or raceways shall be maintained.” The most significant thing about this provision is not what it says, but what it very nearly said, and was stopped from saying at the last minute.

When the **NEC** panel began to seriously question the adequacy of derating factors for mutual conductor heating in the 1987 Code edition, it didn’t stop with the new values (which are still in the **NEC**) in what is now (a). It also was going to add a table to what is now (b). This table would have mandated an *additional* set of derating factors for conduit and tubing run on trapeze hangers where the spacing was less than a full raceway diameter apart! The table was multidimensional in that the additional penalties would have applied not just side-to-side, but also vertically in the event more than one trapeze was stacked up the same set of threaded rods. For example, three trapeze hangers with six raceway runs each, and with less than a raceway diameter separation in both dimensions, would have produced an additional derating factor of 0.74. Even two conduits on a trapeze hanger, if the conduits were separated by less than a full raceway diameter, would have generated an additional factor of 0.94. There was also language that probably would have been applied as a complete prohibition against any separation less than a quarter of a raceway diameter.

UL, as it has so many times, saved the industry by running tests in the comment period showing that with any type of conventional conduit clamps on adjacent conduits in the trapeze hanger, there was enough separation and air flow so the mutual heating was negligible. Anyone with an ounce of common sense and field experience already knew that. Since no one is throwing bushel baskets of conduits on trapeze hangers without securing them with some kind of hardware, we can pretty much ignore (b). No loss experience was ever documented to support the inclusion of either the note or the derating factors in the original proposal. However, be advised that it is a Code violation to throw bushel baskets of conduits on trapeze hangers without securing them individually with some kind of hardware that provides a modicum of spacing.

Part **(B)(3)(c)** was new in the 2008 **NEC**, and is based on substantial research surrounding the effects of heat re-radiating from rooftops on raceways and cables exposed to direct sun. The rule, substantially decreased in severity in the 2017 **NEC**, now only applies rooftop adders to wiring mounted within 23 mm ($\frac{7}{8}$ in.) of the roof. In such cases, a 33°C (60°F) temperature correction is

applied to the rated outdoor ambient temperature. The dimension was chosen as an approximation of the spacing afforded by shallow profile strut. The resulting temperature to be taken through the ampacity correction factors in Table 310.15(B)(16) becomes the sum of the number in the table based on raceway position, and the normal ambient temperature for the geographic location. There is a note that suggests using the ASHRAE Handbook to look up ambient temperature data. An exception in the 2017 **NEC** exempts conductors with XHHW-2 from these requirements due to the robust thermal performance of the insulation. Note that the 2017 **NEC** added a new thermoset conductor insulation style for wet locations (XHWN-2) but that is not as yet correlated here.

The ASHRAE publication is based on 30 years of data, and looks at three different percentiles for the 3-month period from June through August. The 0.4 percent number is the temperature that will be exceeded for 0.4 percent of the total time in a 1-month period. Since a month is 720 h, this temperature will be exceeded for 3 h a month. The tables also calculate 1.0 and 2.0 percent numbers the same way. The number usually employed for these purposes is the 2.0 percent number, corresponding to 14 h a month. In the example that follows, we will use Hartford, Connecticut, for which the 2.0 percent number is 32°C (90°F). The Copper Development Association has an extensive extract of this data from many U.S. cities available online.

example An IMC conduit will supply a rooftop air-conditioning unit, routed 4.5 m (15 ft) across the roof running on Minerallac style conduit supports that hold the conduit ½ in. off the roof. The unit has a nameplate FLA of 120 A and it will be connected to a 480Y/277-V system using THHN/THWN-2 copper wire, with the conduit as the equipment grounding conductor. What size wire and conduit is required?

answer: The wire size must be initially selected on the basis of the 75°C column in Table 310.15(B)(16) based on 110.14(C)(1)(b), but using 125 percent of the FLA per 440.32.

$120 \text{ A} \times 1.25 = 150 \text{ A}$. Note that this is to be used as the operating current for Code purposes.

The wire cannot be smaller than 1/0 AWG in order to not overheat the terminations. However, now we need to look at conductor ampacity. The ampacity of this wire is 170 A from the table before adjustments. As previously noted, the conduit supports hold the raceway less than the minimum limit of 23 mm (7/8 in.) away from the roof, so the prescribed temperature adder must be applied of 33°C (60°F), resulting in an applicable temperature of 150°F (66°C). According to the correction factors in Table 310.16(B)(2)(a), this results in a correction factor of 0.58. Since the table ampacity is 170 A, the ampacity on the roof will be $170 \text{ A} \times 0.58 = 99 \text{ A}$. The wire is far too small, but would generally have been allowed prior to the 2008 **NEC**. Without the rooftop adjustment the ampacity correction factor is 0.96, for 163 A. The 33°C (60°F) adder lowered the resulting ampacity by 64 A.

Three sizes up, 4/0 AWG (table ampacity = 260 A), just works: $260 \text{ A} \times 0.58 = 151 \text{ A}$.

Part (B)(5) In the determination of conduit size, neutral conductors must be included in the total number of conductors because they occupy space as well as phase conductors. A completely separate consideration, however, is the relation of neutral conductors to the number of conductors, which determines whether ampacity derating must be applied to conductors in a conduit, as follows.

Neutral conductors that carry only unbalanced current from phase conductors (as in the case of normally balanced 3-wire, single-phase or 4-wire, 3-phase circuits supplying resistive loads) are not counted in determining ampacity derating of conductors on the basis of the number in a conduit, as described. A neutral conductor used with two phase legs of a 4-wire, 3-phase system to make up a 3-wire feeder is not a true neutral in the sense of carrying only current unbalance. Such a neutral carries the same current as the other two conductors under balanced load conditions and must be counted as a

phase conductor when more than three conductors in conduit are derated.

The technical basis for the full-current loading on the 3-wire feeder neutral from a wye system is based on phasor analysis that shows that if you have a circuit consisting of two-phase conductors and a neutral from a wye distribution with 100 A of line-to-neutral current on each phase conductor, perfectly balanced, the neutral will carry 100 A as well. Note that the identical load profile connected to a single-phase distribution would result in a zero ampere loading on the neutral. Further, as the load on one of the phase conductors in this example decreases, the load on the neutral does decline slightly, reaching a minimum of about 87 A ($\frac{1}{2}\sqrt{3} \times$ highest load) and then rising again to 100 A when the load on the more lightly loaded phasor reaches zero and we are left with 100 A in what has become effectively a two-wire circuit. Therefore, these neutrals are effectively fully loaded at all times and must be counted accordingly. By the way, the minimum loading in these cases occurs when one phasor carries 100 A and the other is carrying one-half that amount or 50 A.

Because the neutral of a 3-phase, 4-wire wye branch circuit or feeder to a load of fluorescent, metal-halide, mercury, or sodium lamp lighting or to electronic data processing equipment—the so-called information technology equipment—or any other nonlinear load will carry harmonic current even under balanced loading on the phases (refer to 220.61), such a neutral is not a true noncurrent-carrying conductor and must be counted as a phase wire when the number of conductors to arrive at an ampacity derating factor is determined for more than three conductors in a conduit. As a result, all the conductors of a 3-phase, 4-wire branch circuit or feeder to a fluorescent load would have an ampacity of only 80 percent of their nominal ampacity from Table 310.15(B)(16) or other ampacity table. Because the 80 percent is a derating of ampacity, the conductors must be protected at the derated ampacity value.

Figure 310-21 shows four basic conditions of neutral loading and the need for counting the neutral conductor in loading a circuit to fluorescent or mercury ballasts, as follows:

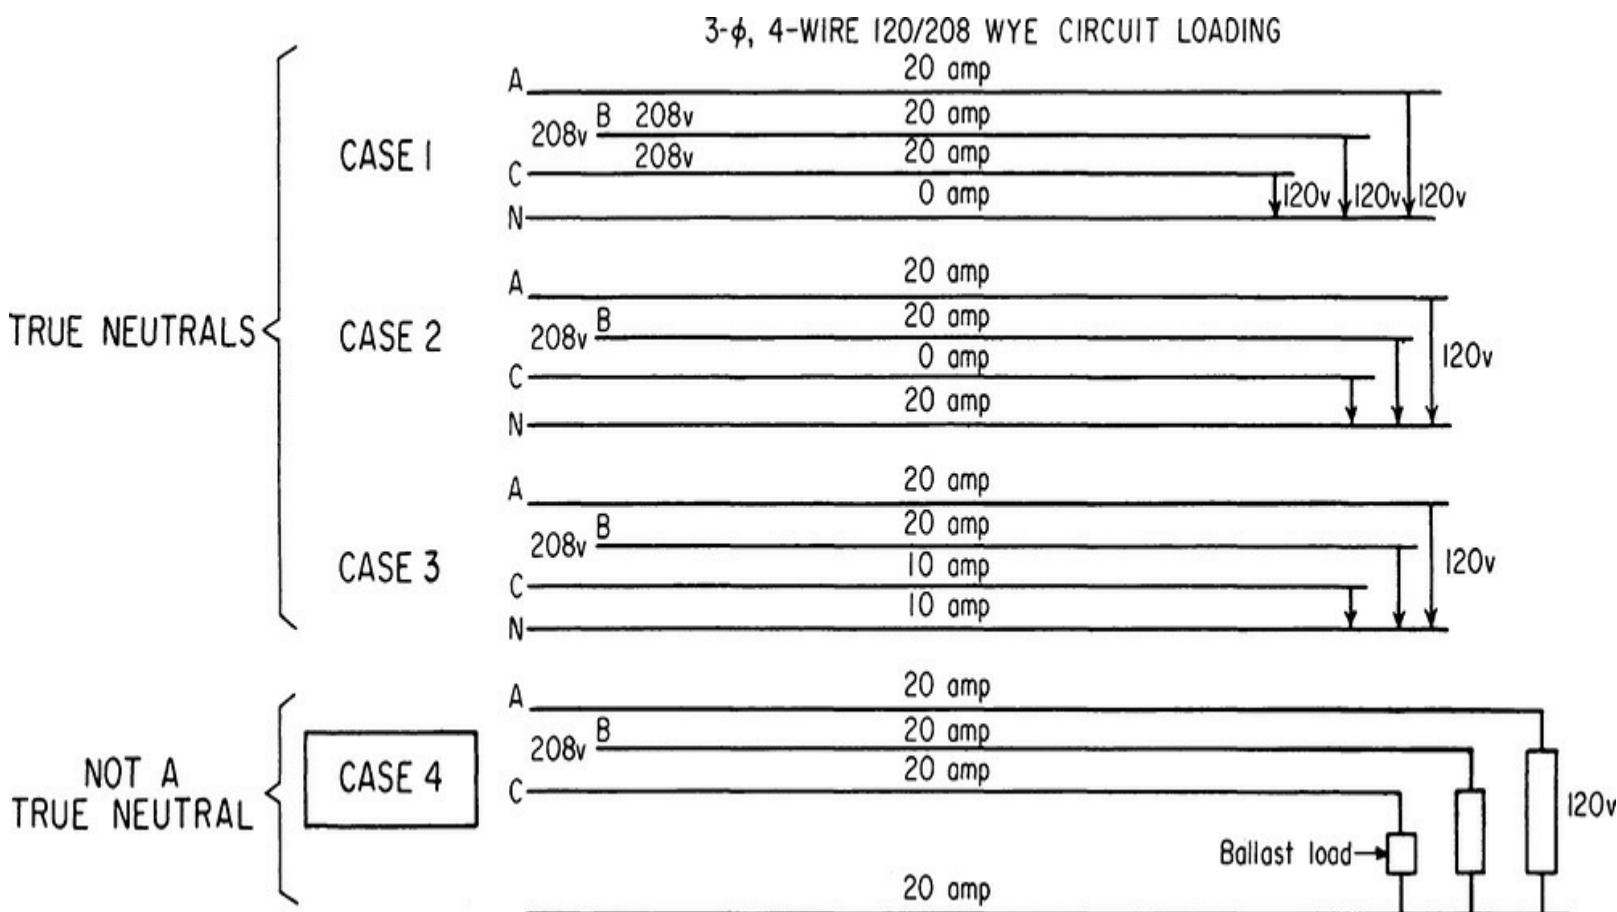

Fig. 310-21. All neutrals count for conduit fill, but only “true neutrals” do not count in determining ampacity derating for number of conductors in a raceway or cable [Part (B)(5)(b)]. (Sec. 310.15.)

Case 1—With balanced loads of equal power factor, there is no neutral current, and consequently no heating contributed by the neutral conductor. For purposes of heat derating according to the Code, this circuit produces the heating effect of only three conductors.

Case 2—With two phases loaded and the third unloaded, the neutral carries the same as the phases, but there is still the heating effect of only three conductors.

Case 3—With two phases fully loaded and the third phase partially loaded, the neutral carries the difference in current between the full phase value and the partial phase value, so that again there is the heating effect of only three full-load phases.

Case 4—With a balanced load of fluorescent ballasts, third-harmonic current generation causes a neutral current approximating phase current, and there will be the heating effect of four conductors. Such a neutral conductor must be counted with the phase conductors when the load-current limitation due to conduit occupancy is determined, as required in part (C) of part (B)(5).

Part (B)(6) This note makes it clear that an equipment grounding conductor or bonding conductor, which under normal conditions is carrying no current, does not have to be counted in determining ampacity derating of conductors when more than three conductors are used in a raceway or cable. As a result, equipment grounding and bonding conductors do not have to be factored into the calculation of required ampacity derating specified in part (B)(3). Part (C) is the Neher-McGrath method of ampacity calculations. Refer to the extensive discussion in 310.15(A)(1) for more information on this approach and how it contrasts with the ampacity table approach.

310.60. Conductors Rated 2001 to 35,000 Volts. Since the 1975 edition, the **NEC** has added a vast amount of information and data for conductors rated over 600 V, up to 35 kV. For instance, Tables 310.60(C)(67) through (86) give maximum continuous ampacities for copper and aluminum solid dielectric insulated conductors rated from 2001 to 35,000 V. Note that there are two ampacity columns in the tables, one for 90°C and one for 105°C. This sets up a comparable situation to the one at 600 V and below where there are termination rules and ampacity rules. In this case, however, the terminations take on the 90°C column per 110.40 regardless of conductor choice, but the 105°C numbers can be used as the starting point for ampacity calculations based on environmental factors. This section also includes, in 310.60(C)(4), an ambient temperature ampacity correction table and corresponding formula to the one at 310.15(B)(2) for 600 V and lower applications.

310.104. Conductor Constructions and Applications. Table 310.104(A) presents application and construction data on the wide range of 600 V insulated, individual conductors recognized by the **NEC**, with the appropriate letter designation used to identify each type of insulated conductor. The table title states that its contents apply to conductors “rated 600 V.” The 2014 **NEC** has added an interesting footnote to the title and therefore applicable to all conductors throughout, stating that “Conductors can be rated up to 1000 V if listed and marked.” [Figure 310-22](#) shows a typical detail on applications, as covered for Type THW conductors in **NEC** Table 310.104(A). Type THW wire has a special application provision for electric-discharge lighting, which makes THW an acceptable answer for installers needing a 90°C conductor for wiring end-to-end fixtures in compliance with Sec. 410.68.

Fig. 310-22. THW wire has the 90°C rating required of conductors within 3 in. (76 mm) of a ballast. (Secs. 410.68 and 310.104.)

Important data that should be noted in Table 310.104(A) are as follows:

1. The designation for “thousand circular mils” is “kcmil,” which has been substituted for the long-time designation “MCM” in this table and throughout the **NEC**.
2. Type MI (mineral insulated) cable may have either a copper or an alloy steel sheath.
3. Type RHW-2 is a conductor insulation that is moisture- and heat-resistant rubber with a 90°C rating, for use in dry and wet locations.
4. Type XHHW-2 is a moisture- and heat-resistant cross-linked synthetic polymer with a 90°C rating, for use in dry and wet locations.
5. The suffix “LS” designates a conductor insulation to be “low smoke” producing and flame retardant. For example, Type THHN/LS is a THHN conductor with a limited smoke-producing characteristic.
6. Type THHW is a moisture- and heat-resistant insulation, rated at 75°C for wet locations and 90°C for dry locations. This is similar to THWN and THHN without the outer nylon covering but with thicker insulation. These insulation styles are also available with a “-2” suffix, enabling use in wet applications at the full 90°C rating.
7. All insulations using asbestos—A, AA, AI, AIA, AVA, etc.—have been deleted from Table 310.104(A) because they are no longer made.

Conductors intended for 600 V (and up to 2000 V) general wiring under the requirements of the National Electrical Code are required to be one of the recognized types listed in Code Table 310.104(A) and not smaller than No. 14 AWG. The National Electrical Code does not contain detailed requirements for insulated conductors because these are covered in separate standards such as those of Underwriters Laboratories Inc.

Table 310.104(A) permits maximum operating temperatures of 90°C (194°F) in dry and damp (but not “wet”) locations for Types FEP, FEPB, RHH, XHHW, and THHN wire; but the load-current ratings for 14, 12, and 10 AWG copper conductors and 12 and 10 AWG aluminum conductors are limited to those permitted by the maximum overcurrent protection ratings given in 240.4(D). One

reason is the inability of 15-, 20-, and 30-A CBs to protect these sized conductors against damage under short-circuit conditions. The other reason is that the wiring devices that are commonly connected by these sizes of conductors are not suitable for conditions encountered at higher current loadings.

Conductors for medium-voltage circuits (over 2000 V) must satisfy Tables 310.104(B) through (E) as applicable, and the ampacity values given in Tables 310.60(C)(67) through (86) subject to the conditions in 310.60.

310.106. Conductors. Part (C) generally requires that 8 AWG and larger conductors must be stranded when they are installed in conduit, EMT, or any other “raceway.” The use of an insulated or stranded 8 AWG copper conductor is permitted as the equipment bonding conductor required by 680.23(B)(2)(b). But only a solid 8-AWG copper conductor is permitted by 680.26(B) at swimming pools for bonding together noncurrent-carrying metal parts of pool equipment—metal ladders, diving board stands, pump motor frames, lighting fixtures in wet niches, and so on. The reason is that in the first instance the wire will be pulled into a raceway, and in the second the conductor will be used for multiple bonding connections in exposed or corrosive locations where stranded wire does not survive.

Although conductors are generally required by part (D) to be insulated for the phase-to-phase voltage between any pair of conductors, bare conductors may be used for equipment grounding conductors, for bonding jumpers, for grounding electrode conductors generally, and for grounded neutral conductors in certain locations (230.22, 230.30, 230.41, 230.62, 250.140, and 338.3).

The application shown in Fig. 310-23 is a commonly encountered violation of 310.106(D) because it involves an unauthorized use of a bare conductor. 250.140 exception permits grounding of existing ranges, cooktops, and ovens to the neutral conductor, and then only where “the grounded conductor (the neutral) is insulated” or is a bare neutral of an SE cable that originates at the service equipment. Where supplied from a new circuit, a separate equipment ground must be provided.

Fig. 310-23. This is a controversial application because many believe it to be authorized by 250.140. Actually, however, it is one that violates Secs. 310.106(D) and 250.140, because it does not conform to Condition (3) of the exception thereto, and therefore is not “specifically permitted

elsewhere in this Code to be covered or bare.” [Sec. 310.106(D).]

310.106(D) states that “conductors shall be insulated,” except where covered or bare conductors (see definition in Art. 100) are specifically permitted elsewhere in the Code. As noted above, the applicable rule in Art. 250 does not allow this arrangement on new installation, or on uninsulated neutrals under any other circumstance than Type SE cable is used, and only if the branch circuit originates at the service panel. The same objection would apply to any other wiring method.

Although the basic rule of this section requires conductors to be insulated, a note refers to 250.184 on the use of solidly grounded neutral conductors in medium-voltage systems. As an exception to the general rule that conductors must be insulated, 250.184 does permit a neutral conductor of a solidly grounded wye system to have insulation rated at only 600 V (Fig. 310.24). It also points out that a bare copper neutral may be used for service-entrance conductors or for direct buried feeders, and bare copper or copper-clad aluminum may be used for overhead sections of outdoor circuits.

Fig. 310-24. A note refers to neutral conductors of solidly grounded high-voltage systems. [Secs. 250.184 and 310.106(D).]

310.110. Conductor Identification. For part (A), refer to the discussion given for 200.6 and 200.7. For part (B), refer to 250.119(A) and (B). 310.12(A) and 200.6(E) recognize the use in multiconductor cables of a grounded conductor that is not white throughout its entire length, provided that only qualified persons will service the installation. The rule requires that such grounded conductors be identified by white marking at their termination at the time of installation.

Similarly, a grounding conductor in a multiconductor cable may be identified at each end and at every point where the conductor is accessible by stripping the insulation from the entire exposed length or by coloring the exposed insulation green or by marking with green tape or green adhesive labels.

Part (C) for ungrounded conductors now simply defers to 210.5(C) for branch circuit and 215.12 for feeders on color (or other method of) coding. The method used cannot render the required conductor markings in 310.120(B)(1) unreadable.

ARTICLE 312. CABINETS, CUTOUT BOXES, AND METER SOCKET ENCLOSURES

312.1. Scope. Cabinets and cutout boxes, according to the definitions in Art. 100, must have doors (cutout boxes can also have telescoping covers), and are thus distinguished from large boxes with covers consisting of plates attached with screws or bolts. Article 312 applies to all boxes used to enclose operating apparatus—that is, apparatus having moving parts or requiring inspection or attention, such as panelboards, cutouts, switches, circuit breakers, control apparatus, and meter socket enclosures. The article does not apply to medium-voltage applications unless “specifically referenced” in another provision. One example of such a reference is 490.3(B).

312.2. Damp and Wet Locations. This section addresses “damp and wet locations.” The Code requires all equipment covered by this article to be “placed or equipped” so as to ensure water does not enter or collect within the enclosure. Additionally, a minimum clearance from the mounting surface of $\frac{1}{4}$ in. must be maintained to prevent corrosion of the enclosure. And, fittings at raceway or cable entries in metallic enclosures must be listed for use in “wet locations” where such entry is above the level of any uninsulated live parts. This qualification reflects the fact that any energized part, whether insulated or not, is a live part per the Art. 100 definition. The clearance to the mounting surface is not required for nonmetallic enclosures on nonabsorbent surfaces, as noted by the exception. The rule about wet location fittings being required for entries above a certain level answers a long-standing question as to whether a conventional SE cable connector suitable for dry locations can be used with SE cable exiting from the bottom of an outdoor meter socket. The answer is that it can be used, but the fitting for the cable entry in the top of the socket does have to be listed for wet locations.

312.3. Position in Wall. [Figure 312-1](#) shows how the $\frac{1}{4}$ -in. (6.35-mm) setback relates to cabinets installed in noncombustible walls.

Fig. 312-1. In masonry wall, cabinet does not have to be flush with wall surface—as it does in wood wall. (Sec. 312.3.)

312.4. Repairing Noncombustible Surfaces. The gap between the enclosure that uses a flush-mounted cover and adjacent finished surfaces—where the surface is plaster, drywall, or plasterboard—shall not be greater than 3 mm ($1/8$ in.). This makes the rule identical to the comparable rule in 314.21. Both 312.3 and 312.4, and their counterparts in Art. 314, address issues related to when ordinary building construction will be allowed to complete an electrical enclosure. Review the commentary following 314.21 for more information regarding the intent behind these requirements.

312.5. Cabinets, Cutout Boxes, and Meter Socket Enclosures. Part (C) makes clear that all cables used with cabinets or cutout boxes must be attached to the enclosure. NM cable, for instance, does not have to be connected by clamp or connector device to a single-gang nonmetallic outlet box as in 314.17(C), but must *always* be connected to KOs in panelboard enclosures and other cabinets (Fig. 312.2). If installations require concealed wiring, spare conduits should be stubbed to accessible areas, such as above the lift-out ceiling-panel construction in common use today. In such areas this section includes an allowance for running multiple nonmetallic cable assemblies through a vertical riser. This facilitates the use of Type NM cables for light commercial construction; a surface panel can go on the wall at a convenient point with a single large riser conduit stub poked through the suspended ceiling to receive the cables. There are numerous limitations to be observed, but the neat and workmanlike result often makes this approach worthwhile. Specifically, the installation must meet the following conditions:

Any cable (BX, NM, etc.) must be secured to any cabinet or cutout box, whether metal or nonmetallic

Fig. 312-2. All cables must be secured to all cabinets or cutout boxes. (Sec. 312.5.)

- The cables must have entirely nonmetallic sheaths.
- The raceway must enter the top of the cabinet.
- The raceway must be nonflexible, such as EMT.
- The raceway must be no shorter than 450 mm (18 in.), nor longer than 3.0 m (10 ft).
- Every cable entering the raceway end must be secured not over 300 mm (12 in.) from the entry point to the raceway.
- The raceway must extend directly above the cabinet.
- The raceway must not penetrate a structural ceiling.
- The raceway must be equipped with fittings on both ends to protect the cables from abrasion.
- The outer raceway end must be sealed or plugged by an approved means to prevent debris from falling into the cabinet. Duct seal is often used for this purpose.
- The cables that run to the enclosure must have their sheaths intact through the entire raceway section.
- The raceway must be supported in accordance with the rules that apply to the wiring method employed.
- The cable-fill limitations in [Chap. 9](#) of the **NEC** must be observed. This means the cables cannot occupy more than 40 percent of the raceway internal cross section, and for elliptical cables, the cable cross section is taken as the area of a circle whose diameter equals the major axis of the ellipse. The raceway sleeve does not constitute a complete wiring system; however, the terms of this exception still reference the fill limits and, for correlation, the exception disqualifies the complete system limitation in Note 2 to the [Chap. 9](#) tables.
- The mutual conductor heating rules, as covered in 310.15(B)(3)(a), must be applied. This is perhaps the most problematic constraint; however, if the raceway riser does not exceed 600 mm (24 in.) in length, those rules can be ignored because the raceway now qualifies as a nipple.

312.6. Deflection of Conductors. Parts (A) and (B) cover a basic Code rule that is referenced in a number of Code articles to ensure safety and effective conductor application by providing enough space to bend conductors within enclosures.

This section addresses a number of major considerations in terms of evaluating the minimum amount of space that must be allowed in enclosures to allow for bending and landing conductors safely. There are two basic starting points for making this analysis, based on whether the conductor

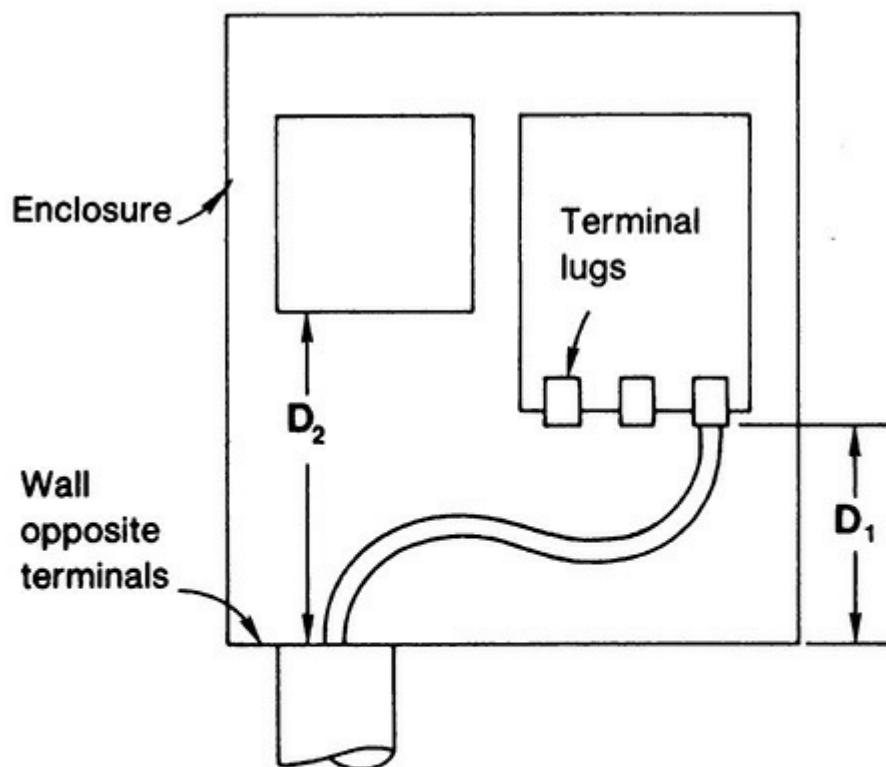

enters the enclosure opposite to the terminal, or at right angles to the terminal. In addition, the conductor material must be considered, because the current aluminum alloy for conductors [AA-8000, in accordance with 310.106(B)] has less spring-back and is easier to bend than the same size in copper. As of the 2017 **NEC**, the allowable bending space dimensions now differ in both of the size/space tables presented in this section for that reason.

One example of how this particular change turned out to be unusually consequential concerned a common installation technique for residential 200A services. If the service cable enters the rear of the panelboard, the rules in 408.55(C), instituted in the 2014 **NEC** and illustrated in [Fig. 408-23](#), will apply. If using aluminum SE cable, the usual approach is to use a 4/0 cable. The enclosure depth must at least equal the required bend radius, and on the prior version of Table 312.6(A) that required a 4 in. cabinet depth. It turns out that many manufacturers standardize on a 3³/₄ or 3¹/₂ in. depth. Adding the revised bending spacing for aluminum wiring (3¹/₂ in.) avoided a costly redesign of this equipment.

The rules for the two basic orientation of entry approaches follow:

1. The conductor does not enter (or leave) the enclosure through the wall opposite its terminals.

This would be any case where the conductor passes through a wall of the enclosure at right angles to the wall opposite the terminal lugs to which the conductor is connected or at the opposite end of the enclosure. In all such cases, the bend at the terminals is a single-angle bend (90° bend), and the conductor then passes out of the bending space. It is also called an *L bend*, as shown at the top left of [Fig. 312-3](#). For bends of that type, the distance from the terminal lugs to the wall opposite the lugs must conform to Table 312.6(A), which requires lesser distances than those of Table 312.6(B) because single bends are more easily made in conductors, and they are easier to land on a terminal.

EVEN THOUGH CONDUCTOR LEAVES ENCLOSURE THROUGH WALL OPPOSITE LUGS, D_1 MAY BE SIZED FROM TABLE 312.6(A) PROVIDED THAT D_2 CONFORMS TO TABLE 312.6(B)

Fig. 312-3. These clearances are minimums that must be observed. (Sec. 312.6.)

2. The conductor enters (or leaves) the enclosure through the wall opposite its terminals. This is a more difficult condition because the conductor must make an offset or double bend to go from the terminal and then align with the raceway or cable entrance. This is also called an *S* or a *Z*

bend because of its configuration, as shown at the top right of [Fig. 312-3](#). For such bends, Table 312.6(B) specifies a greater distance from the end of the lug to the opposite wall to accommodate the two 45° bends, which are made difficult by the short lateral space between lugs and the stiffness of conductors (especially with the plastic insulations in cold weather).

Table 312.6(B) provides increased bending space to accommodate use of factory-installed connectors that are not of the lay-in or removable type and to allow use of field-installed terminals that are not designated by the manufacturer as part of the equipment marking. Exception No. 1 to part (B) is shown in the bottom drawing of [Fig. 312-3](#). This setup is often used in CT enclosures.

Note: For providing Code-required bending space at terminals for enclosed switches or individually enclosed circuit breakers, refer to 404.18. For conductor bending space at panelboard terminals, refer to 408.55. In [Fig. 312-3](#), the clearances shown are determined from Table 312.6(A) or Table 312.6(B), under the column for one wire per terminal. For multiple-conductor circuit makeups, the clearance at terminals and inside gutters has to be greater, as shown under two, three, four, etc., wires per terminal.

Exception No. 2 of part (B) covers application of conductors entering or leaving a meter-socket enclosure, and was based on a study of 100- and 200-A meter sockets with lay-in terminals.

312.8. Switch and Overcurrent Device Enclosures. The basic rule here is a follow-up to the rule of 312.7. This section has been reorganized to present the traditional applications to splices, tapping, and feeding through in (A), and then a separate topic of power monitoring equipment in (B).

Most enclosures for switches and/or overcurrent devices have been designed to accommodate only those conductors intended to be connected to terminals within such enclosures. And in designing such equipment it would be virtually impossible for manufacturers to anticipate various types of “foreign” circuits, feed-through circuits, or numerous splices or taps.

The rule here states that enclosures for switches, CBs, panelboards, or other operating equipment must not be used as junction boxes, troughs, or raceways for conductors feeding through or tapping off, unless designs suitable for the purpose are employed to provide adequate space. This rule affects installations in which a number of branch circuits or subfeeder circuits are to be tapped from feeder conductors in an auxiliary gutter, using fused switches to provide disconnect and overcurrent protection for the branch or subfeeder circuits. It also applies to feeder taps in panelboard cabinets.

In general, the most satisfactory way to connect various enclosures together is through the use of properly sized wireways or auxiliary gutters ([Fig. 312.4](#)) or junction boxes. [Figure 312-5](#) shows a hookup of three motor disconnects, using a junction box to make the feeder taps. Following this concept, enclosures for switches and/or overcurrent devices will not be overcrowded.

Fig. 312-4. Feeder taps in auxiliary gutter keep feeder cables and tap connectors out of switch enclosures. (Sec. 312.8.)

Fig. 312-5. Junction box (arrow) is used for tapping feeder conductors to supply individual motor branch circuits—as shown in inset diagram. (Sec. 312.8.)

There are cases where large enclosures for switches and/or overcurrent devices will accommodate additional conductors, and this is generally where the 40 percent (conductor space) and 75 percent (splices or taps) at one cross section would apply. An example would be control circuits tapped off or extending through 200-A or larger fusible switches or CB enclosures. The csa within such enclosures is the *free gutter wiring space* intended for conductors.

Parts (1) and (2) of this rule are shown in [Fig. 312-6](#) and are applied as follows:

Fig. 312-6. These hookups are permitted where space in enclosure gutters satisfies the exception to the basic rule. (Sec. 312.8.)

example If an enclosure has a gutter space of 3 by 3 in., the csa would be 9 sq in. Thus, the total conductor fill (use Table 5, Chap. 9) at any cross section (including conductors and splices) could not exceed 6.75 sq in. (9×0.75). The actual conductor fill at any cross section (just the wires) could not exceed 3.6 sq in. (9×0.4).

In the case of large conductors, a splice other than a wire-to-wire “C” or “tube” splice would not be acceptable if the conductors at the cross section are near a 40 percent fill, because this would leave only a 35 percent space for the splice. Most splices for larger conductors with split-bolt connectors or similar types are usually twice the size of the conductors being spliced. Accordingly, where larger conductors are to be spliced within enclosures, the total conductor fill should not exceed 20 percent to allow for any bulky splice at a cross section.

Figure 312-7 shows an example of feeder taps made in panelboard side gutter where the cabinet is provided with adequate space for the large feeder conductors and for the bulk of the tap devices with their insulating tape wrap. In accordance with condition (3) of the rule, which was new in the 2011 NEC, if any of these conductors feed through, a warning label must be applied to the cover of the enclosure that puts personnel on notice as to the location of the nearest disconnecting means that is ahead of those conductors. In the case of a panelboard, the requirement for the circuit directory to identify the source of its supply feeder in Sec. 408.4. would be sufficient, unless there are additional conductors passing through that do not energize this particular panel. The intent is to ensure that personnel working in such an enclosure are aware of all sources of energized conductors within it,

especially if some of them are not obvious because they do not energize loads within the enclosure.

Fig. 312-7. In 312.11(C), the Code permits feeding through and tapping off in cabinets for panelboards on feeder risers, where the side gutter is specially oversized for the application. (Secs. 312.8 and 312.11)

Power monitoring equipment is covered in **(B)**, which only applies to enclosures for switches and overcurrent devices, such as panelboard cabinets. This topic has been extensively researched and a UL outline of investigation released that forms an orderly basis for the manufacture and installation of products. The equipment will be allowed in two related forms. The first is a field-installable accessory that is available as an add-on to listed equipment, not unlike surge protectors. The other option will be a listed kit that is field installable in different enclosures. [Figure 312-8](#) shows an example of the former.

Fig. 312-8. Field-installable current transformers, listed to UL 2808 and suitable for placement in panelboard wiring gutter spaces. [312.8(B)(1).] (Courtesy, Siemens)

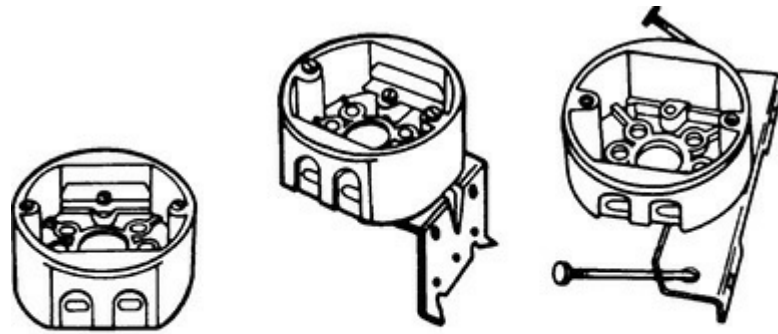

The panel actively considered a much broader requirement, one that would have required listings on any equipment placed in a switch or panelboard enclosure. After receiving extensive negative comments, and reflecting on a wide variety of innocuous intrusions, the panel decided to limit the reach to power monitoring equipment. One example consisted of the tail end of a 50-amp 3-pole 4-wire locking receptacle mounted to the side of a panelboard cabinet. The location was carefully chosen to not create potential conflict with future branch-circuit connections in the wiring gutter. The particular installation was well policed by the inspector. The panel realized that there was no possible way the device manufacturer would ever have been able to obtain a listing that could have anticipated that application, and there was certainly nothing wrong with it. The panel instead took care to leave the section structure in a way that could easily include rules on other topics if a compelling need were demonstrated in a future cycle.

ARTICLE 314. OUTLET, DEVICE, PULL, AND JUNCTION BOXES; CONDUIT BODIES; FITTINGS; AND HANDHOLE ENCLOSURES

314.1. Scope. This rule makes clear that Art. 314 regulates use of conduit bodies when they are used for splicing, tapping, or pulling conductors. And this article does refer specifically to conduit bodies, to more effectively distinguish rules covering *boxes*, *conduit bodies*, and *fittings*. The rules of Art. 314 must be evaluated in accordance with the definitions given in Art. 100 for “conduit body” and “fitting.” Capped elbows and SE elbows are fittings, not conduit bodies, and must not contain splices, taps, or devices. The pieces of equipment described in Art. 314 tie into 300.15, “Boxes or

fittings—where required.”

314.2. Round Boxes. The purpose of this rule is to require the use of rectangular or octagonal metal boxes having, at each knockout or opening, a flat bearing surface for the locknut or bushing or connector device to seat against a flat surface. But round outlet boxes may be used with nonmetallic-sheathed cable because the cable is brought into the box through a knockout, without the use of a box connector to secure the cable to the box. However, the exception to 314.17(C) permits only boxes of “nominal size 2¼ in. by 4 in.,” the so-called single gang boxes, to be used without securing the NM or NMC cable to the box itself—as long as it is stapled to the stud or joist within 8 in. (203 mm) of the box. Because round boxes are *not* single gang boxes, it appears that all such round outlet boxes must be equipped with cable clamps to satisfy the exception to 314.17(C) (Fig. 314.1). Shallow metal boxes with internal clamps for NM cable are acceptable as round boxes.

**Round nonmetallic outlet boxes
may be used only with NM cable**

Fig. 314-1. Round boxes may be used only for connecting cables with internal clamps—such as NM or BX cable. (Sec. 314.2.)

314.3. Nonmetallic Boxes. Growth in the application of nonmetallic boxes over past years is the basis for the two exceptions to this section, which regulate the conditions under which nonmetallic boxes may be used with metal raceways or metal-sheathed cable. The need for and popularity of these boxes developed out of industrial applications where corrosive environments dictated their use to resist the ravages of various punishing atmospheres. In many applications it is desirable to use nonmetallic boxes along with plastic-coated metal conduits for a total corrosion-resistant system. Such application is recognized by the Code in the exceptions of this section, although a limitation is placed requiring “internal” or “integral” bonding means in such boxes (Fig. 314.2).

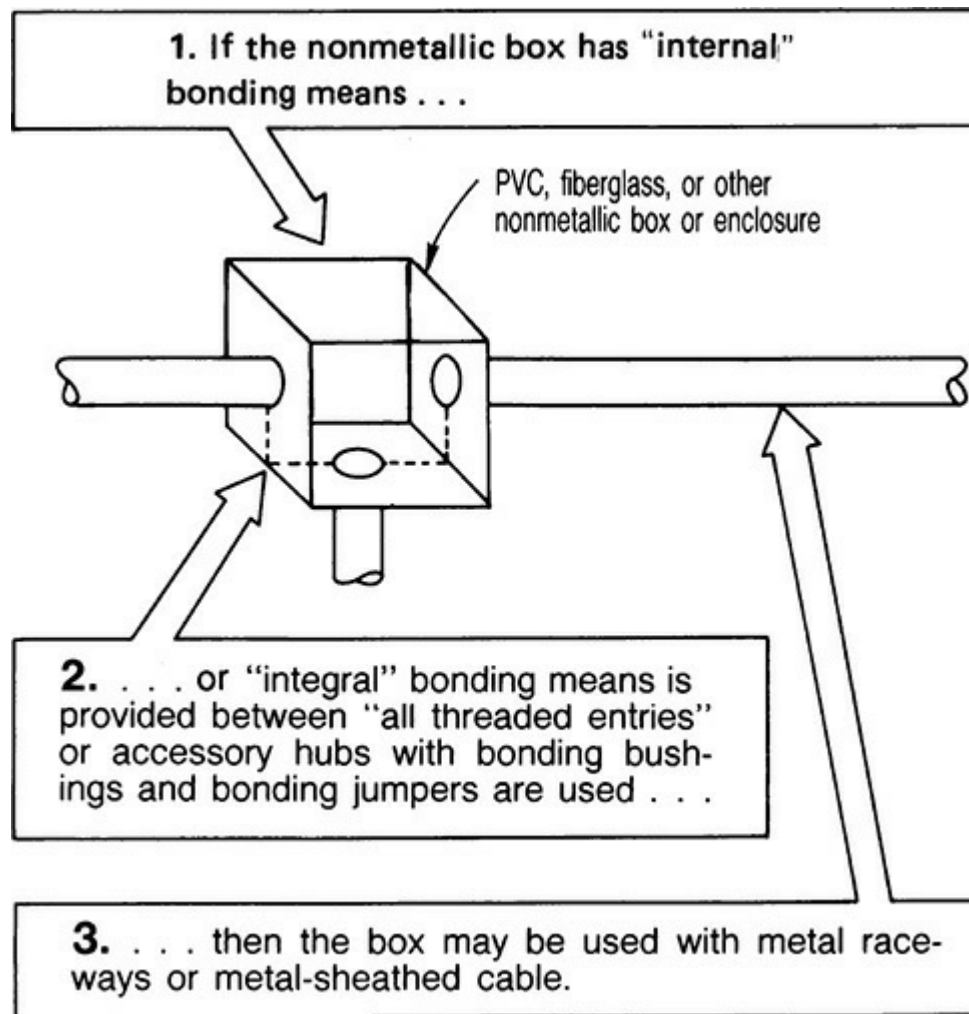

Fig. 314-2. Nonmetallic boxes are recognized for use with metal raceways and metal-sheathed cable. (Sec. 314.3.)

According to the basic rule in the first sentence of this rule, nonmetallic boxes are permitted to be used only with open wiring on insulators, concealed knob-and-tube wiring, nonmetallic sheathed cable, electrical nonmetallic tubing, and rigid nonmetallic conduit (any "nonmetallic raceways"). Exception No. 1 requires internal bonding means in such boxes used with metal cable or raceways. The permission used to apply only to nonmetallic boxes sufficiently large—that is, over 100 cu in. Now, *any* size of box—PVC boxes, fiberglass boxes, or other nonmetallic boxes or enclosures—may be used with metal raceways or metal-sheathed cable. However, for each entry, a bonding bushing would have to be applied in order to provide continuity in the equipment grounding conductor.

Exception No. 2 requires that "integral" bonding means between all "threaded" raceway and cable entries must be provided in the box for all metal conduits or metal-jacketed cables. This exception addresses an entirely different box construction, where a metallic web is positioned within and throughout a nonmetallic (usually fiberglass) enclosure. Many of these boxes are used for hazardous locations that are also extremely corrosive. Some of them even meet the requirements for Class I Division 1. When hubs are added to these boxes using the methods prescribed in the installation instructions, continuity is achieved through the integral web, almost as if the box were all metal. The only constraint imposed in this case is that an equipment grounding terminal must be provided within the box by its manufacturer, which would reach the bonding web. That way if there is equipment in the box that requires a bonding connection, it will be available.

314.4. Metal Boxes. This is now a very simple rule. Ground all metal boxes. Period. The only

exception is when 250.112(I) relieves the need for equipment grounding.

314.15. Damp or Wet Locations. In damp or wet locations, equipment within the scope of Art. 314 must be placed or equipped to prevent moisture from entering or accumulating within the equipment. Boxes, conduit bodies, and fittings used in wet locations must be listed for use in those areas. The left part of Fig. 314-3 shows a fitting which is generally available as a listed item and it has been designed with the openings for the conductors so placed that rain or snow cannot enter the fitting. On the right, it shows a fitting also suitable for a wet location listing; it has a metal cover that slides under flanges on the face of the fitting, and, as required by 230.53, an opening is provided through which any moisture condensing in the conduit can drain out. Note that this is a “service entrance elbow.” It is a short-radius conduit body covered in 314.16(C)(3). It is functionally obsolete for service applications because it does not have the required bending radius for any conductors 4 AWG or larger. It does retain theoretical acceptability for a service to a single small load such as a telephone booth, as covered in 230.42(B) and 230.79(A).

Fig. 314-3. Fittings must be suited to use in wet locations. (Sec. 314.15.)

The 2014 **NEC** has added “outlet box hoods” (the so-called “bubble covers” for in-use receptacle outlets) to the list of enclosures in the first sentence that are required to be placed or arranged to avoid water entry or accumulation in damp or wet locations. In addition, official recognition was granted to the widespread and common practice of drilling weep holes in the underside of boxes to allow condensation to escape instead of slowly degrading the box and its contents from the inside out. The **NEC** now specifies the permitted size and geometry of these holes ($1/8$ to $1/4$ in., diameter specified, only applies to a circle) to assure they stay open but still internal access. Larger sizes are allowable to accommodate a listed drain fitting.

314.16. Number of Conductors in Outlet, Device, and Junction Boxes, and Conduit Bodies. Note that motor terminal housings are excluded from the rules on box conductor

fill. And where any box or conduit body contains 4 AWG or larger conductors, all the requirements of 314.28 on pull boxes must be satisfied. Refer to 314.28 for applications of conduit bodies as pull boxes.

Selection of any outlet or junction box for use in any electrical circuit work must take into consideration the maximum number of wires permitted in the box by 314.16. Safe electrical practice demands that wires *not* be jammed into boxes because of the possibility of nicks or other damage to insulation—posing the threat of grounds or shorts.

This section is broken down into three subparts. Part (A) establishes the volume of a box. Part (B) describes the method for determining how much volume is used by the various conductors, devices, and the like. Part (C) applies to conduit bodies, only.

As of the 2017 **NEC**, the parent language in (A) also includes a volume rule that applies to both of its numbered paragraphs following. If a box contains a barrier, either for system separation between power and class 2, as required in 725.136(A), 800.133(A)(1)(d), etc., or for voltage separation as required in 404.8(B) and 406.5(J), or any other purpose, that barrier must be accounted for in the volume calculation. [Figure 314-4](#) shows a typical example. If the barrier is marked with its volume, then that volume must be apportioned to each side. If it is not marked, and most will not be at present, then metal barriers are assumed to have a volume of $\frac{1}{2}$ in³ and for a nonmetallic barrier a volume of 1.0 in³. The number for steel barriers was developed by taking a length of 4 in., a height of 2 in. and a thickness of 0.0625 in. as required by 314.40(B). A typical nonmetallic barrier was assumed to be about double the thickness as for steel. As noted, any manufacturer who objects is always free to mark his barriers if they differ.

Fig. 314-4. The steel barrier, installed for voltage separation between the two gangs of this gangable masonry box, is assumed to have a volume of 1.0 in^3 , which reduces the volume on each side by half that number, or 0.5 in^3 . [314.16(A).]

As stated in part **(A)(1)** of this section, Table 314.16(A) shows the maximum number of wires permitted in the *standard* metal boxes listed in that table. But that table applies only where all wires in a given box are the same size; that is, all 14 AWG or all 12 AWG. Table 314.16(B) is provided for sizing a box where all the wires in the box are not the same size, by using so much cubic-inch space for each size of wire.

Table 314.16(A) includes the maximum number of 18 AWG and 16 AWG conductors that may be used in various sizes of boxes, and Table 314.16(B) gives the required box space for those sizes of conductors. Because of the extensive use of 18 AWG and 16 AWG wires for fixture wires and for control, signal, and communications circuits, these data are needed to assure safe box fill for modern electrical systems.

As stated in part **(A)(2)**, all other boxes—nonstandard, nonmetallic, or those metal boxes covered by part **(A)(1)** that are stamped with their cubic-inch capacity by the manufacturer—must consider their volume to be that which is stamped on them. And, as stated in the first paragraph of 314.16, the value of volume [part **(A)**] must never be less than the fill [part **(B)**].

Part **(A)(2)** of 314.16 covers boxes—metal and nonmetallic—that are not listed in Table 314.16(A). And the basic way of determining correct wire fill is to count wires in accordance with the intent of 314.16(B) and then calculate the required volume of the box or conduit body by totaling up the volumes for the various wires from Table 314.16(B).

Part **(A)(2)** covers wire fill for metal boxes, up to 1650 cm^3 (100 in^3) volume, that are not listed in Table 314.16(A) and for nonmetallic outlet and junction boxes. Although Code rules have long regulated the maximum number of conductors permitted in metal wiring boxes [such as given in Table 314.16(A)], there was no regulation on the use of conductors in nonmetallic device boxes up to the 1978 **NEC**. Since that time, 314.16(A)(2) requires that *both* metal boxes not listed in Table 314.16(A) and nonmetallic boxes be durably and legibly marked by their manufacturer with their cubic inch capacities to permit calculation of the maximum number of wires that the Code will permit in the box. Calculation of the conductor fill for these boxes will be based on the marked box volume and the method of counting conductors set forth in 314.16(B). The conductor volume will be taken at the values given in Table 314.16(B), and allocations of space as required for wiring devices or for clamps must be made in accordance with the rules of 314.16(B). This requirement for marking of both metal and nonmetallic boxes arises from the wording of 314.16(A)(2), which refers to boxes other than those described in Table 314.16(A) and to nonmetallic boxes.

As shown in [Fig. 314-5](#), a nonmetallic box for a switch has two 14/2 NM cables, each with a 14 AWG ground. The wire count is four 14 AWG insulated wires, plus two for the switch to be installed, and one for the two ground wires. That is a total of seven 14 AWG wires. From Table 314.16(B), at least 32.8 cm^3 (2 in^3) of box volume must be allowed for each 14 AWG. This box must, therefore, be marked to show that it has a capacity of at least 7×2 , or 14, cu in. As shown, the ground wires are connected by a twist-on connector, with one end of the wire brought out to connect to a ground screw on the switch mounting yoke. Such a technique is required to provide grounding of a metal switchplate. Refer to 404.9(B).

Fig. 314-5. Every nonmetallic box must be “durably and legibly marked by the manufacturer” with its cubic-inch capacity to permit calculation of number of wires permitted in the box—using Table 314.16(B) and the additions of wire space required to satisfy 314.16(A)(1). (Sec. 314.16.)

Part **(B)** of 314.16 describes the detailed way of counting wires in a box and subtracting from the permitted number of wires shown in Table 314.16(A) where cable clamps, fittings, or devices like switches or receptacles take up box space. The first sentence requires all the allowances applicable to a box assembled from separate components, such as a ganged device box, be added together to determine the volume of box required from Part (A). The second sentence addresses the reverse issue of barriers, and requires that the allowances applicable to either side be calculated separately in terms of determining the total volume required within each side.

Important details of the wire-counting procedure of part **(B)** are as follows:

1. From the wording, it is clear that no matter how many ground wires come into a box, whether they are ground wires in NM cable or ground wires run in metal or nonmetallic raceways, a fill allowance of only one conductor must be made from the number of wires shown in Table 314.16(A) (Fig. 314.6). Or, as will be shown in later examples, one or more ground wires in a box must be counted as a single wire of the size of the largest ground wire in the box. Any wire running unbroken through a box counts as one wire, provided it is not long enough to be cut in the center of the loop and used as two wires, as defined in 300.14; if it is long enough to count as two wires, then it must be counted as two wires, and the count goes up further on multiple coils. A small hand loop that is only there to assist routing the wire is still only counted once. Each wire coming into a splice device (crimp or twist-on type) is counted as one wire. And each wire coming into the box and connecting to a wiring device terminal is *one* wire.

Any wire passing through counts as one, as follows:

Fig. 314-6. Count all ground wires as *one* wire (or two wires if isolated-ground wires are also used) of the largest size of ground wire in the box. (Sec. 314.16.)

When a number of “isolated-ground” equipment grounding conductors for receptacles come into a box along with conventional equipment grounding wires, each type of equipment ground wires must be counted as one conductor for purposes of wire count when determining the maximum number of wires permitted in a box. When a number of isolated-ground receptacles are used in a box (as for computer wiring), all the isolated-ground conductors count as one fill allowance counted against the number of wires given in Table 314.16(A) as permitted for the particular size of box. And *then*, another allowance of one conductor must be made for any other equipment grounding conductors (*not* isolated-ground wires).

There is one type of wire entry that does not need to be counted, and that is fixture wires smaller than 14 AWG (maximum of 4 with an additional equipment grounding conductor permitted) that enter a box from a domed luminaire canopy or equivalent. This wording

includes the canopies on paddle fan hanger assemblies. The word *domed* is there to assure at least some volume contribution from the canopy; there are luminaires that incorporate what for all intents and purposes is a 100-mm (4-in.) octagon blank cover; in such cases the fixture wires are counted. The domed canopy allowance makes it possible to hang luminaires on ceiling pans that usually have no more than 98.4 cm³ (6.0 in.³) for volume. Until comparatively recently wires smaller than 14 AWG had no mandatory wire fill assigned; however, now that those volumes are assigned, something had to be done to be certain that ceiling pans remained workable.

2. Regarding the addition of wire fill allowances to other such allowances under consideration, for fixture studs, cable clamps, and hickey, does this apply to the previously mentioned items collectively regardless of number and combination, or does it apply to each item individually—such as clamps, plus one; studs, plus one; and so forth?

Answer: It is the intent of parts **(B)(2)** and **(3)** to clarify that a fill allowance of one must be made from the number in the table for each *type* of device used in a box, and this must use the largest conductor in the box as the reference point for the calculation. A fill allowance of one must be made if the box contains cable clamps—whether one clamp or two clamps, a count of only one has to be made. A fill allowance of one must be made if the box contains a fixture stud. A fill allowance of one must be made if the box contains a hickey. Thus, a box containing two clamps but no fixture studs or hickey would have a fill allowance of one from the table number of wires for the clamps. If a box contained one clamp and one fixture stud, a fill allowance of two would be made because there are two *types* of devices in the box.

Then, as given in part **(B)(4)**, in addition to the allowances for clamps, hickey, and/or studs, an allowance of two conductors must be made for each mounting strap that supports a receptacle, switch, or combination device. Note that for large devices that cannot fit in single-gang metal device boxes listed in Table 314.16(A), such as NEMA 14-50R (3-pole 4-wire 50-A 125/250-V) receptacles for ranges, allowances must be taken on the basis of the number of such ganged device boxes required for the device. In this case that would be two such boxes, for a total of four allowances, and if 6 AWG conductors are used, this rule adds another 163.8 cm³ (10 in.³) to the volume.

It should be noted that not all 14-50R devices are alike in today's market; some device manufacturers have shrunk the body size just enough that, even with the actual configuration remaining constant for obvious reasons, the devices will fit in a single gang opening and accept a single-gang faceplate similar to the traditional 3-pole, 3-wire 125/250-V (NEMA 10-50R) receptacles used prior to the 1996 **NEC**. In the example given, such a receptacle, even if configured 3-pole 4-wire grounding, would only add half the volume.

3. Must unused cable clamps be removed from a box? And if clamps are not used at all in a box, must they be removed to avoid the one-wire fill allowance?

Answer: Unused cable clamps may be removed to gain space or fill in the box, or they may be left in the box if adequate space is available without the removal of the clamp or clamps. If one clamp is left, the one-wire allowance must be made. If no clamps are used at all in a box, such as where the cable is attached to the box by box connectors, the one-wire allowance does not take effect.

4. Is the short jumper installed between the grounding screw on a grounding-type receptacle and the box in which the receptacle is contained officially classified as a *bonding jumper*? And is this conductor counted when the box wire count is taken?

Answer: The jumper is classed as a *bonding jumper*. 250.146 uses the wording “bonding jumper” in the section pertaining to this subject. However, whatever it is called, this conductor is not counted because it does not leave the box. The last sentence of 314.16(B)(1) covers that point.

An example of wire counting and correct wire fill for ganged boxes is included in the following examples. *Note:* In the examples given here, the same rules apply to wires in boxes for any wiring method—conduit, EMT, BX, NM.

Examples of Box Wire Fill

The top example in [Fig. 314-7](#) shows how wire fill allowances must be added to account for a box containing cable clamps and a fixture stud. Note this is an example of a domed canopy and the two fixture wires from the luminaire are not counted. The example at the bottom shows a nonmetallic-sheathed cable with three 14 AWG copper conductors supplying a 15-A duplex receptacle (one ungrounded conductor, one grounded conductor, and one “bare” grounding conductor).

FOR A 4x1½-in. OCTAGONAL BOX:

From Table 314.16(A)..... 6 wires
Two cable clamps..... 1 wire
One luminaire stud..... 1 wire

MAXIMUM 12 AWG WIRES: 4

(Note: fixture wires not counted;
they enter from a domed canopy)

NOTE: If NM cable were used, another deduction of one for the two ground wires would make use of this box a violation.

WIRE COUNT	
4 No. 14s	4
Cable clamps	1
Switch or plug	2
Two ground wires	1
TOTAL	8

Table 314.16(A) shows that a 2" X 3" box which is suitable for use with 8 No. 14 wires must be 3 1/2" deep.

Fig. 314-7. Correct wire count determines proper minimum size of outlet box. (Sec. 314.16.)

After supplying the receptacle, these conductors are extended to other outlets and the conductor count would be as follows:

Circuit conductors	4
Grounding conductors	1
For internal cable clamps	1
For receptacle	2
Total	<u>8</u>

The 14 AWG conductor column of Table 314.16(A) indicates that a device box not less than 3 by 2 by 3½ in. (75 by 50 by 90 mm) is required. Where a square box with plaster ring is used, a minimum of 4- by 1¼-in. (100- by 32-mm) size is required.

Table 314.16(A) includes the most popular types of metal “trade-size” boxes used with wires 14 AWG to 6 AWG. Cubic-inch capacities are listed for each box shown in the table. According to paragraph (A)(2), boxes other than those shown in Table 314.16(A) are required to be marked with the cubic-inch content so wire combinations can be readily computed.

Figure 314-8 shows another example with the counting data in the caption. The wire fill in this case may violate the limit set by 314.16(A).

Fig. 314-8 THIS MAY BE A CODE VIOLATION! A 4- × 4- × 1½-in. (102- × 102- × 38-mm) square metal box, generally referred to as a *1900 box*, has four NM cables coming into it. At upper right is a 14/3 cable with 14 AWG ground. The other three cables are 14/2 NM, each with a 14 AWG ground. The red wire of the 14/3 cable feeds the receptacle to be installed in the one-gang plaster ring. The black wire of the 14/3 feeds the black wires of the three 14/2 cables. All the whites are spliced together, with one brought out to the receptacle, as required by 300.13(B). All the ground wires are spliced together, with one brought out to the grounding terminal on the receptacle and one brought out to the ground clip on the left side of the box. The wire count is as follows: nine 14 AWG insulated wires, plus one for all of the ground wires and two for the receptacle. That is a total of 12 14 AWGs. Note that box connectors are used instead of clamps and there is, therefore, no addition of one conductor for clamps. But Table 314.16(A) shows that a 4- × 4- × 1½-in. (102- × 102- × 38-mm) square box may contain only 10 14 AWG wires. Some think that this is *not* a violation. They say that because the area provided by the cover has not been considered. But unless the cubic-inch capacity is marked on the cover, it may *not* be considered. The box is only 49.2 cm³ (3 in.³) short of the required volume. Practical experience in working with this equipment strongly suggests that if this plaster ring (with at least a 13-mm (½-in.) rise is marked with a volume, that volume would be sufficient. Therefore, this comes down to the existence of a marking, which may well be on the other side. (Sec. 314.16.)

Figure 314-9 shows an example of wire-fill calculation for a number of ganged sections of sectional boxes. The photo shows a four-gang assembly of 3- by 2- by 3½-in. (75- by 50- by 90-mm) box sections with six 14/2 NM cables, each with a 14 AWG ground wire and one 14/3 NM cable with a 14 AWG ground. The feed to the box is 14/3 cable (at right side), with its black wire supplying the receptacle which will be installed in the right-hand section. The red wire serves as feed to three combination devices—one in each of the other sections—each device consisting of two switches on a single strap. When finished, the four-gang box will contain a total of six switches and one duplex receptacle. Each of the 14/2 cables will feed a switched load. All the white neutrals are spliced together and the seven bare 14 AWG ground wires are spliced together, with one bare wire brought out to the receptacle ground terminal and one to the ground clip on the bottom of the left-hand section. The four-gang assembly is taken as a box of volume equal to 4 times the volume of one 3- by 2- by 3½-in. (75- by 50- by 90-mm) box. From Table 314.16(A), that volume is 18 cu in. for each sectional box. Then, for the four-gang assembly, the volume of the resultant box is 4 × 18, or 72, cu in. This is the front half of the calculation, set it aside.

Fig. 314-9. Calculation of the proper minimum box size for the number of conductors used in ganged boxes must follow 314.16(A)(1), taking the assembly as a single box of the sum of the volumes of the ganged sections and filling it to the sum of the conductor count. (Sec. 314.16.)

Remember that the box is to be considered as one box, indivisible. Do not waste time trying to apportion volumes or fill allowances by gang. Do not make wire counts by Table 314.16(A) numbers per gang, because they are truncated. For example, the square box in the previous example holds 10 14 AWG wires, but this number is rounded down because the Code limit is a not to exceed number. Its capacity is actually 344 cm^3 (21.0 in.^3); if these were gangable, and several were put together, and you figured on the basis of 10 wires each, you would lose one wire for every two boxes put together.

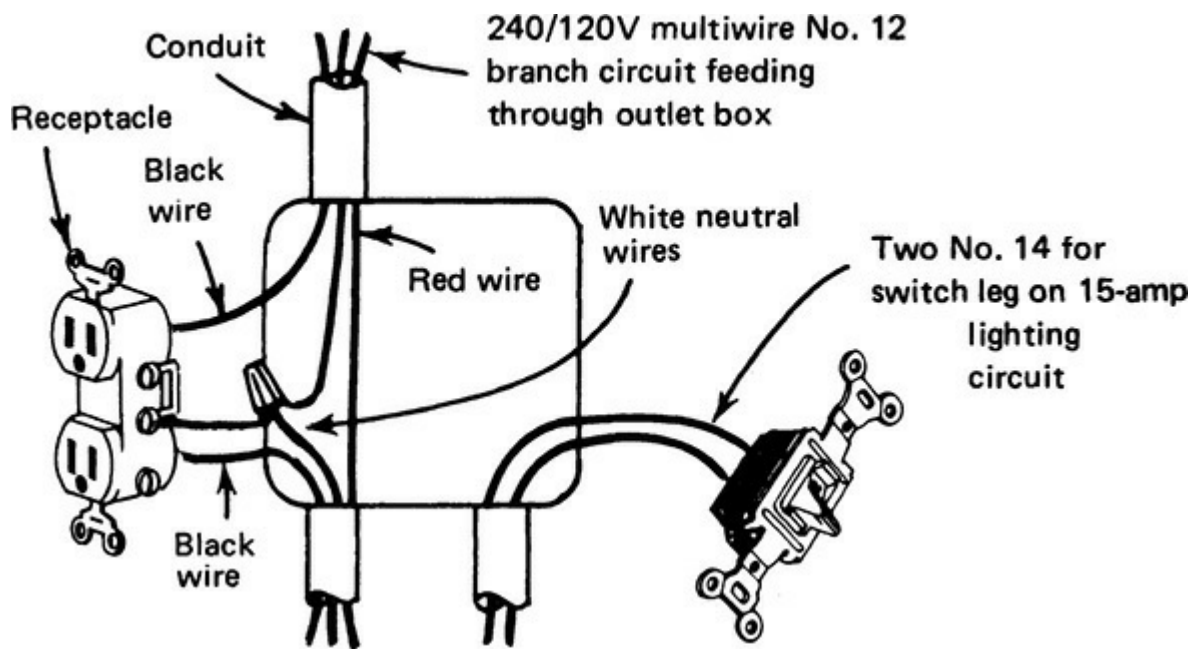

Now sum the fill allowances. There are 15 current-carrying 14 AWG wires in this box, for a fill allowance of: 15 14 AWG conductors. The equipment grounding conductors count collectively as 1 wire, so add 1 14 AWG conductor. The internal cable clamps count collectively as 1 wire, so add 1 14 AWG conductor. The four devices (counted by the strap, not the individual devices) add 2 each for a total of 8 14 AWG conductors. The grand total is 25, and at 32.8 cm^3 (2.00 in.^3) for each, the total required volume is 820 cm^3 (50 in.^3). This is the back half of the calculation; compare it with the front half to determine compliance. The total required is far less than the total provided, so the layout is acceptable.

When different sizes of wires are used in a box, Table 314.16(B) must be used in establishing adequate box size. Using the same method of counting conductors as described in Sec. 314.16(B), the volume of cubic inches shown in Table 314.16(B) must be allowed for each wire, depending on its size. Where two or more ground wires of different sizes come into a box, they must all be counted as a single wire of the largest size used.

When allowances are made from the number of wires permitted in a box [Table 314.16(A)], as

when devices, fixture studs, and the like are in the box, those allowances must “be based on the largest conductors entering the box” in any case where the conductors are of different sizes. This principle is true in such cases because the volume allowances equally affect all the conductors, regardless of size. However, when it comes to counting strap allowances, you only need to count based on the basis of the largest conductor arriving on a given strap, not the largest in the box.

Figure 314-10 shows a calculation with different wire sizes in a box. When conduit or EMT is used, there are no internal box clamps and, therefore, no addition for clamps. In this example, the metal raceway is the equipment grounding conductor—so no addition has to be made for one or more ground wires. And the red wire is counted as one wire because it is run through the box without splice or tap. As shown in the wire count under the sketch, the way to account for the space taken up by the wiring devices is to take each one as two wires of the same size as the largest wire attached to the device—that is, 12 AWG—as required in the end of the first sentence of part (A)(2). Note that the neutral pigtail required by 300.3(B) is excluded from the wire count as it would be under 314.16(A)(1).

Two white No. 12s in splice	_____	2 wires
Pigtail to neutral terminal does not count		
Red wire running directly through box	_____	1 wire
One receptacle strap	_____	2 wires
One switch strap	_____	2 wires
	Total No. 12s =	7 wires

Two black No. 12s to receptacle	_____	2 wires
Two black No. 14s to switch	_____	2 wires
	Total No. 14s =	4 wires

Fig. 314-10. When wires are of different sizes, volumes from Table 314.16(B) must be used. (Sec. 314.16.)

From Table 314.16(B), each 12 AWG must be provided with 36.9 cm^3 (2.25 in.^3)—a total of $7 \times 36.9 \text{ cm}^3$ (2.25 in.^3), or 258.3 cm^3 (15.75 in.^3) for the No. 12s. Then each No. 14 is taken at 32.8 cm^3 (2.0 in.^3)—a total of $4 \times 32.8 \text{ cm}^3$ (2.0 in.^3), or 131.2 cm^3 (8.0 in.^3) for both. Adding the two resultant volumes— $258.3 + 131.2$ ($15.75 + 8$)—gives a minimum required box volume of 389.5 cm^3 (23.75 in.^3). From Table 314.16(A), a $100 \times 100 \times 54 \text{ mm}$ 4- by 4-in. square box $2\frac{1}{8}$ in. deep, with 497 cm^3 (30.3 in.^3) interior volume, would satisfy this application.

For the many kinds of tricky control and power wire hookups so commonly encountered today—such as shown in Fig. 314-11—care must be taken to count all sizes of wires and make the proper volume provisions of Table 314.16(B).

Fig. 314-11. Many boxes contain several sizes of wires—some running through, some spliced, and some connected to wiring devices. Calculation of minimum acceptable box size must be carefully made. The combination switch and receptacle here is on a single mounting strap, which is taken as two wires of the size of wires connected to it. (Sec. 314.16.)

Table 314.16(A) gives the maximum number of wires permitted in boxes. But the last sentence of the first paragraph of 314.16(A)(2) does indicate that boxes may contain more wires if their internal volumes are marked and are greater than shown in Table 314.16(A).

Because the volumes in the table are minimums, most manufacturers continue to mark their products with the actual volume. This in many cases is somewhat greater than the volumes shown in the table. The last sentence of 314.16(A)(2) says that boxes that are marked to show a cubic-inch capacity greater than the minimums in the table may have conductor fill calculated in accordance with their actual volume, using the volume per conductor given in Table 314.16(A)(2).

The 2014 **NEC** has added a new paragraph to 314.16(B)(2) to recognize an invention (Fig. 314.12) designed to speed up the wiring process, especially in residential applications. The NM cable wires do not count in box fill, but those furnished with the clamp assembly do count. The clamp assembly does not require a fill allowance, but the box volume must be measured such that the

volume of any internal portions of the clamp is excluded from its marked capacity. The clamp only accepts comparatively flat cables, and the manufacturer has arranged for the availability of 14/3 and 12/3 NM cable in a flat configuration to work with the assembly.

Fig. 314-12. This combination of a termination fitting and nonmetallic box must be part of a listed combination. [Sec. 314.16(B)(2).]

Conduit bodies must be marked with their cubic-inch capacity, and conductor fill is determined on the basis of Table 314.16(C). Such conduit bodies may contain splices or taps. An example of such application is shown in Fig. 314-13. Each of the eight 12 AWG wires that are “counted” as shown at bottom must be provided with at least 36.9 cm^3 (2.25 in.^3), from Table 314.16(B). The conduit body must, therefore, be marked to show a capacity of not less than $8 \times 36.9 \text{ cm}^3$ (2.25 in.^3), or 295.2 cm^3 (18 in.^3).

All such bodies must be durably and legibly marked by manufacturer with their cubic-inch capacities.

Wire count of fitting:

Fig. 314-13. Conduit bodies no longer must have “more than two entries” for conduit bodies to contain splices or taps. (Sec. 314.16.)

The point of the conduit body rule is simple. If you use a conduit body to add an access point to a raceway or change its direction, but do nothing to the enclosed wires, then its function is to be part of the raceway system, and its size is whatever [Chap. 9](#) requires for the raceways. On the other hand if you use a conduit body to make a splice or support a device or a lampholder, then you are using it as a box and you will size it as if it were a box.

This leads to a practical consideration, and that is that it is almost inconceivable that a conduit body will actually work as a box in cases like this. This example, a very modest run of 4 12 AWG wires with two of them branching out at the tee fitting, comes out requiring 295.2 cm³ (18 in.³) in volume. The wires will fit easily in a metric designator 16 (trade size ½) raceway. Casual inspection of manufacturer’s data for conduit bodies strongly suggests that the smallest tee conduit body with this much volume is a metric designator 35 (trade size 1¼) conduit body. As a practical matter, who in their right mind would be so enamored of conduit bodies that they would redesign the raceway upward by three trade sizes just to make this splice? And be careful about suggesting bushing the larger conduit body down to the size of the raceway. That can be done on rigid metal conduit and

intermediate metal conduit, but on no other wiring methods, and only when they are actually threaded into the enclosure, and only if the volume is below 1650 cm³ (100 in.³), which is true in this case. If those conditions are not met, such as the wiring method being EMT or PVC, then 314.23(E) will have the tee fitting independently supported to structure, instead of being able to rely on the entering raceways. This job would be done with a box in a heartbeat.

Part (C) of 314.16 contains a number of provisions that must be carefully evaluated. [Figure 314-14](#) shows the first rule. For instance, in that drawing, if a conduit body is connected to metric designator 16 (trade size ½) conduit, the conduit and the conduit body may contain seven 12 AWG TW wires—as indicated in Table C8, App. C, for rigid metal conduit—and the conduit body must have a csa at least equal to 2 × 204 mm² (0.314 in.²) (the csa of metric designator 16 [trade size ½] conduit), or 408 mm² (0.628 in.³). That is really a matter for the fitting manufacturers to observe.

Fig. 314-14. For No. 6 and smaller conductors, conduit body must have a csa twice that of largest conduit. (Sec. 314.16.)

The second paragraph of part (C) covers the details shown in [Fig. 314-15](#). The rule requires that where fittings are used as shown in the drawing, they must be supported in a rigid and secure manner. Because 314.23 establishes the correct methods for supporting of boxes and fittings, it must be observed, and that section refers to support by “conduits”—which seems to exclude such use on EMT because the **NEC** distinguishes between “conduit” and “tubing” (EMT), as in the headline for Table 1 of [Chap. 9](#) in the back of the Code book. [Figure 314-15](#) shows typical applications of those conduit bodies for splicing.

Although the basic rule still prohibits splicing and tapping in these fittings . . .

. . . Permission is **now** given to splice in such fittings, if 314.16(B) is satisfied; that is, if—

1. The fitting is marked with its cubic-inch volume . . .

2. The conductor-fill volume is calculated using the wire volumes of Table 314.16(B) and the wire-counting method of 314.16(A)—and that fill does not exceed the fitting's marked volume . . .

3. And the fitting is "supported in a rigid and secure manner"—such as by the "conduit," if the conduit is clamped on each side of the fitting as described in the next-to-last paragraph of 314.23.

Fig. 314-15. Splices may be made in C and L conduit bodies—if the conditions shown in this illustration are satisfied. (Sec. 314.16.)

Refer to the discussion in the text associated with [Fig. 314-13](#) for a full discussion of how unrealistic it is to expect to actually make use of the splicing allowances for conduit bodies. The only possible way out would be if manufacturers made oversize conduit bodies with much larger internal volumes, and that hasn't happened in the 18 years since these same rules have been in the **NEC**. The applications in [Fig. 314-16](#) are indeed common, and they speak to a failure in the industry to enforce the rules. The floodlight needs to go on a box, and the box needs support arranged for it. The

connection at the motor should be in the terminal housing, and yes, the LB needs more support; one way is to use a conduit nipple and threaded coupling out of the LB to a straight Greenfield connector. That would allow the support that should have been provided. That said, there are many small devices out there, such as solenoids, which come with short leads, with no splicing enclosure, and located far from any support point. It is unfortunate indeed when conscientious installers are driven to 90.4 in order to provide workmanlike installations in this area of the trade.

Fig. 314-16. Splicing in C or L conduit bodies is common practice. (Sec. 314.16.)

The third paragraph covers “short-radius conduit bodies.” For generations the conduit bodies listed here and shown in Fig. 314-17 have been in a sort of “no-man’s land.” They meet the Art. 100 definition of a conduit body. They fail the bending space rules in 314.28(A)(2). They are obviously unsuited to enclose splices or devices. So now they have their own special classification, along with some rules to make sure they are applied properly. They must not be used with any conductors 4 AWG and larger, for which bending space rules apply, and they must only serve to change a raceway direction, nothing more. In addition to the items named in the rule, the classification includes flat 90°

fittings with the removable covers that are coplanar with the axis of the raceway entries, and also the little “handy ells” often used at the edge of a box. This requirement used to be a standalone Sec. 314.5, but was moved here because it fits with the other material on conduit bodies.

Fig. 314-17. Four examples of short-radius conduit bodies. [314.16(C)(3).]

314.17. Conductors Entering Boxes, Conduit Bodies, or Fittings. Part (A) requires “openings” to be adequately closed. Compliance with this rule can be achieved using a properly sized and listed enclosure, as is generally required by 300.16. Part (B) requires cables or raceways to be secured to *all metal* outlet boxes, conduit bodies, or fittings—such as by threaded connections, connector devices, or internal box clamps. It also addresses the rules for bringing loom into a box safely so the cable clamps don’t damage the wire. It also requires that when a nonmetallic cable assembly enters a metal box, the sheath must clear the box and any cable clamping mechanism by at least $\frac{1}{4}$ in. This will avoid a metal clamping edge from abrading the insulation on one of the enclosed conductors. This 2017 **NEC** change directly correlates with the longstanding rule in (C) for nonmetallic boxes. The first sentence of part (C) requires that a nonmetallic box must have a temperature rating at least equal to the lowest-temperature-rated conductor entering the box. This rule assumes that the lowest-temperature-rated conductor in a box must be suited to the temperature in the box. The box would, therefore, be properly applied if it has a temperature rating at least equal to that of the lowest-rated conductor. At least $\frac{1}{4}$ in. of the cable sheath must be brought inside the box. Here

too, it also addresses the rules for bringing loom into a box safely so the cable clamps don't damage the wire.

Another very important limitation in this Code section applies to the need for clamping nonmetallic-sheathed cable at a KO where the cable enters anything other than a single gang box. The Code has always accepted the use of nonmetallic-sheathed cable without box clamps or any type of connector where the cable is stapled within 8 in. (200 mm) of the box. The cable is then brought into the box through an NM cable KO on the box, without any kind of a connector at the KO or any clamps in the box (Fig. 314.18). But the intention of the exception to part (C) is that boxes or enclosures other than single gang boxes must be provided with a clamp or connector to secure nonmetallic-sheathed cable to such boxes (Fig. 314.19). *Only single gang nonmetallic boxes may be used without a cable clamp at the box KOs.* Where the Code permits elimination of a cable clamp if the cable is clamped to the stud within 8 in. (200 mm) of the box, the rule specifies that the 8-in. (200-mm) length be measured *along the cable* and not simply from the point of the cable strap to the box edge itself. The idea is to reduce the likelihood that pushing the device back into the box after wiring will be able to force the cable assembly back out of the box.

Fig. 314-18. NM cable does not have to be clamped to single gang boxes. (Sec. 314.17.)

Fig. 314-19. NM cable must be clamped to all nonmetallic boxes that are *not* single gang boxes. (Sec. 314.17.)

When used with open wiring on insulators, knob-and-tube work, or nonmetallic-sheathed cable, nonmetallic boxes have the advantage that an accidental contact between a “hot” wire and the box will not create a hazard.

314.19. Boxes Enclosing Flush Devices. A through-the-wall box is a box which is manufactured to be installed in a partition wall so that a receptacle or switch may be attached to either side; therefore, it is not necessary to use two standard boxes, one facing each side, connected by a jumper. After the devices have been installed on both sides, and the required faceplates secured, the devices are enclosed on all sides and the intent of the rule is satisfied.

If the screws used for attaching the receptacles and switches to boxes were used also for the mounting of boxes, a poor mechanical job would result, since the boxes would be insecurely held whenever the devices were not installed and the screws loosened for adjustment of the device position. Hence the prohibition.

314.20. Flush-Mounted Installations. For flush-mounting applications, a box must be flush with a combustible surface or even project forward; if the surface is not combustible the box can be recessed but not more than 6 mm ($\frac{1}{4}$ in.). As used here, the term *box* includes the components that make up the final enclosure, including extension boxes and plaster rings. If the box is recessed more than is allowed by this rule, a “listed extender” is permitted to make up the difference.

314.21. Repairing Noncombustible Surfaces. For boxes using flush covers and recessed in drywall or plaster surfaces, the plaster or drywall must be repaired so that the gap between the box and the surface does not exceed 3 mm ($\frac{1}{8}$ in.). The spacing allowance provides some relief to installers, because for several generations the requirement was a complete repair. The dimension comes from the fact that when UL evaluates electrical box penetrations in fire-rated assemblies, they assume this gap will exist around the perimeter of the box being tested.

The purpose of 314.20 and 314.21 is to prevent openings around the edge of the box through which fire could be readily communicated to combustible material in the wall or ceiling. Both 314.20 and 314.21, and their counterparts in Art. 312, address issues related to when ordinary building construction will be allowed to complete an electrical enclosure. 314.20 is looking at the cut surface that is perpendicular to the building surface and extending into the opening and concluding that it is acceptable as long as it isn’t combustible and doesn’t extend more than 6 mm ($\frac{1}{4}$ in.). 314.21 is

looking at the plane of the building surface itself and asking, if the enclosure is behind the plane of the finished wall to some extent, how well does the cut-out need to be repaired to prevent a fault in the box from getting past the flush cover and into the wall along the side of the enclosure, and concluding the answer is 3 mm ($1/8$ in.). 314.21 also concludes (implicitly) that it isn't necessary to repair the wall edge if the wall is combustible, because in such cases the enclosure must come all the way out, and at that point the flush cover will pretty well seal to the enclosure walls, as extended if necessary. Therefore, it is not required to bring plastic wood filler to jobs in wood paneling.

None of this discussion is relevant to a surface-mounted style enclosure cover that telescopes over the enclosure walls or seats flat on all four sides, such as a raised cover on an outlet box designed for surface mounting. The box being recessed in the wall to a greater or lesser degree doesn't change the fact that a surface cover will seal to the box and complete the enclosure. If the enclosure is half in the wall and half out, for example, and if the building surface isn't repaired at all and looks ugly, so be it. If it is a penetration in a fire-rated partition, the repair will be required by 300.21, but many applications are not and it is not appropriate to write this rule as though a repair should always be required. The electrical enclosure is complete, and if the owner doesn't like how the wall looks, it can be repaired later. This is why these rules have been modified in recent code cycles to limit their application to flush-mounting situations where, as noted, the building finish is being called upon to complete an electrical enclosure.

314.22. Surface Extensions. The extension should be made as illustrated in Fig. 314-20. The extension ring is secured to the original box by two screws passing through ears attached to the box.

Fig. 314-20. Extension ring must be secured to box for surface extension. (Sec. 314-22.)

As noted in the exception, a surface extension may be made from the *cover* of a concealed box, *if* the cover mounting design is secure, the extension wiring method is flexible, and grounding does not depend upon connection between the box and the cover. This exception to the basic rule, which requires use of a box or extension ring over the concealed box, permits a method that provides a high degree of reliability.

The wording about the cover not falling off if the securing means loosens may need some

explanation. An extension from a blank handy box cover or the like is not a problem because the 6-32 screws would have to come completely out of the box to release the cover. The rule is aimed at extensions from concrete rings or octagon boxes (or round plaster rings) on ceilings that have a usual keyhole-shaped slot for at least one of the 8-32 mounting screws. If those screws loosen, even a little, the cover can turn the required few degrees until the wide end of the slot lines up with the screw head and the cover falls free. To counteract this, some cover designs have a raised detent on the edge of the keyhole slot. The cover cannot turn past this point unless the screw is loosened at least another (roughly) three complete turns, and then the cover is pushed up against gravity and turned the rest of the way. The wording requires this or some other design feature that will keep the cover in place until it is really supposed to come down.

314.23. Supports. The Code rule strictly requires all boxes, conduit bodies, and fittings to be fastened in their installed position—and the various paragraphs of this section cover different conditions of box support for commonly encountered enclosure applications. The one widely accepted exception to that rule—although actually not recognized by the Code—is the so-called throw-away or floating box, which is a junction box used to connect flexible metal conduit from a recessed fixture to flex or BX branch-circuit wiring, in accordance with Sec. 410.117(C) (Fig. 314.21). In such cases, the connection of the fixture “whip” (the 18 in. to 6 ft length of flex with high-temperature wires, for example, 150°C Type AF) is made to the branch-circuit junction box which hangs down through the ceiling opening, and then the junction box is pushed back out of the way in the ceiling space, and the fixture is raised into position. But with suspended ceilings of lift-out panels, there is no need to leave such a loose box in the ceiling space, because connection can be made to a fixed box before the ceiling tiles are laid in place. It is important to remember that this procedure is functionally obsolete for another reason. Most recessed luminaires are required to have thermal protection. This is arranged through a self-contained connection box mounted as part of the luminaire because the test labs need to know exactly where the device will be located so they can test it. Any high-temperature wiring ends in this box, and is not provided in the field to a remote box.

Fig. 314-21. Fixture supply flex is tapped out of junction box fed by flex or BX branch-circuit wiring in ceiling space. Box is later “thrown away,” unattached, into ceiling space. This is not permitted. (Sec. 314.23.)

Figure 314-22 shows the rule of part **(B)(1)** of this section. Note that since everyone has screw guns these days, the rule now addresses screws where nails would have been used previously. Screws have sharp edges all along their shafts, which can damage wiring pushed blindly into the box. So, if screws are used with exposed threads in the box, some kind of sleeving has to be applied over the raw threads. Periodically, it is necessary to drill a mounting hole in a more convenient location than where the manufacturer pre-made hole; now when this is done the inspector gets asked for approval.

Fig. 314-22. Box-mounting nails must not obstruct box interior space. (Sec. 314.23.)

An outlet box built into a concrete ceiling, as shown in [Fig. 314-23](#), seldom needs any special support, per 314.23(G). At such an outlet, if it is intended for a fixture of great weight to be safely hung on an ordinary $\frac{3}{8}$ -in. fixture stud, a special fixture support consisting of a threaded pipe or rod is required, such as is shown in [Fig. 314-24](#).

Fig. 314-23. Box in concrete is securely supported. (Sec. 314.23.)

Fig. 314-24. Box in tile arch ceiling requires pipe-hanger support if very heavy lighting fixture is to be attached to the box stud. (314.23.)

In a tile arch floor (Fig. 314.24), a large opening must be cut through the tile to receive the conduit and outlet box.

The requirement of metal or wood supports for boxes applies to concealed work in walls and floors of wood-frame construction and other types of construction having open spaces in which the wiring is installed. In walls or floors of concrete, brick, or tile where conduit and boxes are solidly built into the wall or floor material, special box supports are not usually necessary.

As covered in part (C), in an existing building, boxes may be flush mounted on plaster or any other ceiling or wall finish. Where no structural members are available for support, boxes may be affixed with approved anchors or clamps. Figure 314-25 illustrates that. For cutting metal boxes into existing walls, “Madison Holdits” are used to clamp the box tightly in position in the opening. Actually, the local inspector can determine acceptable methods of securing “cut-in” device boxes because this provision provides appreciable latitude for such decisions.

1. Inserting box and bracket through wall board.

2. Box anchored to wall.

For clamping boxes to openings cut in existing walls

"MADISON HOLDITS"

STEEL

Fig. 314-25. Part (C) of 314.23 refers to these types of clamping devices. (Sec. 314.23.)

And according to part (D), framing members of suspended ceiling systems may be used to support boxes if the framing members are rigidly supported and securely fastened to each other and to the building structure.

Figure 314-26 shows box-support methods that are covered by part (E) of 314.23 for boxes not over 100 in.³ (1650 cm³) in volume that do not contain devices or support luminaires. Pay close attention because a great number of rules are packed into this paragraph of Code text. The rule there applies to "conduit" (rigid metal conduit and IMC only; see exception following for others) used to support boxes—as for overhead conduit runs. A box may be supported by two properly clamped conduit runs (rigid metal conduit or IMC) that are *threaded into* entries on the box or into field-installed hubs attached to the box. The words "threaded wrenchtight into" purposely exclude a set-screw or compression connector applied to the unthreaded end of a run of conduit. The conduit must

thread into the box. If that can't be done because of problems turning the conduit, then a short nipple and a union can be used, but the conduit system will thread into the box. These words, along with 352.10(H), also exclude PVC conduit as a support. The associated permission to use separate, field-installed hubs offers a relaxation of the previous demand for hubs manufactured with the box, such as FS boxes. This is the only permissible way to support a sheet metal box on the entering raceways: add hubs (the so-called "Myers Hubs") to the box, and then thread RMC or IMC into the hubs, as before. Where locknut and bushing connections are used instead of threaded conduit connections to a threaded hub or similar connection, the box must be independently fastened in place. The orientation of the conduit entries also matters. They must enter on two or more sides because of the substantial distance allowed to the support point, 900 mm (3 ft). If that support distance is reduced to 450 mm (18 in.), then the conduit entries can be on the same side.

Fig. 314-26. Box may be supported by "conduit" that is clamped, but box must not contain or support anything. (Sec. 314.23.) Note that the vapor-tight luminaire installation, as shown in the

center panel, probably would comply with 314.23(F) if the wiring method were rigid or intermediate metal conduit.

The rule as worded would not allow even a conduit body on EMT or PVC to be supported by its raceway entries, and calls for direct support to structure instead. This would be an absurd result and the exception is written to take care of these problems. The exception and the rule are very tightly integrated, and must be read together. The exception begins with a list of wiring methods which include RMC and IMC. Why? Because the rule does not allow for raceway supported enclosures above 1650 cm³ (100 in.³), and many conduit bodies for the larger conduit sizes well exceed this size threshold. However, a conduit body installed under this exception must be no larger than its largest entering raceway. The exception also recognizes the use of “E” fittings that have only a single conduit entry, for obvious reasons.

Note that this does vary from the principle that enclosures must never be supported by a single entry because an enclosure so mounted can easily untwist. “E” fittings are not much larger than the supporting conduit and so there is not much mechanical advantage presented by the fitting in terms of torque in comparison to a FS box or other comparable enclosure.

The question now arises, can a (for example) metric designator 27 (trade size 1) tee fitting be bushed down for all metric designator 21 (trade size ¾) entries? This brings up an important rule of reading Code text, namely, if you comply with a rule, it does not matter what a permissive exception following the rule happens to say. (Mandatory exceptions are extensions of the rule, must be followed if applicable, and in any list of exceptions must be listed first for this reason.) In this case, if the wiring is RMC or IMC and all the rules regarding support are followed, the installation is perfectly OK because the exception following is permissive. However, if you depart from the rule for any reason, then you have to abide by the terms of the exception.

The rules of part (F) of 314.23 are shown in [Fig. 314-27](#). The basic rules and first exception closely follow the rules in (E), except that the support distance drops to 450 mm (18 in.) which is allowed to be all on one side. The exception does not list EMT or PVC because now there is considerable load on the conduit body. [Figure 314-28](#) shows several installations that are in violation of these rules.

Nonthreaded nonmetallic box may be supported by only *metal* conduits.

Fig. 314-27. Boxes fed out of the ground or a concrete floor, patio, or walk must observe these rules. (Sec. 314.23.)

Fig. 314-28. A *single* rigid metal conduit may not support a box, even with concrete fill in the ground (left). Box may not be supported on EMT, even with several connections used (center). Method at right is a violation on three counts: EMT, not “conduit,” supports the box; only one hub on box is connected; box is more than 18 in. above ground. (Sec. 314.23.)

Part (F) has a second exception to cover cantilevered applications where luminaires are on the ends of conduit stems, such as some commercial lighting over sidewalks and billboard lighting, as shown in the upper left of [Fig. 314-29](#). This exception and the work in Part (H)(2) below, was developed in conjunction with a task group with representation from the steel conduit makers, and focused in part on how much force typical threaded joints could be expected to withstand. Note that these are rules for field installations of conduit and boxes. If the conduit stem is provided with the luminaire and is covered by the luminaire listing, then these rules do not apply and the luminaire installation directions take precedence.

Fig. 314-29. Luminaires on conduit stems. [314.23(F) Exception No. 2 and 314.23(H)(2).]

Part **(H)** permits a pendant box (such as one containing a START-STOP button) to be supported from a multiconductor cable, using, say, a strain-relief connector threaded into the hub on the box, or some other satisfactory protection for the conductors. The second part, **(H)(2)**, covers the common practice, especially in industrial occupancies, of hanging HID luminaires from conduit stems, as illustrated in the lower right of [Fig. 314-29](#). These rules also focus on limiting the breaking forces that could be imposed on the threads. Note that the maximum dimension for luminaire horizontal extension from the conduit entry, 300 mm (12 in.), precludes hanging 900 mm (3 ft) or 1.2 m (4 ft) fluorescent luminaires from a single conduit entry support. This is a significant issue with T5 fluorescent luminaire retrofits for previous HID applications.

314.24. Depth of Boxes. Sufficient space should be provided inside the box so that the wires do not have to be jammed together or against the box, and the box should provide enough of an enclosure so that in case of trouble, burning insulation cannot readily ignite flammable material outside the box. The 2008 **NEC** expanded the scope of this section considerably in response to proposals that substantiated fire alarm equipment in particular that was causing installation problems in even large boxes. The proposals wanted to recalculate the volume rules in 314.16. That would not have solved the problem because an item with small volume can still have a long reach backward. The solution was to add language here regulating box depth.

Parts **(A)** and **(B)(5)** were in the Code previously and cover ceiling pans and the 25.4 mm (1-in.) deep boxes used in some special applications such as for doorjamb switches. The fire alarm equipment problem is addressed in **(C)(1)**. Equipment that has been listed for use in certain boxes may, of course, use those boxes.

This section also covers devices, and sets depth requirements based on wire sizes. The dimensions were chosen based on task group research into actual device and conductor dimensions and comparing that with standard box dimensions. The objective is to prevent damage to conductors resulting from devices pinning wires tightly against the back wall of a box in the process of installation. Remember that the inner back planes of many outlet boxes have inwardly punched knockouts as well as the tops and shoulders of mounting hardware, any of which could easily damage a conductor if clearance is not provided.

Item **(2)** covers large power outlets that usually mount in cast boxes and are designed accordingly. Item **(3)** covers the larger devices, such as 3-pole 4-wire range receptacles. The dimension chosen correlates with the standard sized 2¹/₈-in. box depth; as an internal measurement it is 1/16-in. smaller than the standard nominal box dimension. Item **(4)** correlates typical device sizes with standard minimum device box depths, after allowing for the thickness of the steel. This paragraph also contains a backup requirement for a minimum enforceable clearance of ¼ in. because some devices in this category approach 1¾ in. in depth, and a deeper box will be required. Item **(5)** picks up the requirement that existed in the **NEC** since the 1975 edition. It was originally designed to accommodate a device box mounted on a masonry wall with ¾-in. furring plus paneling. Although largely obsolete because of changes over the years in volume allowances, it can still be used, particularly with some sort of box extension. It is limited to 14 AWG wiring accordingly.

314.25. Covers and Canopies. This rule requires every outlet box to be covered up—by a cover plate, a fixture canopy, or a faceplate, which has the openings for a receptacle, snap switch, or

other device installed in a box. An electric discharge luminaire mounted over an outlet box is permitted to substitute for the cover normally required, but it must comply with 410.24(B) in the process, which means it will be punched to allow access to the interior of the box from the luminaire ballast channel without removing the luminaire from the wall surface. The 2014 **NEC** has added a rule requiring cover mounting screws to either match the thread tapping of a box or line up with the manufacturer's instructions; the point is to eliminate the use of random drywall screws for this purpose.

Part **(A)** requires all metal faceplates to be grounded as required by 250.110. As noted in the commentary under that topic, the fact that any wiring method with an equipment ground must connect exposed metal surfaces to the equipment grounding conductor has transformed the practical implementation of the overall requirement. Instead of measuring to grounded surfaces, just look for the equipment ground, and make the connection. For faceplates (covered in Fig. 314-30) use a device with a grounding terminal. This rule is frequently violated for no good reason. For a cover a ground clip (Fig. 250.112) will easily attach to the side of a metal cover, creating a tail that is easily connected. It should be further noted that for a snap switch faceplate, such as the one that would be installed on the box in Fig. 314-30, the grounding termination on the snap switch is generally required whether or not a nonmetallic faceplate is first installed, as covered in 404.9(B).

Fig. 314-30. Grounding switch must be used for metal faceplate on any nonmetallic box. (Sec. 314.25.)

In part **(B)** of 314.25, if the ceiling or wall finish is of combustible material, the canopy and box must form a complete enclosure. The chief purpose of this rule is to require that no open space be left between the canopy and the edge of the box where the finish is wood or other combustible material; however, a 2014 **NEC** change in 410.23 has virtually eliminated this requirement in any practical sense. Where the wall or ceiling finish is plaster, the requirement does not apply, because plaster is not classed as a combustible material; however, the plaster must be continuous up to the box, leaving no opening around the box beyond the 3 mm ($1/8$ in.) allowed in 314.21. Refer to the coverage of the sister requirement in 410.23 for more information on this topic and the impact of the major 2014

NEC change at that location.

314.27. Outlet Boxes. Part (A) requires that any box used at luminaire (or lamp holder) outlets in a ceiling be designed for this purpose and be capable of supporting a luminaire weighing not less than 23 kg (50 lb). Boxes used for the same purpose in a wall must also be designed for the purpose, but if they are not capable of supporting a 23 kg (50 lb) luminaire, they can be used, and must be marked on the inside of the box with the weight they can support if it's anything other than 23 kg (50 lb) (some are more). This requirement means that any boxes with the marking "FOR FIXTURE SUPPORT" on the unit carton will have the required construction and be suitable for supporting a 23 kg (50 lb) luminaire. There have been some nonmetallic boxes that had been listed for intermediate support weights, such as 6.9 kg (15 lb). Although they were marked, most installers weren't looking for the marking, believing that if it had the usual 8-32 screws in one of the usual mounting configurations, it was suitable for a 23 kg (50 lb) load. Boxes suitable for higher weights are marked accordingly. Note that this section formerly did not address box support limits where they were mounted on open framing instead of wall surfaces. The 2014 NEC has closed this loophole by changing the subject heading to "vertical surface" (instead of "wall") outlets. The intent for both numbered paragraphs is the same: Outlet boxes designed for luminaire support are marked to that effect and must be rated for the ability to support at least 50 lb. This is the default and need not be marked. Then, if the manufacturer produces an outlet box that will carry a greater weight and has a listing to prove it, it can be used for up to that weight. The box must be marked, on its interior so the inspector can see it after the large luminaire is in evidence, with the designed capacity.

The exception allows other boxes to support luminaires weighing up to 3 kg (6 lb) to be supported on other boxes not designed for luminaire support, such as device boxes or single-gang plaster rings with 6-32 mounting screw provisions. At least two 6-32 screws must be used to support the luminaire, and this exception only applies when the screws are in shear and not in tension, that is, for a wall- and never a ceiling-mounted luminaire. This exception does not apply to smoke detectors, etc.; refer to (D) for utilization equipment coverage.

Part (B) requires floor boxes to be completely suitable for the particular way in which they are used. Adjustable floor boxes and associated service receptacles can be installed in every type of floor construction. A metal cap keeps the assembly clean during pouring of concrete slabs. After the concrete has cured, this cap can then be removed and discarded and floor plates and service fittings added.

There are two types of floor receptacles, the usual ones and ones for the elevated floors of show windows, etc., where they will not receive the same floor traffic, as per the exception. These are classified by UL as "display receptacles." Although they have a superficial similarity to floor receptacles, floor receptacles are sold with a box and the combination has passed additional tests, including a scrub-water test. Do not confuse the two.

As noted in part (C), a ceiling paddle fan must not be supported from a ceiling outlet box—unless the box is UL-listed as suitable as the sole support means for a fan (Fig. 314.31). The vibration of ceiling fans places severe dynamic loads on the screw attachment points of boxes. But boxes designed and listed for this application pose no safety problems. There are two weight limits in this section. No fan box may serve as the direct support of a paddle fan weighing over 32 kg (70 lb). All fan boxes need to be listed and marked that they are suitable for fan support, and the default weight limit for suitability is a 16 kg (35 lb) fan. Any manufacturer who chooses to design a box for a heavier fan may do so, provided (1) it will not be expected to hold more than 32 kg (70 lb) and (2)

the designed fan weight, whatever it is between 16 kg (35 lb) and 32 kg (70 lb), must be marked on the box. A fan box capable of supporting a 16 kg (35 lb) fan does not require a weight marking, because that is the default suitability.

Fig. 314-31. Support for ceiling fans must be suited to the dynamic loading of the vibrating action. [Sec. 314.27(D).]

The second paragraph addresses widespread reports of attempts at deceit on the part of some unscrupulous builders, who have bedrooms roughed in without the expense of fan boxes, but wired to tacitly encourage their customers to hang fans anyway. If a spare, separately switched conductor is run to a ceiling box in a location that will accommodate a paddle fan (e.g., ceiling boxes 18 in. from a wall, perhaps for track lighting with wall washer luminaires, would not be caught in this requirement) then a listed fan box must be installed. There have been many attempts to address this, all failing on the legitimate uses of multiple switched conductors run to a ceiling box, including chandeliers with split loads.

This wording received a unanimous vote due to the magical word “spare.” If the owner or builder doesn’t want the fan box, then the owner doesn’t run a spare wire. And there are legitimate reasons to avoid a fan box requirement. Not all ceiling boxes are simple, particularly in locations with raceway wiring; in such areas it is common to branch the perimeter receptacle outlets from a ceiling overhead luminaire outlet box. This may involve large steel boxes, even with extension boxes, and plaster rings. Combinations such as these will never be available as listed fan boxes because there is insufficient market to support their development.

In addition, it is very important to remember that it never has been and still is not a requirement to hang a paddle fan on a listed fan box. It is only a requirement to use the fan box *if it will be the sole support of the fan*. Often ceilings are deliberately framed so as to be capable of receiving ¼-in. lag bolts run through the fan bracket, through the crow-foot pattern mounting holes in the back of the box, and into the framing member. Such an arrangement does not require a listed fan box. At least one major paddle fan manufacturer sells its fans with such lag bolts, and includes instructions (these are listed fans so the instructions are enforceable) to run the bolts into framing, and not use a fan box. The wording as of the 2011 **NEC**, by focusing on the word “spare,” neatly accommodates these legitimate concerns; again, if one wants to avoid the fan box requirement, simply don’t run the spare

wire.

Part **(D)** was new for the 2008 **NEC** and covers utilization equipment mounted on outlet boxes. The rules in 314.27(A) carry over, but the 3 kg- (6-lb) exception differs in one key respect because there is no orientation limitation; the box can be mounted on the ceiling or on a wall.

Part **(E)**, new for the 2017 **NEC**, addresses the new locking support receptacles now covered in the revised definition of “receptacle” in Article 100. Refer to [Fig. 100-28](#) for a photo of one of these receptacles, together with a luminaire to the side outfitted with compatible hardware. The locking support and mounting receptacle must be listed for the support of compatible attachment fittings, and the combination must be identified for the allowable weight and orientation. In other words, if it can be used on a vertical surface it must say so, etc. If the receptacle is mounted within a box, as in the case of the one shown in [Fig. 100-28](#), then a double volume allowance must be applied, in accordance with 314.16(B)(4). Note that 422.18(2) contains correlating language that recognizes the support of paddle fans in accordance with these rules.

314.28. Pull and Junction Boxes and Conduit Bodies. As noted in 314.16, conduit bodies must be sized the same as pull boxes when they contain 4 AWG or larger conductors, if the conductors are required to be insulated. Grounding electrode conductors are routinely installed in conduit for protection, in raceways sized to carry the one conductor. Conduit bodies for the smaller raceways do not meet the dimensional requirements of this section. Because the size rules have primarily to do with protecting the long-term integrity of insulated conductors, the rules need not be applied in these cases.

For raceways containing conductors of 4 AWG or larger size, the **NEC** specifies certain minimum dimensions for a pull or junction box installed in a raceway run. These rules also apply to pull and junction boxes in cable runs—but instead of using the cable diameter, the minimum trade size raceway required for the number and size of conductors in the cable must be used in the calculations. Basically, there are two types of pulls—straight pulls and angle pulls. [Figure 314-32](#) covers straight pulls. [Figure 314-33](#) covers angle pulls. In all the cases shown in those illustrations, the depth of the box only has to be sufficient to permit installation of the locknuts and bushings on the largest conduit. And the spacing between adjacent conduit entries is also determined by the diameters of locknuts and bushings—to provide proper installation. Depth is the dimension not shown in the sketches.

EXAMPLES:

1.

$L = 8 \times 2 \text{ in.} = 16 \text{ in. minimum}$
 $W = \text{Whatever width is necessary to provide proper installation of the conduit locknuts and bushings within the enclosure.}$

2.

The 3-in. conduit is the largest.

Therefore—

$L = 8 \times 3 \text{ in.} = 24 \text{ in. minimum}$

$W = \text{Width necessary for conduit locknuts and bushings.}$

Fig. 314-32. In straight pulls, the length of the box must be not less than 8 times the trade diameter of the largest raceway. (Sec. 314.28.)

EXAMPLE:

The 3-in. conduit is the largest.

Therefore—

$$L_1 = 6 \times 3 \text{ in.} + (2 \text{ in.} + 2 \text{ in.}) = 22 \text{ in. min.}$$

$$L_2 = 6 \times 3 \text{ in.} + (2 \text{ in.} + 2 \text{ in.}) = 22 \text{ in. min.}$$

$$D = 6 \times 3 \text{ in.} = 18 \text{ in., minimum distance between raceway entries enclosing the same conductors}$$

Fig. 314-33. Box size must be calculated for angle pulls. For boxes in which the conductors are pulled at an angle or in a U, the distance between each raceway entry inside the box and the opposite wall of the box must not be less than 6 times the trade diameter of the largest raceway in a row. And the distance must be increased for additional raceway entries by the amount of the maximum sum of the diameters of all other raceway entries in the same row on the same wall of the box. The distance between raceway entries enclosing the same conductors must not be less than 6 times the trade diameter of the larger raceway. (Sec. 314.28.)

According to the rule of part (A)(2), in sizing a pull or junction box for an angle or U pull, if a box wall has more than one row of conduits, “each row shall be calculated separately and the single row that provides the maximum distance shall be used.” Consider the following:

A pull box has two rows of conduits entering one side (or wall) of the box for a right-angle pull. What is the minimum required inside distance from the wall with the two rows of conduit entries to the opposite wall of the box?

Row 1: One metric designator 63 (trade size 2½) and one metric designator 27 (trade size 1) conduit

Row 2: One metric designator 16 (trade size ½), two metric designator 35 (trade size 1¼), one metric designator 41 (trade size 1½), and two metric designator 21 (trade size ¾) conduits

Calculate as prescribed by this rule. Note that in accordance with the metrication rule in 314.28(A), these calculations must be done expressing the raceway size using the metric designator (trade size) units as actual dimensions in the system of measurement being employed. Based on the

expected market for this book, the calculations going forward will be in the English system of units. Calculating each row separately and taking the box dimension from the row that gives the maximum distance:

Row 1: $6 \times$ largest raceway ($2\frac{1}{2}$ in.) + other entries (1 in.) = 16 in.

Row 2: $6 \times$ the largest raceway ($1\frac{1}{2}$ in.) + other entries [$\frac{1}{2}$ in. + ($2 \times 1\frac{1}{4}$ in.) + ($2 \times \frac{3}{4}$ in.)] = 9 in. + $\frac{1}{2}$ in. + 4 in. = $13\frac{1}{2}$ in.

Result: The minimum box dimension must be the 16-in. dimension from run No. 1, which “provides the maximum distance” calculated.

Some of the rules for angle pull spacings also apply to splices in pull boxes. As shown in [Fig. 314-34](#), when a pull box is used for a splice enclosure, the distance between conduit entries and the opposite wall must meet the six times rule, increased, if applicable, by other entries on the same side. However, because the conductors are spliced together, they are necessarily not “the same conductor” and therefore there is no rule governing the distance between the conduits of the same circuit. The principles are illustrated in [Fig. 314-34](#).

Fig. 314-34. The opposite wall spacing rule applies to splices; however, the spacing rule between the same conduits of a circuit does not. [Sec. 314.28(A)(2).]

[Figure 314-35](#) shows a more complicated conduit and pull box arrangement, which requires more extensive calculation of the minimum permitted size. In the particular layout shown, the upper metric designator 78 (trade size 3) conduits running straight through the box represent a problem separate from the metric designator 53 (trade size 2) conduit angle pulls. In this case the metric designator 78 (trade size 3) conduit establishes the box length in excess of that required for the metric designator 53 (trade size 2) conduit. After computing the metric designator 78 (trade size 3) requirements, the box size was calculated for the angle pull involving the metric designator 53 (trade size 2) conduit.

Four 3" conduits - straight pull
 Length of box - $8 \times 3" = 24"$
 Width of box - 5" for each conduit
 $C = 4 \times 5" = 20"$ (3" locknut takes 4")

Fig. 314-35. A number of calculations are involved when angle and straight pulls are made in different directions and different planes. (Sec. 314.28.)

Figure 314-36 shows another consideration in sizing a pull box for angle conduit layouts. A pull box is to be installed to make a right-angle turn in a group of conduits consisting of two metric designator 78 (trade size 3), two metric designator 63 (trade size 2 1/2), and four metric designator 53 (trade size 2) conduits. Subparagraph (2) of 314.28(A) gives two methods for computing the box dimensions, and both must be met; here again for calculations we will use English units.

Fig. 314-36. Distance between conduits carrying same cables has great impact on box size. (Sec. 314.28.)

First method:

$$\begin{aligned}
 6 \times 3 \text{ in.} &= 18 \text{ in.} \\
 1 \times 3 \text{ in.} &= 3 \\
 2 \times 2\frac{1}{2} \text{ in.} &= 5 \\
 4 \times 2 \text{ in.} &= 8 \\
 \hline
 \text{Total} &= 34 \text{ in.}
 \end{aligned}$$

Second method:

Assuming that the conduits are to leave the box in the same order in which they enter, the arrangement is shown in Fig. 314-37, and the distance A between the ends of the two conduits must be not less than $6 \times 2 \text{ in.} = 12 \text{ in.}$ It can be assumed that this measurement is to be made between the centers of the two conduits. By calculation, or by laying out the corner of the box, it is found that the distance C should be about $8\frac{1}{2} \text{ in.}$

STRAIGHT RUN

Type C conduit body must have length L equal to 8 times diameter of the raceway

Examples

If four No. 4 THHN are used in 1-in. conduit, conduit body must be at least 8 in. long.

If four 500 kcmil XHHW are used in 3-in. conduit, conduit body must be at least 24 in. long.

ANGLE RUN

From 314.28(A)(2):

$L1$ = at least 6 times diameter of raceway (inside dimension)

$L2$ = at least equal to the distance given in Table 312.6(A) for the given size of conductor, as shown in the column for *one wire per terminal*

$L3$ = at least 6 times diameter of raceway

Examples

If four No. 4 THW conductors are used in 1¼-in. conduit, minimum dimensions would be calculated as follows:

$$L1 = 6 \times 1\frac{1}{4} \text{ in.} = 7.5 \text{ in.}$$

$$L2 = 2 \text{ in., from Table 312.6(A) for one No. 4 conductor per terminal}$$

$$L3 = 6 \times 1\frac{1}{4} \text{ in.} = 7.5 \text{ in.}$$

If four 500 kcmil THW conductors are used in 3½-in. conduit, minimum dimensions would be:

$$L1 = 6 \times 3\frac{1}{2} \text{ in.} = 21 \text{ in.}$$

$$L2 = 6 \text{ in., from Table 312.6(A)}$$

$$L3 = 6 \times 3\frac{1}{2} \text{ in.} = 21 \text{ in.}$$

Fig. 314-37. Conduit bodies must be sized as pull boxes under these conditions. (Sec. 314.28.)

The distance B should be not less than 30½ in. (774.7 mm) approximately, as determined by

applying practical data for the spacing between centers of conduits,

$$30\frac{1}{2} \text{ in.} + 8\frac{1}{2} \text{ in.} = 39 \text{ in.}$$

In this case the box dimensions are governed by the second method. The largest dimension computed by either of the two methods is of course the one to be used. Of course, if conduit positions for conduits carrying the same cables are transposed—as in [Fig. 314-32](#)—then box size can be minimized.

The most practical method of determining the proper size of a pull box is to sketch the box layout with its contained conductors on a paper.

[Figure 314-37](#) shows how the rules of 314.28(A) apply to conduit bodies.

Important: The exception given in 314.28(A)(2) establishes the minimum dimension of L2 for angle runs, but this exception applies only to conduit bodies which have the removable cover opposite one of the entries, such as a Type LB body. Types LR, LL, and LF do not qualify under that exception, and for such conduit bodies the dimension L2 would have to be at least equal to the dimension L1 (i.e., 6 times raceway diameter). Be very careful in shopping for type “LB” conduit bodies that will enclose large conductors in big raceways. Many manufacturers have read 314.28(A) (2) and make so-called mogul conduit bodies that meet the 6 times rule. However not many of them have read the entire rule all the way through, and made their large conduit mogul fittings with extended noses that accommodate Table 312.6(A) dimensions for large conductors. For example, a metric designator 78 (trade size 3) “LB” conduit body expected to carry 3 600 kcmil THW conductors must have 8 in. of distance between the conduit stop on the short end and the inside of the cover, dimension “L2” in [Fig. 314-37](#). There is at least one “LB” fitting on the market designed exactly this way, but very few. Most, at least as of this writing, violate these rules and should be rejected for larger sized conductors.

Subparagraph (3) of 314.28(A) permits smaller pull or junction boxes where such boxes have been listed for and marked with the maximum number and size of conductors and the conduit fills are *less* than the maximum permitted in Table 1, [Chap. 9](#). This rule provides guidelines for boxes that have been widely used for years, but which have been smaller than the sizes normally required in subparagraphs (1) and (2). These smaller pull boxes must be listed by UL under this rule. The usual application of this provision is not to pull boxes but to conduit bodies marked for a fill that is smaller than the entering raceways could normally carry.

For example, a conduit body might be marked “3 4/0 XHHW MAX.” If you are using three XHHW conductors, then the marking means exactly what it says. Of course that doesn’t happen often. For any other insulation style or number of conductors, take the marking and translate it to a total cross-sectional area of wire fill, using the numbers in Table 5 of [Chap. 9](#) at the end of the Code book. That is your maximum fill, regardless of what Table 4 might say the raceway can hold. Compare that maximum with what you need to install, and decide whether you need to look for a full mogul conduit body or whether you can use the smaller one. In the case of PVC, you will usually be stuck with a reduced size, and the only alternative will be to either increase the raceway size or use a pull box sized to the rules given here. Note that the Canadian Electrical Code does not contain a comparable rule. During times of market instability, PVC conduit bodies manufactured only for use in Canada often show up in the USA without the required markings and should be rejected.

There is another issue regarding the markings for reduced fill. At one time, the markings customarily stated not only the size of the conductor, but also the style of insulation that was used

during the pull test. This is critical information because as described in the previous paragraph, if you are using different insulation or perhaps a combination of conductor sizes, you need the insulation type in order to establish the upper limit of cross-sectional area that can be used for the allowable fill of the conduit body at hand. However, the current edition of the applicable product standard (UL 514B) does not require the insulation type to be included in the marking. For this reason the insulation type has been slowly disappearing. However Sec. 8.4 of UL 514B effectively specifies XHHW as the insulation type to be used in the pull test in most cases. The 2017 **NEC** has now fully addressed this issue, beginning with an amendment to the main rule to expressly validate the procedure just outlined. Then, an informational note was added to explain why the default insulation type to take into a calculation is XHHW.

Actual field example:

Sewage lift station requiring 100A 3-phase 4-wire feeder

Note: minimal neutral load sized by 215.2(A)(2) = 8 AWG

Conduit Body: PVC 1¼ trade size LB, marked “3 WIRE MAX FILL SIZE AWG 2”

Step 1, Maximum allowable fill expressed as cross-sectional area:

$$3(2 \text{ AWG XHHW-2}) = 3(0.1146 \text{ in}^2) = 0.3438 \text{ in}^2$$

Step 2, Check proposed fill using smallest cross-sectional area conductors:

$$3(3 \text{ AWG XHHW-2}) = 3(0.0962 \text{ in}^2) = 0.2886 \text{ in}^2$$

$$1(8 \text{ AWG THWN-2}) = 1(0.0366 \text{ in}^2) = 0.0366 \text{ in}^2$$

$$1(8 \text{ AWG EGC bare}) = 0.0170 \text{ in}^2 = 0.0170 \text{ in}^2$$

$$\text{Total Fill} = 0.3422 \text{ in}^2$$

Calculation succeeds by 0.0016 in²

$$\text{Note: } 3(3 \text{ AWG THWN-2}) = 3(0.0973 \text{ in}^2) = 0.2919 \text{ in}^2$$

Calculation fails by 0.0017 in²

$$\text{Note: } 1(8 \text{ AWG XHHW-2}) = 1(0.0437 \text{ in}^2) = 0.0437 \text{ in}^2$$

Calculation fails by 0.0055 in²

Therefore, any other wire selection would increase the raceway size.

The 2014 **NEC** formally recognizes for the first time, in a new paragraph in 314.28(A)(3), a conduit body that changes the direction of a pipe run by the usual 90°, but for which, unlike a conventional LB, the body of the fitting and the access cover are set at a 45° angle to both entering raceways. They are not widely used because they will not lay up tight to a building corner. However, where they can be used they are much easier to pull through because the resulting conductor loop need not be forced into a full right angle at either end.

These conduit bodies generally, on close examination, result in an actual bend radius imposed on the conductors that is no different or even greater than the radius permitted by Table 2 of [Chap. 9](#) for the entering raceway if the conduit body were replaced by a conduit sweep. Therefore, such a conduit

body results in no reduction of the permitted fill beyond the normal limits imposed by Table 1 of Chap. 9 for the entering raceway. The conduit body must be listed and marked in such a way as to demonstrate that they have been evaluated in accordance with this concept.

314.28 applies particularly to the pull boxes commonly placed above distribution switchboards and which are often, and with good reason, termed *tangle boxes*. In such boxes, all conductors of each circuit should be cabled together by securing them with tie-wraps so as to form a self-supporting assembly that can be formed into shape, or the conductors should be supported in an orderly manner on racks, as required by part (B) of 314.28. The conductors should not rest directly on any metalwork inside the box, and insulating bushings should be provided wherever required by 300.4(G). Figure 314-39 shows an example of this process.

Fig. 314-38. Comparison of special design right-angle conduit body recognized for relaxed bend radius and conventional mogul style LB. [Sec. 314.28(A)(3).]

Fig. 314-39. If a pull box has *any* dimension over 6 ft (1.8 m), the conductors within it must be supported by suitable racking (arrow) or cabling, as shown here for arcproofed bundles of feeder conductors, to keep the weight of the many conductors off the sheet metal cover that attaches to the bottom of the box. (Sec. 314.28.)

For example, the box illustrated in [Fig. 314-36](#) could be approximately 125 mm (5 in.) deep and accommodate one horizontal row of conduits. By making it twice as deep, two horizontal rows or twice the number of conduits could be installed.

Insulating racks are occasionally placed between conductor layers, and space must be allowed for them when they are used.

The rule in (C) requires covers to be provided on boxes that are compatible with the box construction and suitable for the conditions of use. The rule concludes by reiterating the grounding requirement of 314.25(A).

To line up with the recognition in 376.56 of power distribution blocks being added to wireways in the field, part (E) now covers these devices field added into pull and junction boxes. Refer to [Fig. 376-3](#) for a photograph of this equipment in use. The rules in Art. 314 permit this equipment in large boxes (over 100 cu. in.) with an exception permitting equipment grounding terminal bars in smaller boxes. This allows for correlation, for example, with the requirement in 680.23(F)(2)(b) that equipment grounding conductors, if broken, must be spliced on terminal bars and not rely on a twist-on wire connector for continuity.

The requirements for listing and for a cover over the uninsulated live parts line up with the wireway rules. The bending space rule points to 312.6 instead of specifying 312.6(B) because unlike wireways, the conductors terminating in a pull box could be approaching by way of a right angle turn or straight into its terminals. As in the case of wireways, these blocks cannot be applied on the line side of service equipment unless they are listed and marked “suitable for use on the line side of service equipment” or equal. In the short term there are some issues with this, refer to the discussion

at 376.56(B) for more information.

314.29. Boxes, Conduit Bodies, and Handhole Enclosures to Be Accessible. This is the rule that prevents boxes from being buried in walls or otherwise behind building finish without suitable access to their enclosed conductors. For outdoor applications, buried boxes are permitted under the terms of the exception; these terms are both specific and intentionally restrictive. First the box must be below soil that can be easily shoveled, and second, the location of the box must be “effectively identified.” This might involve a map attached to the panelboard supplying the circuit(s) in the box, or some other way of assuring that those who come afterward don’t need to contend with a junction point that is entirely invisible.

314.30. Handhole Enclosures. A handhole enclosure is defined in Art. 100 as an enclosure for use in underground systems that is sized to allow personnel to reach into, but not enter, for the purpose of installing wiring and maintaining it afterward. They may contain electrical equipment, and they can be made with either an open or closed bottom. Most handholes are made with open bottoms, and are used as pull boxes for underground systems.

They must be identified for use on underground systems, and they must be designed and installed to withstand all loads likely to be imposed. The **NEC** identifies a standard (ANSI/SCTE 77-2002) that can be used to evaluate loading on these enclosures. This standard identifies a series of tiers that can be specified based on the expectation of vehicular loading. Tier 5 is for pedestrian use with a safety factor for occasional nondeliberate vehicle traffic; it carries a 5000 lb vertical design load rating. Tier 8 is for sidewalk use with a safety factor for nondeliberate vehicular traffic, with a comparable design load rating of 8000 lb. Tier 15 is for parking lots, driveways, and off roadway uses that are subject to occasional nondeliberate heavy vehicular traffic; here the vertical load rating is 15,000 lb. They are now commonly available in designs evaluated to an even more robust performance level of Tier 22.

Handhole enclosures have the same sizing rules related to wire bending space as for manholes. There is an instance where a different set of rules applies, however. If a raceway enters through the bottom plane of a bottomless enclosure, the measurements are taken from the end of the conduit or cable assembly. When such an entry is opposite a removable cover, as it would be in this case, the spacing rules change. For wires operating at 600 V and below, the minimum distance becomes the one-wire-per-terminal distance in Table 312.6(A) for the conductor sizes involved, as previously discussed. For medium-voltage wiring the distance is 12 times the shielded cable diameter and 8 times the diameter for unshielded conductors.

Handhole enclosures are renowned for filling up with sand and water, particularly for the ones without bottoms, which is usually the case. All wiring and splicing provisions must be listed for wet locations for this reason. In addition, if a handhole enclosure has a metal cover, it must be bonded to an equipment grounding conductor (usual case) or to a grounded circuit conductor if the application is on the line side of service equipment. This is a critical safety issue. There have been many fatalities, of both people and their pets, from energized handhole covers.

314.40. Metal Boxes, Conduit Bodies, and Fittings. This section through 314.44 covers construction of boxes. UL data on application of boxes supplement this Code data as follows:

1. Cable clamps in outlet boxes are marked to indicate the one or more types of cables that are suitable for use with that clamp.
2. Box clamps have been tested for securing only one cable per clamp, except that multiple-section

clamps may secure one cable under each section of the clamp, with each cable entering the box through a separate KO.

Part (B) covers the thickness of metal for boxes in the usual outlet and device box sizes, and is primarily of interest to manufacturers and testing laboratories. However, it is important to recognize that boxes are not required to be listed, although almost all of these boxes are. Note that permission is granted in Exception No. 1 for boxes to be made of different alloys or with special construction details (such as ribbing), and if listed as having equivalent strength in comparison to the plain vanilla product, they can be used.

Part (C) of this section covers the pull boxes regulated by 314.28. UL data on such boxes are important and must be related to the Code rules. Listed pull and junction boxes may be sheet metal, cast metal, or nonmetallic, and all of these have a volume greater than 100 cu in. (1650 mm³). These boxes are frequently made in sheet metal shops to accommodate particular field conditions and the decision not to require listings on these boxes is a very deliberate one in the **NEC**. Therefore, these construction requirements, together with the applicable UL standard (UL 50), have frequent field applications. Boxes marked “raintight” or “rainproof” are tested under a condition simulating exposure to beating rain. *Raintight* means water will not enter the box. *Rainproof* means that exposure to beating rain will not interfere with proper operation of the apparatus within the enclosure. Use of a box with either designation must satisfy 314.15, which notes that boxes in wet locations (such as outdoors where exposed to rain or indoors where exposed to water spray) must prevent moisture from entering *or* accumulating within the box. That is, water *may* enter the box if it does not accumulate in the box, where the box is drained. A box that is raintight or rainproof may satisfy that rule. Be sure, though, that any equipment installed in a box labeled “rainproof” is mounted within the location restrictions marked in the box. Boxes in wet locations must be fully listed for wet locations.

In part (D) of 314.40, *connection provisions for a grounding conductor is required in metal box*. This rule is intended to ensure a suitable means within a metal box to connect the equipment grounding conductor that is required to be used with such wiring methods to provide equipment grounding.

Part IV. Pull and Junction Boxes for Use on Systems Over 1000 V, Nominal.

314.70. General. This part of the article covers pull and junction boxes that are components of systems operating over 600 V. The dimensional requirements in this part squarely address conduit bodies and handhole enclosures for the first time in the 2011 **NEC**. It would generally be difficult, but not necessarily impossible on smaller cables, particularly unshielded ones at lower voltages, to meet the 8 times (unshielded) or 12 times (shielded) the cable diameter provision in 300.34 for bending radii opposite removable covers (think in terms of “LB” conduit bodies). Note that 314.70(B)(2) was amended in the 2017 **NEC** to reference 314.28(A)(3). This is an attempt by the code-panel to call attention to the right angle pull conduit bodies manufactured with two 45° hubs in terms of being potentially applicable to medium-voltage applications due to the lengthened pull radius. See [Fig. 314-38](#) and associated commentary.

Handhole enclosures also make their debut for medium-voltage applications. This application is very common; the dimensional requirements were already in 314.30(A) by reference, so nothing changes in this regard.

314.71. Size of Pull and Junction Boxes, Conduit Bodies, and Handhole Enclosures.

Figure 314-40 shows the rules on sizing of pull boxes for high-voltage circuits. In addition, this part of Art. 314 includes spacing rules for a conduit entry opposite a removable cover that correlates with a similar provision in 314.28(A)(2) Exception. Here the requirement uses the minimum bend radius as given in 300.34.

STRAIGHT PULLS

All covers for boxes enclosing circuits over 600 volts must be permanently marked "DANGER: HIGH VOLTAGE KEEP OUT" on the outside in block-type letters at least 1/2 in. high

L - not less than 48 times the outside diameter, over sheath, of the largest shielded or lead-covered conductor or cable entering the box, OR not less than 32 times the outside diameter of the largest nonshielded conductor or cable.

NOTE: The box length must be 48 times the conductor or cable diameter, not the conduit diameter.

ANGLE PULLS

Cover must be marked DANGER-HIGH VOLTAGE-KEEP OUT

L1, L2, L3—not less than 36 times the outside diameter, over sheath, of the largest conductor or cable

Fig. 314-40. Minimum dimensions are set for high-voltage pull and junction boxes. For multiple angle pulls, increase the dimension by the size of the additional entries on the same wall. [Sec. 314.71.]

314.72. Construction and Installation Requirements. Part (E) requires that covers of pull and junction boxes for systems operating at over 600 V must be marked with readily visible lettering at least ½ in. (12.7 mm) high, warning “DANGER HIGH VOLTAGE KEEP OUT.”

All required warning signs must be properly worded to include the command “KEEP OUT.” While certain sections of the Code, such as this one, as well as 110.34(C), clearly require the inclusion of the command “KEEP OUT,” be aware that courts have held that warning signs that fail to include some sort of instruction or command with respect to an appropriate action that must be taken are inadequate and constitute negligence on the part of the individual posting the sign. Always include some phrase that will tell the individual what to do about the condition or hazard that exists.

ARTICLE 320. ARMORED CABLE: TYPE AC

320.2. Definition. Armored cable (Type AC) contains insulated conductors of a type accepted for general wiring applications in the **NEC**. The conductors are enclosed in an armor comprised of steel or aluminum interlocking tape. The armor is arranged with an internal bonding strip of aluminum or copper “in intimate contact with the armor for its entire length.” Type AC cable, which is commonly called BX, has largely been supplanted in the market by the interlocking-armor style of metal-clad cable. However, certain applications, especially patient care areas of health care facilities, require a wiring method where the outer margin of the wiring method, whether raceway or cable assembly, qualifies as an equipment grounding return path, and Type AC cable inherently qualifies for this use. A recent addition to this list is 210.12(A)(5), which specifically enumerates the steel version of this cable as an acceptable cabled wiring method acceptable under those provisions (Fig. 320.1).

Fig. 320-1. Type AC cable contains insulated conductors plus bonding conductor under the armor. (Sec. 320.2.)

Armored cable assemblies of 2, 3, 4, or more conductors in sizes No. 14 AWG to No. 1 AWG—such conductors may even incorporate an optical-fiber cable—conform to the standards of the Underwriters Laboratories. These standards cover multiple-conductor armored cables for use in accordance with the **National Electrical Code**, in wiring systems of 600 V or less, with conductors having insulation rated for temperatures of 90°C, as called for by 320.80 where the cable is embedded in thermal insulation. As of the 2017 **NEC**, Type AC cable must be listed (320.6).

320.10. Uses Permitted. Type AC armored cable can be used in all types of electrical systems for power and light branch circuits and feeders. Figure 320-2 shows use of three runs of 12/2 BX for the supply and two switch legs to a combination light-heat-fan unit in a bathroom. One 12/2 is the supply and the other cables control the appliance as shown in the wiring diagram. But the use of two 12/2 cables for the switch legs violates 300.20 because the neutral is not kept with all the conductors it serves. As a result, induction heating could be produced. A single run of 12/4 cable to the

appliance would be necessary.

Fig. 320-2. Cable runs of 12/2 BX are used at junction box (above) which was then equipped with switches and pilot light (right) for light-heat-fan unit. Use of two 12/2 cables, with neutral in only one cable, is a violation of the concept covered in Sec. 300.20. A 12/4 cable could serve for all switch legs and satisfy the Code rule. (Sec. 320.10.)

As stated in the note following this section, the list of items in this “uses permitted” section is not intended to completely enumerate all permitted uses. These sections must be read in conjunction with “uses not permitted” section that follows to zero in on where particular issues lie that the **NEC** wants to address. For example, it is clear that this cable can be used embedded in a plaster finish on masonry construction, but only where those locations are classified as dry. It can also run in hollow block voids, but only if not subject to excessive moisture or dampness, which could well be all wet locations but probably not all damp locations; the local inspector would need to determine that in the field. [Figure 320-3](#) shows an example of a permitted hazardous location use of the cable, which is also not (and need not be) itemized on the list.

Fig. 320-3. The informational note following 320.10 indicates the list is not all inclusive and 504.20 recognizes BX cable for limited use in hazardous locations. (Sec. 320.10.)

320.15. Exposed Work. This section requires cables to “closely follow the surface of the building” where unexposed. Of course, this is to be correlated with the rules in 320.30. That is, where needed for flexibility [part (2)], or where used as fixture whips [part (3)] of 320.30, the requirement to “closely follow” the contour of the wall space is waived. In addition, use of joist bottoms is permitted where not subject to physical damage.

320.23. In Accessible Attics. These rules also apply to Type NM cable installations because 334.23 specifically incorporates them by reference. Part (A) applies to all attic and roof spaces accessible by a permanent ladder or stair, and to other accessible attic locations within 1.8 m (6 ft) of the outside edges of the scuttle hole. Any cables run on top of floor joists, or across rafters or studs within 2.1 m (7 ft) of the floor or the tops of the floor joists must be protected by guard strips at least as high as the cable diameter. Cables run on and parallel to the sides of framing members do not require guard strips but must meet the spacing rules in 300.4(D).

320.30. Securing and Supporting. Armored cable must be secured and supported by approved staples, straps, or similar fittings, as shown in Fig. 320-4. Note that a requirement to secure a cable is more restrictive than a requirement to support the cable. For example, Type AC cable must be supported at intervals, a condition that can be met by routing it through successive holes in framing member, and it must be secured at terminations, a condition that requires preventing all movement such as by using a staple.

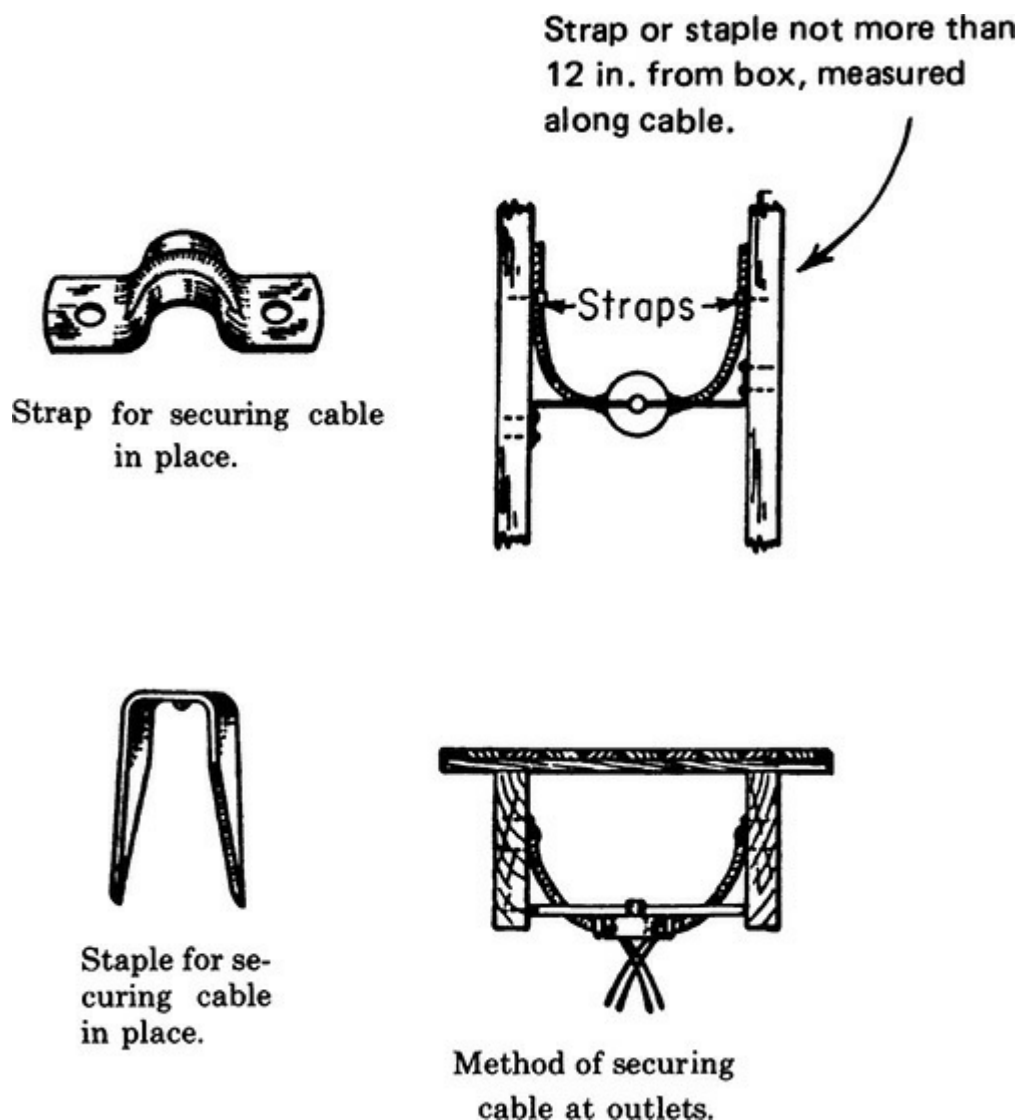

Fig. 320-4. BX must be clamped every 4½ ft (1.4 m) and within 12 in. (300 mm) of terminations. Cable ties, if listed for “securement and support,” are also permitted. (Sec. 320.30.)

In exposed work, both as a precaution against physical damage and to ensure a workmanlike appearance, fastenings should be spaced not more than 600 to 750 mm (24 to 30 in.) apart. In concealed work in new buildings, the cable must be supported at intervals of not over 1.4 m (4½ ft) for Type AC to keep it out of the way of possible injury by mechanics of other trades. In either exposed work or concealed work, the cable should be securely fastened in place within 300 mm (1 ft) of each outlet box or fitting so that there will be no tendency for the cable to pull away from the box connector. Take care to observe the minimum bend radius for this cable, 5 times its diameter measured to the inner edge of the bend, as given in 320.24. Sharper bends can and often will break the convolutions, creating a hazardous condition.

Part (2) of 320.30(D) limits Type AC cable to not over a 600-mm (2-ft) unclamped length for flexibility where such a cable feeds motorized equipment (such as a fan or unit heater) or connects to any enclosure or equipment where the flexibility of the ac length will isolate and suppress vibrations. Similarly, part (3) of this section permits lengths of ac up to 1.8 m (6 ft) long to be used without any staples, clamps, or other support where used in a hung ceiling as a lighting fixture whip or similar whip to other equipment (Fig. 320.5). This permits use of ac in the same manner as permitted for flexible metal conduit (Greenfield) or liquidtight flexible metal conduit in lengths from 0.45 to 1.8 m (1½ to 6 ft) as a connection from a circuit outlet box to a recessed lighting fixture [410.117(C)]. This

use of unclamped BX is an exception to the basic rule that it be clamped every 1.4 m (4½ ft) and within 300 mm (12 in.) of any outlet box or fitting. Part (1) recognizes the acceptability of fishing in Type AC cables, for which additional securing and supporting is not required.

Fig. 320-5. Armored cable (Type AC) may be used for 6-ft (1.8-m) fixture whips, without supports, in an “accessible ceiling.” (Sec. 320.30.)

Note that the requirements on clamping or securing of Type AC must be observed for applications in suspended-ceiling spaces, whether for air handling, as covered in 300.22(C), or non-air handling. The wording of part (C) in 320.30 recognizes that in horizontal runs the hole in the framing member is to be considered as satisfying the support requirements given in this section.

320.40. Boxes and Fittings. Note that a termination fitting—that is, a box connector—must be used at every end of Type AC cable entering an enclosure or a box (Fig. 320.6) unless the box has an approved built-in clamp to hold the cable armor, provide for the bonding of the armor to the metal box, and protect the wires in the cable from abrasion.

Fig. 320-6. Connectors for BX entering a panelboard cabinet or other enclosure must use approved fittings—some type of single-connector or duplex type (as shown, with two cables terminated at each connector through a single KO). (Sec. 320.40.)

A standard type of box connector for securing the cable to knockouts or other openings in outlet boxes and cabinets is shown in Fig. 320-7. A plastic bushing, as shown, must be inserted between the armor and the conductors. The plastic bushing, which can be seen through slots in the connector after installation, prevents the sharp edges of the armor from cutting into the insulation on the conductors and so grounding the copper wire.

Plastic bushing to protect the conductors in Type AC cable from the sharp edges of the armor.

Box connector for Type AC cable

Fig. 320-7. Every BX termination must be equipped with a protective bushing and a box connector or clamp built into the box. (Sec. 320.40.)

The box shown in Fig. 320-8 is equipped with clamps to secure Type AC cables, making it

unnecessary to use separate box connectors. The other box shown is similar but has the cable clamps outside, thus permitting one more conductor in the box. See 314.16(A)(1).

Fig. 320-8. A box connector fitting is not required if box includes cable clamps for Type AC cable. (Sec. 320.40.)

As covered in the last sentence of 320.40, “a box, fitting, or conduit body”—such as a C conduit body—must be used where Type AC cable is connected to another wiring method. [Figure 320-9](#) shows a typical application of this technique, in accordance with 300.15(F).

Fig. 320-9. This connection of BX to conduit or other cable is specifically recognized. Where there is no splice, a “from-to” connector may be used. (Sec. 320.40; see also 300.15(F) with the conductors unspliced at the transition.)

320.80. Ampacity. This section makes it clear that the current-carrying capacity of Type AC cable must be established in accordance with the rules of 310.15. The last part of this rule places an additional limitation on the use of Type AC run in thermal insulation. As is the case with Types NM, NMB, and NMC, Type AC cable must be provided by the manufacturer with 90°C-rated insulation, *but* it must be loaded to no more than the 60°C value shown in Table 310.15(B)(16). Although it is permissible to use the 90°C current value shown in Table 310.15(B)(16) for the purposes of derating, the actual load carried must be no greater than the current value shown for the particular size and conductor material.

The wording of this section actually understates the true problem for cables run in thermal insulation. By allowing derating to occur from the 90°C column for such cables, the **NEC** allows users to ignore factors that increase the retention of heat in the cable until they reach the point of reducing the ampacity below the 60°C value, which in most cases is to allow them to be ignored altogether. Meanwhile, particularly for large, heavily loaded cables, even the 60°C numbers are too

high. Review the discussion associated with 310.15(A)(3) for detailed information on this topic.

320.100. Construction. Note that Type AC cable is recognized for branch circuits and feeders, but *not* for service-entrance conductors, which *must* be one of the cables or wiring methods specified in 230.43. Type MC (metal-clad) cable, such as interlocked armor cable or the other cables covered in Art. 334, is recognized by 230.43 for use as service-entrance conductors.

Because the armor of Type AC cable is recognized as an equipment grounding conductor by 250.118(9), its effectiveness must be ensured by using an “internal bonding strip,” or conductor, under the armor and shorting the turns of the steel jacket. The ohmic resistance of finished armor, including the bonding conductor that is required to be furnished as a part of all, except lead-covered armored cable, must be within values specified by UL and checked during manufacturing. The bonding conductor run within the armor of the cable assembly is required by the UL standard.

Because the function of the bonding conductor in Type AC cable is simply to short adjacent turns of the spiral-wrapped armor, there is no need to make any connection of the bonding conductor at cable ends in enclosures or equipment. The conductor may simply be cut off at the armor end.

Construction of armored cable must permit ready insertion of an insulating bushing or equivalent protection between the conductors and the armor at each termination of the armor—such as the so-called red head.

320.104. Conductors. As required by the second paragraph in 320.80, armored cable (BX) installed within thermal insulation must have 90°C-rated conductors (Types THHN, RHH, XHHW), but the ampacity must be taken as that of 60°C rated conductors. This requirement recognizes that the heat rise on conductors operating with reduced heat-dissipating ability (such as those surrounded by fiberglass or similar thermal insulation) requires that the conductors have a 90°C-rated insulation. That temperature might be reached even with the wires carrying only 60°C ampacities. Although the wires must have 90°C insulation, they must not be loaded over those ampacity values permitted for TW (60°C), as shown in Table 310.15(B)(16).

320.108. Equipment Grounding Conductor. This section requires that Type AC cable provide “an adequate path” for fault current. This is accomplished by the No. 16 aluminum bonding strip that runs the length of the cable’s sheath. This bonding strip shorts out the high impedance of the coiled metal jacket and provides a UL-listed ground path.

ARTICLE 322. FLAT CABLE ASSEMBLIES: TYPE FC

322.2. Definition. Type FC cable is a flat assembly with three or four parallel 10 AWG special stranded copper conductors. The assembly is installed in an approved U-channel surface metal raceway with one side open. Then tap devices can be inserted anywhere along the run. Connections from tap devices to the flat cable assembly are made by *pin-type* contacts when the tap devices are fastened in place. The pin-type contacts penetrate the insulation of the cable assembly and contact the multistranded conductors in a matched phase sequence (phase 1 to neutral, phase 2 to neutral, and phase 3 to neutral).

Covers are required when the installation is less than 8 ft from the floor. The maximum branch-circuit rating is 30 A.

Figure 322-1 shows the basic components of this wiring method.

Fig. 322-1. Type FC wiring system uses cable in channel, with tap devices to loads. (Sec. 322.2.)

322.10. Uses Permitted. Figure 322-2 shows a Type FC installation supplying lighting fixtures. As shown in the details, one tap device provides for circuit tap-off to splice to cord wires in the junction box; the other device is simply a fitting to support the fixture from the lips of the channel. Flat cable assemblies must be listed (322.6).

Fig. 322-2. Limited application of Type FC cable system includes use as branch-circuit wiring method to supply luminaries. (Sec. 322.10.)

ARTICLE 324. FLAT CONDUCTOR CABLE: TYPE FCC

324.1. Scope. This article covers design and installation regulations on a branch-circuit wiring system that supplies floor outlets in office areas and other commercial and institutional interiors. (See [Fig. 324-1.](#)) The method may be used for new buildings or for modernization or expansion in existing interiors. FCC wiring may be used on any hard, sound, smooth floor surface—concrete, wood, ceramic, and so forth. The great flexibility and ease of installation of this surface-mounted flat-cable wiring system meet the need that arises from the fact that the average floor power outlet in an office area is relocated every 2 years.

Fig. 324-1. Flat conductor cable (FCC) supplies terminal base for floor-outlet pedestal at exact location required for desk in office area. FCC is taped in position over an insulating bedding tape and then covered with a flat steel tape (not yet installed here) to protect the three conductors (hot leg, neutral, and equipment grounding conductor) in the flat cable. Carpet squares are used to cover the finished cable runs.

Undercarpet wiring to floor outlets eliminates any need for core drilling of concrete floors—avoiding noise, water dripping, falling debris, and disruption of normal activities in an office area. Alterations or additions to Type FCC circuit runs are neat, clean, and simple and may be done during office working hours—not requiring the overtime labor rates incurred by floor drilling, which must be done at night or on weekends. The FCC method eliminates use of conduit or cable, along with the need to fish conductors.

Type FCC wiring offers versatile supply to floor outlets for power and communication—at any location on the floor. The flat cable is inconspicuous under the carpet squares. Elimination of floor penetrations maintains the fire integrity of the floor, as required by 300.21.

A typical system might use separate flat-cable circuit layouts for 120-V power to floor-pedestal receptacles, telephone circuits, and data communications lines for CRT displays and computer units. For 120-V power, the flat cable contains three flat, color-coded (black, white, and green), 12 AWG copper conductors for 20-A circuits—one hot conductor, one neutral, and one equipment grounding conductor. Telephone circuits use flat, 3-pair, 26 AWG gauge conductors. And data connection circuits use flat RG62A/U coaxial cable that is only 0.09 in. (2.25 mm) high.

324.2. Definitions. The various components of a Type FCC system are described here. [Figure 324-2](#) shows typical components of an FCC system. Sec. 324.6 requires the cable and fittings used with it to be listed.

(a)

(b)

(c)

Fig. 324-2. Typical components of a Type FCC system: (a) Bottom shield in place. (b) Connecting the conductor. (c) Coil of top shield.

324.10. Uses Permitted. This section describes the acceptable uses for Type FCC. Part (A) recognizes the use of Type FCC for both general-use branch circuits and individual branch circuits, while (B)(1) and (2) regulate the maximum voltage rating (not more than 300 V between conductors) and current rating (not more than 20 A for general-purpose branch circuits, or 30 A for individual branch circuits) permitted for Type FCC.

324.12. Uses Not Permitted. This wiring method, prior to the 2017 **NEC**, was prohibited from residential, school, and hospital buildings, even in administrative areas. The fear was that such areas would be converted to other purposes and unauthorized persons would have routine access to the wiring. Although this prior concern was never really addressed, the panel went ahead and the **NEC** now allows the wiring method in the administrative areas of school and hospital buildings.

324.18. Crossings. Not more than two FCC cable runs may be crossed over each other at any one point. To prevent lumping under the floor carpets, this rule permits no more than two Type FCC cables to be crossed over each other at a single point. This applies to FCC power cable and FCC communications and data cables.

In 324.41, “Floor Coverings,” the Code restricts the maximum size of carpet squares used to cover the Type FCC. Carpet squares used to cover Type FCC wiring must not be larger than 1 m (39.37 in.) square. This rule eliminates questions that arose about the possibility of using single “squares” of broadloom carpet large enough to cover a floor from wall to wall. In addition, the carpet squares must be put down with a release-type adhesive.

In making an undercarpet installation, usual thinking would dictate installation of the cable layout first and then placement of the floor covering of carpet squares over the entire area. But some installers have found it easier and less expensive to first cover the entire floor area with the self-adhesive carpet squares and then plan the circuit layouts to keep the cable runs along the centerlines of carpet squares and away from the edges of the squares. After the layout is determined, it is a simple matter to lift only those carpet squares along the route of each run, install the cable and pedestal bases, and replace the self-stick carpet squares to restore the overall floor covering. That approach has proved effective and keeps carpet cutting to the middle of any square.

In 324.60, the Code calls for grounding of metallic shields—commonly employed in Type FCC assemblies to prevent interference on communication circuits. This rule further stipulates that those connectors be specifically designed for connecting the metallic shield to ground.

ARTICLE 326. INTEGRATED GAS SPACER CABLE: TYPE IGS

326.2. Definition. Type IGS cable is a “factory assembly of one or more conductors, each individually insulated and enclosed in a loose-fit nonmetallic flexible conduit.” The cable is for underground use—including direct earth burial—for service conductors, feeders, or branch circuits. It must not, however, be used as interior wiring or exposed in contact with any building. Sizes available for this product run are metric designators 53, 78, and 103 (trade sizes 2, 3, and 4). The introduction of this cable to the **NEC** was recommended on the following basis:

Underground cable costs are increasing at a high rate. A need exists for lower material costs and reduced cost for installation. Failures on underground cables are increasing, particularly direct-burial types.

The new cable system overcomes all the above problems. The new cable system has the advantage of low first cost for materials and low installation cost. It eliminates the need for field pulling of cables into conduits and eliminates the cost of assembly of conduit in the field. The new system may be directly buried, plowed in, or bored in for further savings. It is a cable and conduit system.

A tough natural-gas-approved pipe is used as the conduit. When it is pressurized, it will withstand much abuse. The gas pressure keeps out moisture and serves to monitor the cable for damage by insects or mechanical damage that can lead to future failure. The gas pressure can even be attached to an alarm to sound a loss of pressure or to trip a CB for hazardous locations. However, a loss of pressure in the cable will not cause it to fail. Even on dig-ins, the gas serves to warn the digger. The gas prevents combustion and burning on cable failure. The SF₆ gas is nontoxic, odorless, tasteless, and will not support combustion. It acts to put out a fire.

UL has tested a 3/C 250 MCM [kcmil] Type IGS-EC 600-V cable in 2-in. conduit. The UL test at zero gauge pressure shows a breakdown voltage between conductors of 14,000 V after numerous short-circuit, breakdown, and humidity tests. When the cable is single conductor, the breakdown voltage is even higher on loss of pressure, as the polyethylene pipe or conduit provides additional insulating value.

An award-winning installation was made in 1979 at 5 kV. Three installations of 3/C 250 MCM [kcmil] Type IGS-EC cable have been made for residential underground service entrances in Oakland, California. The first was made in May of 1979 and all have been successful.

326.80. Ampacity. This section indicates that Type IGS cable must have its ampacity determined in accordance with Table 326.80 for either single or multiconductor cable.

ARTICLE 328. MEDIUM-VOLTAGE CABLE: TYPE MV

328.2. Definition. This is a very limited definition of a Code designation—Type MV. This cable must be listed (328.6). This cable type is constructed in accordance with provisions published by Underwriters Laboratories as part of the applicable Guide Card information, as follows:

Medium-Voltage Cable (PITY)

Medium-voltage cables are rated 2400 to 35,000 volts.

They are single or multiconductor, aluminum or copper, with solid extruded dielectric insulation and may have an extruded jacket, metallic covering, or combination of both over the single conductors or over the assembled conductors in a multiconductor power cable.

All insulated conductors rated higher than 2400 volts have electrostatic shielding. Cable rated 2400 volts is nonshielded.

Nonshielded cables are intended for use where conditions of maintenance and supervision ensure that only competent individuals service and have access to the installation.

Shielded cable is marked either “MV-90” or “MV-105” and is suitable for use in wet or dry locations at 90° or 105°C.

Nonshielded cable is marked either “MV-90” indicating suitability for use in wet or dry locations at 90°C maximum or “MV-90 Dry Locations Only” indicating suitability for use only in dry locations at 90°C maximum.

Cables marked “oil resistant I” or “oil resistant II” are suitable for exposure to mineral oil at 60° or 75°C, respectively.

Cables marked “sunlight resistant” may be exposed to the direct rays of the sun.

Cables intended for installation in cable trays in accordance with Art. 392 of the **National Electrical Code** are marked “For Use in Cable Trays” (or “For CT Use”).

Cables with aluminum conductors are marked with the word “aluminum” or the letters “AL.”

Cables are marked with their conductor size, voltage rating, and insulation level (100% or 133%).

The basic standard used to investigate products in this category is UL1072, “Medium-Voltage Power Cables.”

The Listing Mark of Underwriters Laboratories Inc. on the product is the only method provided by UL to identify products manufactured under its Listing and Follow-Up Service. The Listing Mark for these products includes the name and/or symbol of Underwriters Laboratories Inc. (as illustrated in the Introduction of this Directory) together with the word “LISTED,” a control number and the following product name: “Medium-Voltage Cable.”

Medium-Voltage Cable, Classified in Accordance with UL 1072, with Metric Conductor Sizes (PIVW)

This category covers medium-voltage cables rated 2001 to 35,000 volts and in conductor sizes 10 through 500 sq mm.

The cable complies with all requirements specified in UL 1072 “Medium-Voltage Power Cables,” except that metric conductor sizes are used instead of AWG sizes. The cable is for use in jurisdictions where metric conductor sizes are required or permitted.

The cable is single or multiconductor, aluminum or copper, with solid extruded dielectric insulation. An extruded jacket, metallic covering, or combination of both may be provided over single conductors or over the assembled conductors in a multiconductor power cable.

All insulated conductors rated 2400 V and higher have electrostatic shielding. Cables rated 2400 V are nonshielded.

Nonshielded cables are intended for use where conditions of maintenance and supervision ensure that only competent individuals service and have access to the installation.

Shielded cable is marked “MV-90” or “MV-105” and is suitable for use in wet or dry locations at 90° or 105°C.

Nonshielded cable is marked either “MV-90” indicating suitability for use in wet or dry locations at 90°C maximum, or “MV-90 Dry Locations Only.”

Cable marked “oil resistant I” or “oil resistant II” is suitable for exposure to mineral oil at 60° or 75°C, respectively.

Cable marked “sunlight resistant” may be exposed to the direct rays of the sun.

Cable intended for installation in cable trays is marked “For CT Use” or “For Use In Cable Trays.”

Cables with aluminum conductors are marked with the word “Aluminum” or the letters “AL.”

Cables are marked with conductor size in sq mm, voltage rating and insulation level (100% or 133%).

The basic standard used to investigate products in this category is UL1072, “Medium-Voltage Power Cables.”

The Certification Mark of Underwriters Laboratories Inc. on the product, the attached tag, the

reel, or the smallest unit container in which the product is packaged is the only method provided by UL to identify these products manufactured under its Classification and Follow-Up Service.

328.10. Uses Permitted. Because the Code has an article and cable designation (Type MV) for cables operating above 2000 V up to 35,000 V, it may be expected that electrical inspection authorities will insist that all cables in that voltage range must be Type MV to satisfy the **NEC**.

Great care should be exercised in determining the attitude of local inspection authorities toward the meaning of this article. In particular, the relationship of 110.8 to Art. 328 should be determined. 110.8 states that “only wiring methods recognized as suitable are included in this Code.” The question to be answered is: Will electrical inspection agencies require all medium-voltage conductors to be Type MV? Or will inspection agencies accept medium-voltage conductors not specifically designated Type MV? In other words, because the Code has an accepted type of high-voltage cable, will it be permissible to use high-voltage cables that are not of this accepted type? The answer seems to be no. This is especially true when the OSHA insistence on listed equipment is considered. In addition, for circuits in common use up to 600 V, 110.8 has consistently been interpreted to require that *any* conductor or cable must be one of the types specifically designated in the Code—Table 310.104(A) or elsewhere in Arts. 300 to 398. That is, conductors must be Type TW, THW, or one of the other designated types, and cable must be Type AC, NM, MI, MC, or other designated cable. It would be a Code violation to use any non-Code-designated wire or cable for systems up to 2000 V. It would, therefore, seem to be similarly contrary to Code to use a non-Code-designated cable for higher-voltage circuits inasmuch as there is a Code-designated type (Type MV) for such applications. In addition, the 2011 **NEC** added a new Sec. 328.14 requiring these cables to only be installed, terminated, and tested by qualified persons.

Refer to Table 310.104(B) on Type MV conductors and to 392.22(C) and 392.80(B) for use of Type MV cables in tray.

ARTICLE 330. METAL-CLAD CABLE: TYPE MC

330.2. Definition. This article covers “Metal-Clad Cable,” as listed by UL under that heading in the *Guide Card information* [see discussion at 110.3(B) for details]. This section defines the type of cable assemblies covered by this article (Fig. 330.1). The definition for metal-clad cable—“a factory assembly of one or more insulated circuit conductors with or without optical fiber members enclosed in an armor of interlocking metal tape, or a smooth or corrugated tube”—makes this category the successor to former Type ALS and Type CS cables.

Fig. 330-1. These are some of the constructions in which Type MC cable is available. (Sec. 330.2.) Note that the conductors comprising the center cable (5000 V) would require shielding to meet the current requirements in 310.10(E).

Aluminum-sheathed (ALS) cable had insulated conductors with color-coded coverings, cable fillers, and overall wrap of Mylar tape—all in an impervious, continuous, closely fitting, seamless tube of aluminum. It was used for both exposed and concealed work in dry or wet locations, with approved fittings. CS cable was very similar, with a copper exterior sheath instead of aluminum.

Because the rules of these three cable types have been compiled into a single article, use of any one of the Type MC cables must be evaluated against the specific rules that now generally apply to all such cables. The Code no longer contains the designations Type ALS and Type CS. They are included now as either smooth or corrugated styles as applicable along with interlocked armored cable as Type MC cables.

Type MC is rated by UL for use up to 2000 V. Cable rated 2400 to 35,000 V is listed as Type MV. Type MC cable is recognized in three basic armor designs: (1) interlocked metal tape, (2) corrugated, or (3) smooth metallic sheath.

330.6. Listing Requirements. This cable, as of the 2017 **NEC**, is required to be listed, along with its connecting fittings. The application rules for these connectors require careful study. Only approved, UL-listed connectors and fittings are permitted to be used with any Type MC cable. Such fittings are listed in the UL Guide Card listings as “Metal-Clad Cable Connectors (PJOX).” **Figure 330-2** shows typical approved connectors for interlocked-armor Type MC cable. As shown at left, 600-V terminations for interlocked-armor cable to switchgear or other enclosures in dry locations can be made with connectors, a locknut, and a bushing in the typical basic assembly shown. The bushing is generally optional because Type MC cable is not a raceway and 300.4(G) does not apply. In damp locations, compound-filled or other protective terminations may be desired. Medium-voltage connectors (5 through 35 kV) are generally filled with sealing compound, and individual conductors are terminated in a suitable manner, depending upon whether the conductors are shielded. Or the IA cable may terminate in a pothead for positively sealed and insulated terminations indoors or outdoors.

Fig. 330-2. Terminations for interlocked-armor cables must be approved devices, correctly installed. (Sec. 330.6.)

Type MC cable must terminate in connectors designed for the particular cable involved. Pay particular attention to differences between MC and AC cable terminations, for example. The **NEC** doesn't require anti-short bushings for Type MC cable, although one leading manufacturer does make them available for that purpose, and many contractors choose to use them anyway. They are not required because the throat designs of listed connectors keep the conductors away from the cut edges of the armor. In addition, since these connectors may have to handle ground-fault currents, they are tested with their designed cable types for this duty. Those tests have no validity beyond the cable types actually tested.

Before you run MC (or any other cable), look closely at the box or shipping carton for the connectors. Particularly in the case of Type MC cable, you'll find very specific size ranges given.

For example, the box might indicate suitability for smooth Type MC in a particular range of cable diameters, corrugated in a range of diameters, and interlocking with a range of conductor configurations. If you don't find your particular application, select a different connector. The same principle applies to internal box connectors. Look at the shipping carton for the box, because the label (for a listed box) will always tell you what cables the internal clamps are designed for.

330.10. Uses Permitted. Although this section clearly lists all the permitted applications of any of the various forms of Type MC cable, care must be taken to distinguish between the different constructions, based on the Code rules (Fig. 330.3). For a long time, the interlocked-armor Type MC and the corrugated-sheath Type MC have been designated by UL as "intended for aboveground use." But part (5) of this section recognizes Type MC cable as suitable for direct burial in the earth, when it is identified for such use.

Fig. 330-3. ALS (aluminum-sheathed) Type MC cable was used for extensive power and light wiring in refrigerated rooms and storage areas of a store. The ALS was surface mounted (exposed) on clamps in this damp location. Because the cable assembly is a tight grouping of conductors within the sheath, there would be no passage of warm air from adjacent nonrefrigerated areas through the cable which crosses the boundaries between the areas. It was therefore not necessary to seal the cables to satisfy Sec. 300.7(A). (Sec. 330.10.)

Note that item (11) includes the specific characteristics that must be met in order to qualify a particular cable style as suitable for wet locations. The 2014 **NEC** modified this rule by requiring a corrosion-resistant jacket over the metallic covering regardless of the inner construction detail. Item (12) recognizes single-conductor Type MC cable; care must be taken in such cases to track inductive

heating issues 300.21(B), special ampacity calculations [330.80(B)], and termination issues [110.14(C)].

330.12. Uses Not Permitted. Type MC cables are permitted by 330.10 to be used exposed or concealed in dry or wet locations. But such cable must not be subjected to destructive, corrosive conditions—such as direct burial in the earth, in concrete, or exposed to cinder fills, strong chlorides, caustic alkalis, or vapors of chlorine or of hydrochloric acids, unless protected by materials suitable for the condition.

330.15. Exposed Work. This wiring method, especially in the smaller branch circuit sizes, has largely supplanted type AC cable in the market. Because it is increasingly used for comparable applications, this section, new in the 2017 **NEC**, has been cut and pasted from 320.15. Refer to further discussion at that location for more information.

330.24. Bending Radius. Figure 330-4 shows the bending-radius rules for the “smooth-sheath” Type MC cables. Cable with interlocked or corrugated armor must have a bending radius not less than 7 times the outside diameter of the cable armor. To conform to ICEA rules on bending radius for shielded conductors in MC cable, the minimum value must be either 12 times the diameter of one of the conductors within the cable or 7 times the diameter of the MC cable itself, whichever is greater. For medium-voltage applications with shielded cables, the minimum bending radius is 12 times the cable diameter for a single-conductor makeup, and 7 times the overall diameter of a multiconductor makeup, as applicable.

Bends: Radius (R) shall not be less than:

- (a) 10 times OD for cables with OD $\frac{3}{4}$ in. or less.
- (b) 12 times OD for cables with OD over $\frac{3}{4}$ in. but not over $1\frac{1}{2}$ in.
- (c) 15 times OD for cables with OD over $1\frac{1}{2}$ in.

Fig. 330-4. Minimum radius values prevent excessively sharp, destructive bending of Type MC cable, or its predecessors, Type ALS or CS cable. (Sec. 330.24.)

330.30. Securing and Supporting. Figure 330-5 shows the maximum permitted spacing of supports for the larger-sized Type MC cable. The interlocked-armor Type MC has commonly been used on cable tray, as permitted in part (A)(6) of 330.10 if it is identified for this use (Fig. 330.6). In addition to the 1.8 m (6 ft) interval, smaller cables—those with four or fewer conductors smaller than No. 8—must also be secured within 300 mm (12 in.) of “each box, cabinet, fitting, or other cable termination.” In addition, part (C) recognizes the common practice of entraining cables through successive holes in framing members.

Fig. 330-5. Surface mounting of Type MC cable must be secured. Smaller sizes are additionally required to be secured within 300 mm (12 in.) of terminations. (Sec. 330.30.)

Fig. 330-6. Any Type MC cable is recognized for use in cable tray, and the interlocked-armor version has been widely used in tray, as shown here. (Sec. 330.30.)

The 2014 **NEC** has made two changes that extend support intervals in this section. Small cables whose normal first point of support is 12 in. can, in the case of the interlocking armor type of cable, have that distance go out to 36 in. in instances where flexibility is required after the installation is complete. It also added permission to extend the support interval for vertical runs of very large MC cables, those with ungrounded conductors no smaller than 250 kcmil, from the customary 6 to 10 ft.

Part **(D)** recognizes that Type MC cable can be fished without concern for periodic supports. It also recognizes that a cable connector can, in effect, be considered a point of support, at least in suspended ceilings. As in the case of Type AC cable, these cable ties must be listed for this function. This is an extremely practical allowance that avoids the necessity for supports near the cable terminations. Note that this also supersedes the normal requirement for securing within 300 mm (12 in.) of terminations for smaller cables. See also the discussion at 320.30 for Type AC cable for more information on this topic.

330.80. Ampacity. In addition to the normal ampacity considerations, it should be noted that Type MC cable is available in single-conductor configurations, with special ampacity considerations. The usual application for these configurations is cable tray, and the allowance to use messenger cable ampacities correlates with 392.80(A)(2)(d) and 392.80(B)(2)(c). Note that these enhanced ampacities apply to the middle of a cable run and do not excuse compliance with 110.14(C) [or 110.40 for medium-voltage applications] at wiring terminations. Step-up terminators with tails that

comply with applicable Table 310.15(B)(16) ampacities may be available, or the run can be brought through a pull box with the wire sizes adjusted prior to arrival at equipment terminals.

330.108. Equipment Grounding Conductor. Generally the smooth and corrugated types of MC cable have sufficient cross-sectional area of metal in their armors such that the armor itself qualifies as the equipment grounding conductor, although not always; if additional grounding conductors are incorporated, they must be used as part of the equipment grounding system, right along with the cable armor. Interlocking metal tape, without modification, is never suitable for equipment grounding because the spiral path adds too much impedance. Type AC cable solves this problem with the bonding tape and the paper filler, because the tape is held in firm contact with the armor, and as such it shorts the convolutions. Traditionally, Type MC with interlocking armor always carried an additional equipment grounding conductor, usually with green insulation and sized per 250.122. This conductor had to terminate in boxes and it counted for a required fill allowance in 314.16.

Recently one manufacturer solved the grounding continuity problem across interlocking MC cable armor by using a bare, fully sized aluminum equipment grounding conductor against the armor and on the outside of the plastic wrap that goes over the circuit conductors. This product can be used similarly to Type AC cable, without a separate grounding conductor entering the box. In addition, for instances where the connector and locknut cannot be relied upon for grounding continuity, such as for 480Y/277 system circuits running into cabinets with concentric knockouts, the bare wire can be left as long as the circuit conductors and brought to an equipment grounding terminal in the enclosure. Even Type AC cable isn't capable of that trick because the little aluminum bonding strip does not qualify as an equipment grounding conductor. Here again, make certain to correlate the listing information for the connectors with the type of MC cable being used. Refer also to the commentary on this point contained in the coverage at 250.118(10), where this method of equipment grounding is recognized.

ARTICLE 332. MINERAL-INSULATED, METAL-SHEATHED CABLE: TYPE MI

332.2. Definition. The data from the UL Guide Card information [see discussion at 110.3(B) for details] expand on the definition ([Fig. 332.1](#)) and cover application notes as follows.

Fig. 332-1. Type MI is a single- or multiconductor cable that requires special termination. (Sec. 332.2.)

Mineral-insulated metal-sheathed cable is labeled in a single-conductor construction from 16 AWG through 500 kcmil single conductor, two- and three-conductor from 16 AWG through No. 4 AWG, four-conductor from No. 16 AWG through No. 6 AWG, and seven-conductor Nos. 16, 14, 12, and 10 AWG. The exterior sheath may be of copper or alloy steel. There is also a signaling circuit style available with a 300 V rating and configured for 16 and 18 AWG in 2-, 3-, 4-, and 7-conductor put-ups. It is available with a copper sheath (the usual configuration) in which case the sheath is qualified as an equipment grounding conductor, and also with an alloy steel sheath that does not so qualify.

The standard length in which any size is furnished depends on the final diameter of the cable. The smallest cable, 1/C No. 16 AWG, has a diameter of 0.216 in. and can be furnished in lengths of approximately 1900 ft. Cables of larger diameter have proportionally shorter lengths. The cable is shipped in paper-wrapped coils ranging in diameter from 3 to 5 ft. As of the 2017 **NEC**, this cable must be listed.

The original intent behind development of this cable was to provide a wiring material that would be completely noncombustible, thus eliminating the fire hazards resulting from faults or excessive overloads on electrical circuits. To accomplish this, it is constructed entirely of inorganic materials. The conductors, sheath, and protective armor are of metal. The insulation is highly compressed magnesium oxide, which is extremely stable at high temperatures (fusion temperature of 2800°C).

332.10. Uses Permitted. This section describes the general use of mineral-insulated metal-sheathed cable, designated Type MI. Briefly, it basically includes general use as services, feeders, and branch circuits in exposed and concealed work, in dry and wet locations, for underplaster extensions and embedded in plaster, masonry, concrete, or fill, for underground runs, or where exposed to weather, continuous moisture, oil, or other conditions not having a deteriorating effect on the metallic sheath (Fig. 332.2). The temperature rating of the cable for conventional power

applications is limited by the rating of the end-seal fitting, which necessarily includes organic compounds for sealing purposes. UL sets the maximum rating of current end-seal designs as covered in the Guide Card information that is current as of this writing at 90°C in dry locations and 60°C in wet locations. The cable itself, however, is recognized for 250°C in special applications. Permissible current ratings will be those given in Table 310.15(B)(16) (or, under engineering supervision, in Table B.310.3 in Annex B in the back of the **NEC** book). Type MI cable in its many sizes and constructions is suitable for all power circuits up to 600 V.

Fig. 332-2. Type MI is recognized for an extremely broad range of applications—for any kind of circuit, indoors or outdoors, wet or dry, and even in hazardous locations, as where MI motor branch circuits supply pumps in areas subject to flammable gases or vapors. (Sec. 332.10.)

There is no question that MI cable can be used “in underground runs” as indicated in 332.10(10). But there is the matter of the additional qualification that it be “suitably protected against physical damage and corrosive conditions.” Although the copper sheath of MI cable has good resistance to corrosion, acid soils may be harmful to the copper sheath. Direct earth burial in alkaline and neutral soils would generally be expected to create no problems, but in any direct burial application MI cable with an outer plastic or neoprene jacket would ensure effective application and provide

compliance with the additional language in part (10) of 332.10. Such jacketed MI cables are available, and have been successfully used in direct burial applications. As in the case of Type MC cable, the permitted minimum bending radius is limited by Sec. 332.24, to amounts that are related to the outer diameter of the cable.

332.40. Boxes and Fittings. Part (A) calls for connections of Type MI cable to be carefully made in accordance with UL and manufacturers' application data to ensure effective operation (Fig. 332.3).

Fig. 332-3. Termination fitting for Type MI cable must be an approved connector, with its component parts assembled in proper sequence. [Sec. 332.40(A).]

Part (B) of 332.40, "Terminal Seals," presents a rule that is applied in conjunction with that of 332.40(A) to ensure *both* sealing of the cable end and means for connecting to enclosures (Fig. 332.4).

This typical fitting is approved for MI termination in hazardous locations, in accordance with 501.10.

Fig. 332-4. MI cable termination must provide end sealing and connection means. [Sec. 332.40(B).]

332.80. Ampacity. The amount of heat that a run of MI cable can tolerate is governed by the

temperature rating of the end-seal connector, which is 90°C in dry locations. For multiconductor configurations, look in Table 310.15(B)(16) in that column and read out the ampacity. If the conductor size does not change prior to landing on a circuit breaker, then 110.14(C) applies and a lower-temperature ampacity column may need to be substituted. This is really no different from other multiconductor cables with 90°C insulation, such as Type MC cable.

However, this cable can be and very frequently is run as single-conductor cable, and 332.80(B) allows its ampacity to be calculated from Table 310.15(B)(17). This permission is conditioned on a maintained spacing between adjacent cable groupings equal to not less than 2.15 times the outside diameter of the single largest cable in a group. For single conductor 4/0, that is 17.4 mm (0.684 in.) in diameter, the spacing would need to be about 37.4 mm (1.5 in.) between cable bundles. Even after the spacing is settled, however, there are other concerns that have to be addressed, as follows:

When it is run in this form, 332.21 requires that the cables be grouped to minimize the induced voltages on the cable sheaths. When this happens, the individual cables are not free to radiate their heat to the extent normally presumed for a conductor using free-air ampacities from Table 310.17. Consider a 3-phase, 4-wire makeup using the 4/0 AWG Type MI cable already mentioned, which comes out of the 90°C column of Table 310.17 at 405 A. Is this a way to avoid running 500 kcmil as pipe and wire? It might be, but read on.

When the cable is grouped, each cable does not radiate its heat as well. And in fact, loading 4/0 AWG MI cable to 405 A after it has been grouped or bundled results in a steady-state temperature within the bundle significantly higher than 90°C. This is a known fact; however, the MI cable manufacturers correctly pointed out that there are no end seals in the middle of one of these runs. The only thing there is copper and magnesium oxide. These items can withstand temperatures far higher than even temperatures over 90°C indefinitely without damage. Therefore, it has been conclusively demonstrated that yes, the cable bundles will run hot, but Table 310.15(B)(17) ampacities are not unreasonable for this type of cable applied in just this way.

The next issue is to bring this cable, in this heated state, to the panel, and then into the panel for terminations. This means getting the hot cables in the bundle to cool off enough so the end seal temperature operates within its temperature rating (90°C). This means spreading the cables out to a certain amount for a certain length, neither of which is specified in the **NEC**. That means requesting information from the cable manufacturer's engineering department, and then following their recommendations, which should be documented. Strictly by way of illustration, informal conversations have resulted in informal suggestions in the 300 to 450 mm (1 to 1½ ft) range, but that will need to be determined properly.

The final step is to make certain that the terminations stay within the usual 75°C limits prescribed in 110.14(C)(1)(b). Here the MI cable manufacturers seem to be quite aware of this issue. They have a range of step-up sizing terminations that incorporate upsizing terminating tails that match typical ampacity combinations. For example, a step-up connector rated for 4/0 MI cable and providing a 500 kcmil tail for termination purposes is a stock item with the leading manufacturer of Type MI cable.

ARTICLE 334. NONMETALLIC-SHEATHED CABLE: TYPES NM, NMC, AND NMS

334.1. Scope. This section makes clear that nonmetallic-sheathed cable must be installed *and* manufactured as required here.

334.2. Definition. Nonmetallic-sheathed cable is one of the most widely used cables for branch circuits and feeders in residential and light commercial systems (Fig. 334.1). Such cable is commonly and generally called “Romex” by electrical construction people, even though the word *Romex* is a registered trade name of the General Cable Corp. Industry usage has made the trade name a generic title so that nonmetallic-sheathed cable made by any manufacturer might be called Romex. This generic usage of a trade name also applies to the term *BX*, which is commonly used to describe any standard armored cable, made by any manufacturer—even though the term *BX* is a registered trade name of General Electric Co. Type NM cable has an overall covering of fibrous or plastic material that is flame-retardant and moisture-resistant. Type NMC is similar, but the overall covering is also fungus-resistant and corrosion-resistant. The letter C indicates that it is corrosion-resistant Type NM cable must be listed (334.6), along with its associated fittings.

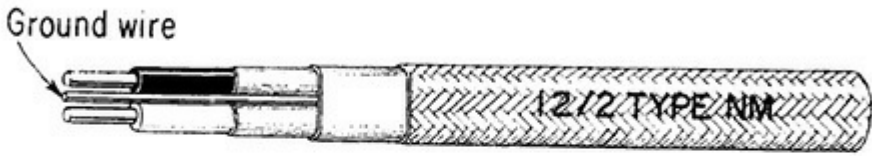

Type	Construction	Application
 <p data-bbox="357 938 505 1006">NM (Art. 334)</p>	<p data-bbox="626 938 994 1233">Non-metallic sheathed cable. Rubber or thermoplastic insulated conductors, with or without separate grounding conductor, covered by heavy paper wrapping and braid or plastic.</p>	<p data-bbox="1022 938 1390 1233">For interior wiring, exposed or concealed in dry locations. Must not be used exposed to corrosive fumes or vapors or embedded in concrete, masonry, fill or plaster.</p>
 <p data-bbox="357 1483 505 1551">NMC (Art. 334)</p>	<p data-bbox="626 1483 994 1710">Same as type NM cable except that it has a corrosion-resistant outer covering of non-fibrous material, such as neoprene or thermoplastic.</p>	<p data-bbox="1022 1483 1390 1778">For interior wiring, in same ways as type NM, except that it may be embedded in plaster or run in chase if a 1/16-in. steel plate is provided for protection against nails.</p>

Fig. 334-1. Two of the three separate types of nonmetallic-sheathed cable are shown here. (Sec. 334.100.) Since these drawings were made, changes in the product standard have made conventional Type NM cable much smaller in overall size because the paper wrap has been eliminated (subject to a cold-weather pull-through-the-joists test) and now only the bare equipment grounding conductor has paper around it. Type NMC has largely been supplanted in the market by Type UF cable.

334.10. Uses Permitted. This type of wiring may be used either for exposed or for concealed wiring (Fig. 334.2) in any kind of building or structure.

Fig. 334-2. Although NM cable is most widely used for branch circuits, the larger sizes (No. 8 and up) are commonly used for feeders, as run here from apartment disconnects to tenant panelboards. (Sec. 334.10.)

1. NM cable may be used in one-family dwellings, together with their attached or detached garages and their storage buildings.
2. NM cable may be used in two-family dwellings, together with the same list of accessory

buildings that applies to single-family houses.

3. NM cable may be used in multifamily dwellings.

4. NM cable may be used in other structures.

But for multifamily dwellings or other buildings or structures, the use of NM is permitted *only* if these locations are *permitted to be* of Type III, Type IV, or Type V construction as given in **NFPA5000®** (see Code Annex E). This is a critical point. The acceptability of NM cable depends not on how the building is actually constructed, but rather on what the applicable building code would permit the construction to be based on the occupancy. A small multifamily dwelling that meets the size and area tables of the local building code for Type V construction, and yet was constructed to Type II standards, may still use Type NM cable. For nonresidential applications, however, Type NM cable must be concealed within stud or joist cavities (or other protected areas) that have a finish construction that provides a minimum of a 15-min finish rating as defined in listings of fire-rated assemblies. This generally includes 12.7 mm (½ in.) drywall.

Note that there is also permission [334.10(5)] for NM cables to be pulled in to [Chap. 3](#) raceways that would be allowed in the construction. This has a certain internal logic since if EMT is safe with THHN inside, why shouldn't it be safe with NM cable built around THHN in the same location? Why anyone would buy and install NM cable where straight THHN would do is another question, but the exception appears to be harmless.

Type NM or NMC cable must be “identified” for use in cable trays. This requirement essentially calls for UL listing and marking on the cable to make it “recognized” as suitable for installation in cable trays. Type NM or NMC cable can also be fished into hollow voids of masonry block or tile construction.

Although NM cable is limited to use in “normally dry locations,” NMC—the corrosion-resistant type—is permitted in “dry, damp, moist, or corrosive locations.” Because it has been widely used in barns and other animals’ quarters where the atmosphere is damp and corrosive (due to animal vapors), NMC cable is sometimes referred to as “barn wiring.”

Part **(B)** says that Type NMC that is run in a shallow chase in masonry, concrete, or adobe and covered over must be protected against nail or screw penetration by a 1.59-mm (1/16-in.) (minimum) steel plate. This allowance does not extend to NM or NMS cables.

Part **(C)** specifies those permissible uses for Type NMS, which is a hybrid cable containing power, signaling, communication—voice/data/video—and even optical-fiber cable. This cable type was originally put in the Code to correlate with the former Art. 780 on closed-loop circuiting, where all outlets remained de-energized until a suitable plug was connected. This action would wake up a central controller and announce that a stipulated load was now connected, so a power draw could be provided that corresponded to the load. If the appliance malfunctioned and started to draw too much power, the circuit would be de-energized by the controller. The system was essentially foolproof, but never managed to gain any market share, and as of the 2008 Code cycle, Art. 780 has been deleted. Type NMS cable now relates to intelligent energy management systems that rely on signaling between an outlet and a central control system, and it can carry other systems as well, such as communications. The construction requirements in 334.116(C) assure that the system separation rules in [Chaps. 7](#) and [8](#) of the **NEC** are respected in these cable constructions.

334.12. Uses Not Permitted. The first subpart of this rule eliminates the use of any nonmetallic-sheathed cable where it is not already permitted by 334.10, regardless of occupancy type

(Fig. 334.3). Guidance regarding building type can be found on the building permit, and Table E.1 in Annex E of the Code, presented here as Tables 334-1A and 334-1B, can also be of assistance. Perhaps the best guidance can be provided by the local building department. Remember, the rule is based not on what the building is, but what it could be, and that is entirely within the purview of the building department.

The 3-story limitation has been eliminated.

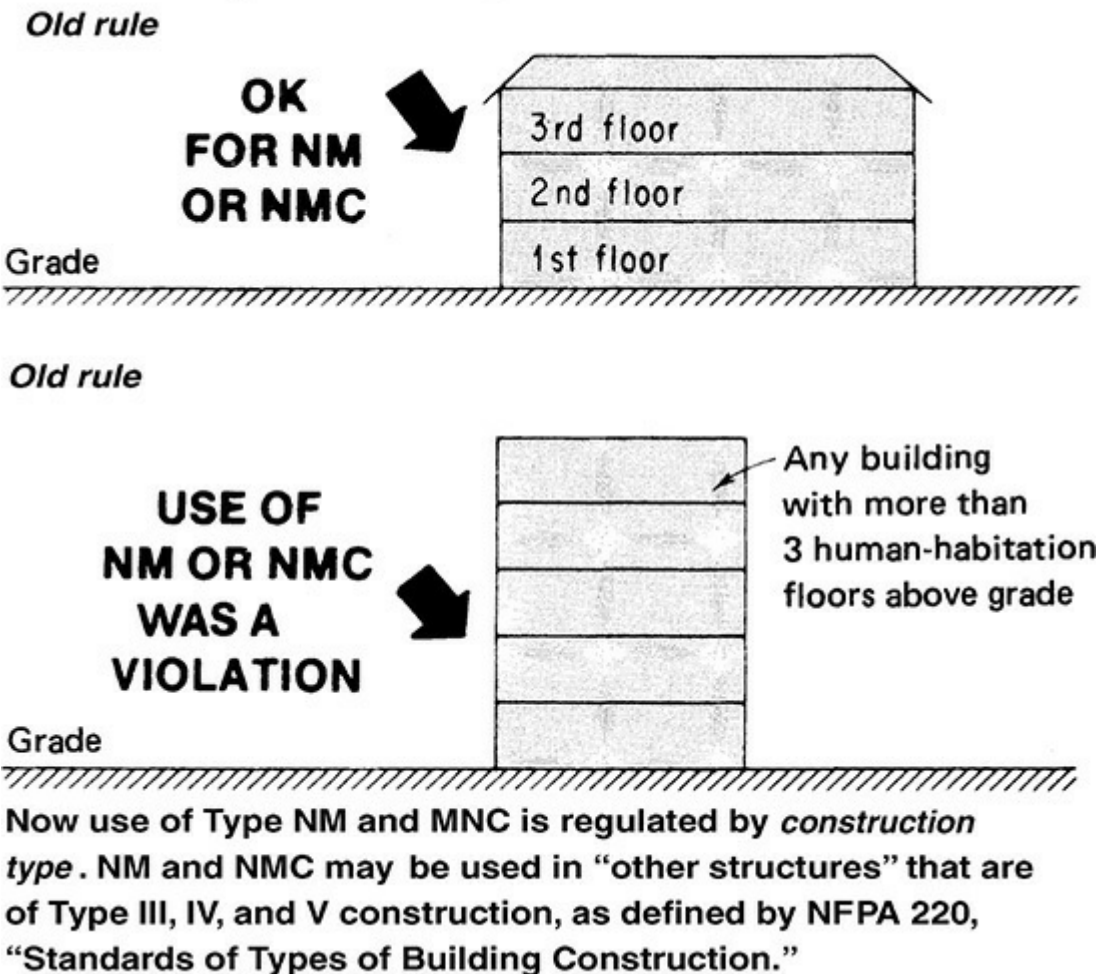

Fig. 334-3. Nonmetallic-sheathed cable is limited in application. [Sec. 334.12(A).]

The whole approach of using building construction types to define the permitted scope of a wiring method is unique in the history of the **NEC**, although some rules of transformer installations do include these references. The wording of the change originated in a special task group that met in the summer of 1999 to try to sort out where the real issues were in NM cable usage. The reversal of the three-story limitation was also implemented in a very unusual way because it was imposed by the **NFPA** Standards Council in the 2002 **NEC** after it had been rejected at all steps in the usual Code amendment process. The Council action was based on the entire record before it, including **NFPA** fire statistics that showed no association between Type NM cable and fire prevalence, and the report of the **NFPA** Toxicity Advisory Committee to the effect that in a fire the contribution of Type NM cable jacketing materials is a negligible fraction of the total smoke load.

It was also very clear at the time that major housing interests were prepared to expend significant resources litigating any continuing three-story limitation on grounds that would challenge the technical validity of the rule, and quite possibly the technical objectivity of the **NEC** panel. Furthermore, the

rule had attracted the attention of housing activists, who identified it as a source of artificially inflated housing costs, and who were advocating state legislative attacks on the rule that would have undermined the traditional political independence of the local **NEC** adoption process in some major jurisdictions. The Standards Council decision seems to have been successful; those attacks are now moot, and the political challenges in this area have lessened.

The response from the **NEC** Committee after the Standards Council action has been a steady erosion of the reach of Type NM cable in nontraditional occupancies, while carefully leaving unchanged the basic approach of using construction types to define the applicability of the wiring method. No change is more emblematic of this process than 334.12(A)(2), which is a backdoor prohibition against the use of NM cable above any suspended ceiling in smaller commercial occupancies, a practice that had been done under the old one- to three-stories rule for decades. Because all of these spaces are accessible through removal of ceiling tiles, the areas meet the definition of “exposed” in Art. 100, and the prohibition is complete.

This 2005 **NEC** change replaced wording from the task group, implemented in the 2001 Standards Council action, which prohibited running NM cable in nonresidential suspended ceilings where it was “in open runs.” The concept was that these ceilings were often used for random storage, and if NM cable ran from bar joist to bar joist on 1.2-m (4-ft) centers, the regular support rule would still be met but the cable would be subject to damage. The “in open runs” prohibition still allowed the cable in the ceiling, as long as it was protected with a running board or equal. The only substantiation behind making the change (2005 **NEC**) from “in the open” to “exposed” was that “exposed” was a defined term. A change that removes a wiring method from a good portion of a market, and in the teeth of public comments detailing the gravity of the change, does not turn on an editorial desire to use a defined term. This and comparable issues will undoubtedly fester for some time to come.

As covered in part **(12)(B)(2)**, Types NM and NMS *are* effectively prohibited from embedding in plaster and so forth ([Fig. 334.4](#)). Given the robust nature of NMC, it is specifically permitted for such application, but it is also necessary to protect the cable against the possibility of being damaged by driven nails—such as nails used to hang pictures or add construction elements on the wall. Sufficient protection against nail puncture of the cable is provided by a cover of corrosion-resistant coated steel of at least 1.59 mm ($1/16$ in.) thickness (or equivalent protection from a listed nail plate). Such metal protection must be run for the entire length of the cable where it is run “in shallow chase.” The metal strip protection must be run in the chase and then covered with the plaster or adobe (or similar) finish. But it must be carefully noted that NM, NMC, and NMS are prohibited by 334.12(A)(9) from embedment in cement, concrete, or aggregate—which is distinguished from plaster.

Fig. 334-4. This was permitted by previous editions of the Code and may still be acceptable. (Sec. 334.10)

334.15. Exposed Work. Figure 334-5 shows the details described in parts (A) and (B) of this section. The rules of this section tie into the rules of part (C), covering use in unfinished basements, which are really places of “exposed work.”

Table 334-1B Maximum Number of Stories for Types V, IV, and III Construction

Methods of installing nonmetallic-sheathed cable in an unfinished basement. A, through joists; B, on side or face of joist or beam; C, on running board.

Fig. 334-5. This applies to unfinished basements and other exposed applications. (Sec. 334.15.)

As covered in part (C) to 334.15, cables containing Nos. 14, 12, or 10 conductors must be run through holes drilled through joists, or installed on running boards. When running parallel to joists, any cable must be stapled to the wide, vertical face of a joist and never to the bottom edge. But, as shown in Fig. 334-6, larger cables may be attached to the bottom of joists when run at an angle to the joists. For mounting on the unfinished wall of a basement, there is now language in this location that allows NM cable to be sleeved in a raceway with a protective fitting at the upper end. Of course, this

permission has already been in the NEC [300.15(C)] for over 35 years.

Note: Method shown is a VIOLATION for cables containing Nos. 14, 12, or 10 conductors

Fig. 334-6. Only large cables may be stapled to bottom edge of floor joists. [Sec. 334.15(C).]

334.17. Through or Parallel to Framing Members. This rule reiterates requirements on 300.4, and emphasizes that the grommets required for the use of NM cable in steel-stud construction must be designed to remain in place and be listed for the purpose of cable protection. There is one additional requirement in 300.4(B)(1) not mentioned here that needs to be emphasized in this regard: for NM cable, the grommet must encompass the entire cut opening. There is a V-shaped grommet design that is open at the top; these are not acceptable for NM cable. In the process of pulling through, especially if the holes don't line up perfectly, the unprotected upper edge has been known to severely damage cables.

334.30. Securing and Supporting. Figure 334-7 shows support requirements for NM or NMC cable. Figure 334-8 shows a violation, both of this section and also 300.11(D) because cables tied together as shown amount to cables supporting cables. In concealed work the cable should, if possible, be so installed that it will be out of reach of nails. Care should be taken to avoid wherever possible the parts of a wall where the trim will be nailed in place—for example, door and window casings, baseboards, and picture moldings. See 300.4. NM cable is also permitted to be fished, and run in suspended ceilings [residential only per 334.12(A)(2)] with up to 1.4 m (4½ ft) of unsupported cable to a luminaire.

Fig. 334-7. NM or NMC cables must be stapled every 4½ ft (1.4 m) where attached to the surfaces of studs, joints, and other wood structural members. It is not necessary to use staples or straps on runs that are supported by the drilled holes through which the cable is pulled. But there must be a staple within 12 in. (300 mm) of every box or enclosure in which the cable terminates. This illustrates the distinction between support intervals, which the stud drillings provide, and securement, which only the staples provide. Cable ties, if listed for “securement and support,” are also permitted; their usual application is above suspended ceilings. (Sec. 334.30.)

Fig. 334-8. Absence of stapling of the NM cables within 12 in. (300 mm) of entry into the panelboards is a clear violation of Sec. 334.15. (Sec. 334.30.) Support of one cable from another also violates 300.11(D).

Connectors listed for use with Type NM, NMS, or NMC cable (nonmetallic-sheathed cable) are also suitable for use with flexible cord or service-entrance cable *if* such additional use is indicated on the device or carton. Connectors listed under the classifications “Armored Cable Connectors” and “Conduit Fittings” may be used with nonmetallic-sheathed cable when that is specifically indicated on the device or carton. Connectors for NM, NMS, or NMC cable are also suitable for use on Type UF cable (underground feeder and branch-circuit cable—**NEC** Art. 340) in dry locations, unless otherwise indicated on the carton. Each connector covered in the listing is recognized for connecting only one cable or cord—unless it is a duplex connector for connecting two cables or if the carton is marked to indicate use with more than one cable or cord.

Part (C) covers a wiring device configured with a self-contained enclosure that does not require a separate outlet or device box. There must be not less than 300 mm (1 ft) of an unbroken cable loop (or 150 mm [6 in.] of free cable ends) left at the opening so the device can be serviced. This application is also covered in 300.15(E), and in the majority of cases the result is a flush installation in a building wall. They are also noted in 334.40(C).

334.40. Boxes and Fittings. In part (A), the Code presents requirements for “Boxes of Insulating Material.” By using nonmetallic outlet and switch boxes, a completely nonmetallic wiring system is provided. Such a system has economic and other advantages in locations where corrosive vapors are present. See 314.3.

In 334.40(B), “Devices of Insulating Material,” note that use of switch and outlet devices without boxes is limited to exposed cable systems and for repair wiring in existing buildings. These are primarily surface-mounted devices also covered in 300.15(H). They were far more common about 50 years ago, and were commonly used to provide snap switches and receptacles in summer cottages with NM cable surface mounted on unfinished framing. Unlike the surface-mounted switches and receptacles of many decades ago, the “interconnector” devices are routinely used today. The terminology and related applications were revisited in the 2014 **NEC** cycle in order to address the permitted uses of these concealable NM cable splicing devices that have been recognized in 545.13 for decades. They are recognized here without boxes for concealed “repair wiring” only. This reference must not be confused with that of subpart (C) as given in 334.30, which refers to approved wiring devices that incorporate their own wiring boxes, so they are devices “without a *separate* outlet box” and not devices “without boxes.”

334.80. Ampacity. The second sentence requires that NM, NMS, and NMC cables always have their conductors applied to the ampacity of Type TW wire—that is, the 60°C ampacity from Table 310.15(B)(16). However, the insulation on the conductors must be rated at 90°C. This provides an additional margin for error and helps prevent overheating of Type NM where installed, say, in the attic of a residential occupancy located in the New Mexico desert. The ambient temperature would soar in the summer, unless the attic was air conditioned.

The last paragraph of 334.80 correlates the use of NM cable to the rule of 310.15(B)(3), which says:

...where single conductors or multiconductor cables are stacked or bundled longer than 24 in. without maintaining spacing and are not installed in raceways, the allowable ampacity of each conductor shall be reduced as shown...

Bundled NM, NMS, or NMC cables will require ampacity derating in accordance with 310.15(B)(3) when the whole bundle is tightly packed, thereby losing the ability of the inside cables to dissipate the heat generated in them. An example of this is shown in [Fig. 310-20](#). This is true of NM cables as well as any other cables. And the derating percentage from the table in 310.15(B)(3)(a) must be based on the total number of insulated conductors in the group. For instance, fourteen 3-wire 14 AWG cables would have to be ampacity derated to 35 percent of the conductor ampacity [$14 \times 3 = 42$ conductors at 35 percent, from Table 310.15(B)(3)(a)], which, at 9 A ($25 \text{ A} \times 0.35 = 9 \text{ A}$) would immediately disqualify them from use, particularly for receptacle circuits. Also note that since this rule now goes directly to Table 310.15(B)(3)(a) and bypasses the heat-sink exception, there is no way around this except for drilling more holes. The same issue applies to the draft-stop limitation following, where if ever more than two NM cables are draft- (or fire-) stopped in the same framing hole, regardless of the length of penetration, the table derating factors apply.

The wording of this section understates the problem for installations that are embedded in thermal insulation. By allowing derating to occur from the 90°C column for such cables, the **NEC** allows users to ignore factors that increase the retention of heat in the cable until they reach the point of reducing the ampacity below the 60°C value, which in most cases is to allow them to be ignored altogether. Meanwhile, particularly for large, heavily loaded cables, even the 60°C numbers are too high. Review the discussion associated with 310.15(A)(3) for detailed information on this topic.

ARTICLE 336. POWER AND CONTROL TRAY CABLE: TYPE TC

336.2. Definition. This article covers the use of a nonmetallic-sheathed power and control cable, designated Type TC cable (TC is the abbreviation for *tray cable*) (Fig. 336.1). The cable is an assembly of two or more insulated conductors, with or without associated bare or covered grounding conductors, under a nonmetallic jacket. Type TC cable must be listed (336.6). It is a cable that can be used for power and lighting applications, as well as control and signaling functions, including Class 1 control circuits as well as non-power-limited fire alarm wiring.

Fig. 336-1. This typical 3-conductor tray cable contains bare equipment grounding conductors. (Sec. 336.2.)

336.10. Use Permitted; 336.12. Uses Not Permitted. It is not permitted to be made with a metallic cable armor either under or over the nonmetallic jacket; however, metal shielding is permitted, and where employed, the minimum bending radius of the cable must not be less than 12 times the cable diameter. Otherwise, the minimum allowable bend radius is based on the cable diameter, with 4 times the diameter allowed for cables 25 mm (1 in.) or thinner, 5 times for cables up to 50 mm (2 in.), and 6 times for larger cables. In addition to cable tray usage, Type TC cable is permitted to run within raceways and on messenger wires, but for outdoor applications in direct sun it must be identified for that use. It may be directly buried, but also only if so identified, and it may also be used in wet locations if made resistant to moisture and corrosive agents.

Type TC cable is available with a more robust configuration [covered in (10)(7)] that will meet the crush and impact tests that apply to metal-clad cable, Type MC. This form is identified as Type TC-ER. For industrial occupancies with qualified maintenance and supervision, Type TC-ER is permitted to exit a cable tray and run to utilization equipment or devices, provided also that it has continuous mechanical support, such as strut, angles, or channels. In addition, if not threatened with physical damage, Type TC-ER is permitted to run unsupported between cable tray transitions, or from cable trays to utilization equipment or devices as long as the unsupported distance does not exceed 1.8 m (6 ft). Where the cable exits the tray, mechanical support must be provided so the required bend radius is maintained.

The 2017 **NEC**, responding to a input from the standby generator industry, now recognizes a new style of TC-ER tray cable, permitted in one- and two-family dwelling units. It is made up of both

power and control conductors, and must carry an additional designation “JP” (which stands for joist pull, and means the cable assembly has undergone the UL cold environment pull through joists test). It must generally meet the installation requirements for Type NM cable; however, where used to run between a permanent standby generator and the transfer equipment, it avoids the ampacity limits in 334.80. Some varieties of this cable carry the control wiring conductors cabled with power conductors, but within their own nonmetallic jacket that meets the construction requirements of Type NM cable. This effectively makes the arrangement acceptable in terms of system separation rules. Refer to the discussion at 725.136(I) for details.

UL data on “Power and Control Tray Cable” include the following:

Power and Control Tray Cable (QPOR)

This category covers Type TC power and control tray cable intended for use in accordance with Art. 336 of ANSI/NFPA 70, “**National Electrical Code**” (NEC). The cable consists of one or more pairs of thermocouple extension wires or two or more insulated conductors, with or without one or more grounding conductors, with or without one or more optical fiber members and covered with a nonmetallic jacket. A single grounding conductor may be insulated or bare and may be sectioned. Any additional grounding conductor is fully insulated and has a distinctive surface marking. The cable is rated 600 or 2000 V.

The cable is certified in conductor sizes 18 AWG to 1000 kcmil copper or 12 AWG to 1000 kcmil aluminum or copper-clad aluminum. Conductor sizes within a cable may be mixed. Thermocouple extension conductors are certified in sizes 24 to 12 AWG.

PRODUCT MARKINGS

Cable with copper-clad aluminum conductors is surfaced printed “AL (CU-CLAD)” or “Cu-clad Al.”

Cable with aluminum conductors is surface printed “AL.”

Cable employing compact-stranded copper conductors is so identified directly following the conductor size, wherever it appears (surface, tag, carton, or reel), by “compact copper.” The abbreviations “CMPCT” and “CU” may be used for compact and copper, respectively.

Tags, reels, and cartons for products employing compact-stranded copper conductors have the marking: “Terminate with connectors identified for use with compact-stranded copper conductors.” For termination information, see Electrical Equipment for Use in Ordinary Locations (AALZ).

If the type designation of the conductors is marked on the outside surface of the cable, the temperature rating of the cable corresponds to the rating of the individual conductors. When this marking does not appear, the temperature rating of the cable is 60°C unless otherwise marked on the surface of the cable.

Cable investigated for use where exposed to direct rays of the sun is marked “sunlight resistant.”

Cable investigated for direct burial in the earth is so identified.

Cable suitable for use between cable trays and utilization equipment in accordance with NEC 336.10(7) is surface marked with the suffix “-ER.”

Cable consisting of thermocouple extension wires is surface marked “THCPL EXTN,” “For thermocouple extension use only” or “Thermocouple extension wire only.”

Cable surface marked “Oil Resistant I” or “Oil Res I” is suitable for exposure to mineral oil at 60°C. Cable suitable for exposure to mineral oil at 75°C is surface marked “Oil Resistant II” or “Oil Res II.”

Cable that complies with the Limited Smoke Test requirements specified in UL 1685, “Vertical-Tray Fire-Propagation and Smoke-Release Test for Electrical and Optical-Fiber Cables,” is surface marked with the suffix “-LS.”

Cable containing optical fiber members is identified with the suffix “-OF.”

Regarding cable seals outlined in Art. 501 of the **NEC**, Type TC cable has a sheath that is considered to be gas/vapor tight but the cable has not been investigated for transmission of gases or vapors through its core.

RELATED PRODUCTS

Connectors and fittings for use with this cable are covered under Power and Control Tray Cable Connectors (QPOZ).

Some connectors and fittings covered under Outlet Bushings and Fittings (QCRV), Nonmetallic-sheathed Cable Connectors (PXJV), and Service Entrance Cable Fittings (TYZX) are also suitable for use with this cable when specifically marked on the device or carton.

ADDITIONAL INFORMATION

For additional information, see Electrical Equipment for Use in Ordinary Locations (AALZ).

REQUIREMENTS

The basic standard used to investigate products in this category is ANSI/UL 1277, “Electrical Power and Control Tray Cables with Optional Optical-Fiber Members.”

UL MARK

The Certification Mark of UL on the attached tag, reel, or on the smallest unit package in which the product is packaged is the only method provided by UL to identify products manufactured under its Certification and Follow-Up Service. The Certification Mark for these products includes the UL symbol, the words “CERTIFIED” and “SAFETY,” the geographic identifiers, and s file number.

ALTERNATE UL MARK

The Listing Mark of Underwriters Laboratories Inc. on the product is the only method provided by UL to identify products manufactured under its Listing and Follow-Up Service. The Listing Mark for these products includes the UL symbol (as illustrated in the Introduction of this Directory) together with the word “LISTED,” a control number, and the product name as appropriate: Power and control tray cable that contains copper or copper-clad aluminum conductors has the product name “Power and Control Tray Cable Type TC”; power and control tray cable that contains aluminum conductors has the product name “Aluminum Power and Control Tray Cable Type TC.”

Note that this cable appears to be for cable tray only, but Type TC is recognized by 336.2 for use in raceway or with messenger support, in addition to use in tray.

Although item (4) of 336.12 has the effect of prohibiting the use of Type TC tray cable directly buried in the earth, the rule is modified by the phrase “unless identified for such use.” The result of this wording is to permit Type TC cable to be directly buried in the earth where the cable is marked or otherwise generally recognizable as suitable for this use. The product listing information (above)

directly recognizes this possibility. This permission for direct burial was added because the cable assembly was designed to withstand such application and because Type TC cable has been successfully and effectively used directly for years in many installations (Fig. 336-2 with burial conforming to 300.5). Such cable is listed for direct earth burial by UL, and the performance record has been excellent.

Fig. 336-2. Type TC (power and control tray cable) is recognized for direct earth burial. (Sec. 336.12.)

ARTICLE 338. SERVICE-ENTRANCE CABLE: TYPES SE AND USE

338.2. Definition. The Code contains few specifications for the construction of this cable; it is required to be listed (338.6) and beyond a few general specifications in Part III of the article, it is left to Underwriters Laboratories Inc. to determine what types of cable should be approved for this purpose. The types listed by the Laboratories conform to the following data:

This category covers service-entrance cable (TYLZ) designated Type SE and Type USE for use in accordance with Art. 338 of ANSI/NFPA 70, “**National Electrical Code**” (NEC).

Service-entrance cable, rated 600 V, is Listed in sizes 14 AWG and larger for copper, and 12 AWG and larger for aluminum or copper-clad aluminum.

The cable is designated as follows:

Type SE—Indicates cable for aboveground installation. Both the individual insulated conductors and the outer jacket or finish of Type SE are suitable for use where exposed to sun. Type SE cable contains Type RHW, RHW-2, XHHW, XHHW-2, THWN, or THWN-2 conductors. Maximum size is 4/0 AWG copper or 300 kcmil aluminum or copper-clad aluminum.

Types USE and USE-2—Indicates cable for underground installation including direct burial in the earth. Maximum size is 2000 kcmil. Cable in sizes 4/0 AWG copper, aluminum, or copper-clad aluminum, and smaller and having all conductors insulated is suitable for all of the underground uses for which Type UF cable is permitted by the NEC. Multiconductor Type USE cable contains conductors with insulation equivalent to RHW or XHHW. Multiconductor Type USE-2 contains insulation equivalent to RHW-2 or XHHW-2 and is rated 90°C wet or dry. Single- and multiconductor Types USE and USE-2 are not suitable for use in premises. Single- and multiconductor Types USE and USE-2 are not suitable aboveground except to terminate at the service equipment or metering equipment. Both the insulation and the outer covering, when used, on single- and multiconductor Types USE and USE-2, are suitable for use where exposed

to sun.

Submersible Water Pump Cable—Indicates a multiconductor cable in which 2, 3, or 4 single-conductor Types USE or USE-2 cables are provided in a flat or twisted assembly. The cable is certified in sizes 14 AWG to 4/0 AWG inclusive, copper, and 12 AWG to 4/0 AWG inclusive, aluminum or copper-clad aluminum. The cable is tag marked “For use within the well casing for wiring deep-well water pumps where the cable is not subject to repetitive handling caused by frequent servicing of the pump units.” The insulation may also be surface marked “Pump Cable.” The cable may be directly buried in the earth in conjunction with this use.

For termination information, see *Electrical Equipment for Use in Ordinary Locations (AALZ)*.

Based upon tests which have been made involving the maximum heating that can be produced, an uninsulated conductor employed in a service cable assembly is considered to have the same current-carrying capacity as the insulated conductors even though it may be smaller in size.

Figure 338-1 shows two basic styles of service-entrance cable for aboveground use. The one without an armor over the conductors is referred to as Type SE Style U—the letter U standing for “unarmored.” That cable is sometimes designated as Type SEU. The cable assembly with the armor is designated Type ASE cable, with the A standing for “armored.”

SERVICE ENTRANCE cables may consist of either copper or aluminum phase conductors (A) covered by heat resistant insulation (B) and moisture-resistant braid or tape (C) color coded for circuit identification, while basic assembly is enclosed by concentric neutral (D). Unarmored Type SE Style U is covered by variety of tapes (F) and outer braid (G) such as glass and cotton impregnated with moisture resistant and flame retardant finish labelled with pertinent data. Armored Style A additionally contains flat steel armor (E) as protection against physical abuse.

Fig. 338-1. Two types of aboveground SE cable. (Sec. 338.2.)

Figure 338-2 shows another type of SE cable, known as Style SER—the letter R standing for “round.” In a typical assembly of that cable, three conductors insulated with Type XHHW cross-link polyethylene are cabled together with fillers and one bare ground conductor with a tape over them and gray PVC overall jacket. For use aboveground in buildings, it is suitable for operation at 90°C in dry locations or 75°C in wet locations unless the insulation designation has the suffix “-2” in which case it is suitable for 90°C for both locations.

Fig. 338-2. Style SER cable contains individual conductors and no concentric neutral. (Sec. 338.2.)

For 3-phase, 4-wire grounded services, the three insulated conductors—a black, a red, and a blue—are used as the phase legs of the service, and the bare conductor is used as the neutral. For other applications that cable configuration can be used as a feeder or branch circuit to a power load with a bare equipment grounding conductor, and this form of cable is also available with black, red, and white insulated conductors for single-phase applications, including the supply of downstream panels, and black, red, blue, and white 5-wire configurations for 3-phase equivalent loads.

Figure 338-3 shows multiconductor Type USE cable for underground (including direct earth burial) applications of service or other circuits. Type USE may consist of one, two, or three conductors. If it has no building wire designation, its insulation will burn, and it is absolutely excluded from any interior wiring whatsoever by 338.12(B)(1). Where used aboveground it must terminate where it emerges from the ground, such as at a meter socket, as covered in 338.12(B)(2). It is recognized for use as aerial cable, provided it is in the multiconductor form, identified as suitable for aboveground use, and run on a messenger. Some cables have both a “USE” designation and also a building wire designation, such as “RHW.” This cable can continue into a building. The basic temperature rating for this cable is 75°C and that limit applies unless a different number is marked on the cable.

Fig. 338-3. Type USE cable may be multiconductor or single-conductor cable. (Sec. 338.2.)

Depending on whether USE cable is used for service entrance, for a feeder, or for a branch circuit, burial depth must conform to 300.5 and its many specific rules on direct burial cable.

338.10. Uses Permitted. As would be expected, where used as service conductors, Type SE must comply with Art. 230, “Services.”

Part (B) recognizes use of service-entrance cable for branch circuits and feeders within buildings or structures, provided that all circuit conductors, including the neutral of the circuit, are insulated. Such use must conform to Art. 334 on installation methods—the same as those for Type NM cable.

Part (B)(2) covers, in the exception, the permitted uses of service-entrance cable that contains a bare conductor for the neutral, of which there are only two. This exception permits the use of SE cable for circuits supplying existing ranges, wall-mounted ovens, and counter-mounted cooking units (Fig. 338.4). And in such cases, the bare conductor may be used as the neutral of an existing branch circuit as well as the equipment grounding conductor (see 250.140).

Fig. 338-4. Although previously permitted, SE cable with bare neutral may be used for branch circuits to a range or other cooking units, but *only* on “existing installations.” (Sec. 338.10.)

SE cable is also permitted to be used as a feeder from one building to another building, with the bare conductor used as a grounded neutral, but now only for an existing premises wiring system in accordance with 250.32(B)(1) Exception No. 1. Or an SE cable with a bare neutral may be used as a feeder within a building, if the bare neutral is used *only* as the equipment grounding conductor and one of the insulated conductors within the cable is used as the neutral of the feeder. (See Fig. 338-5.)

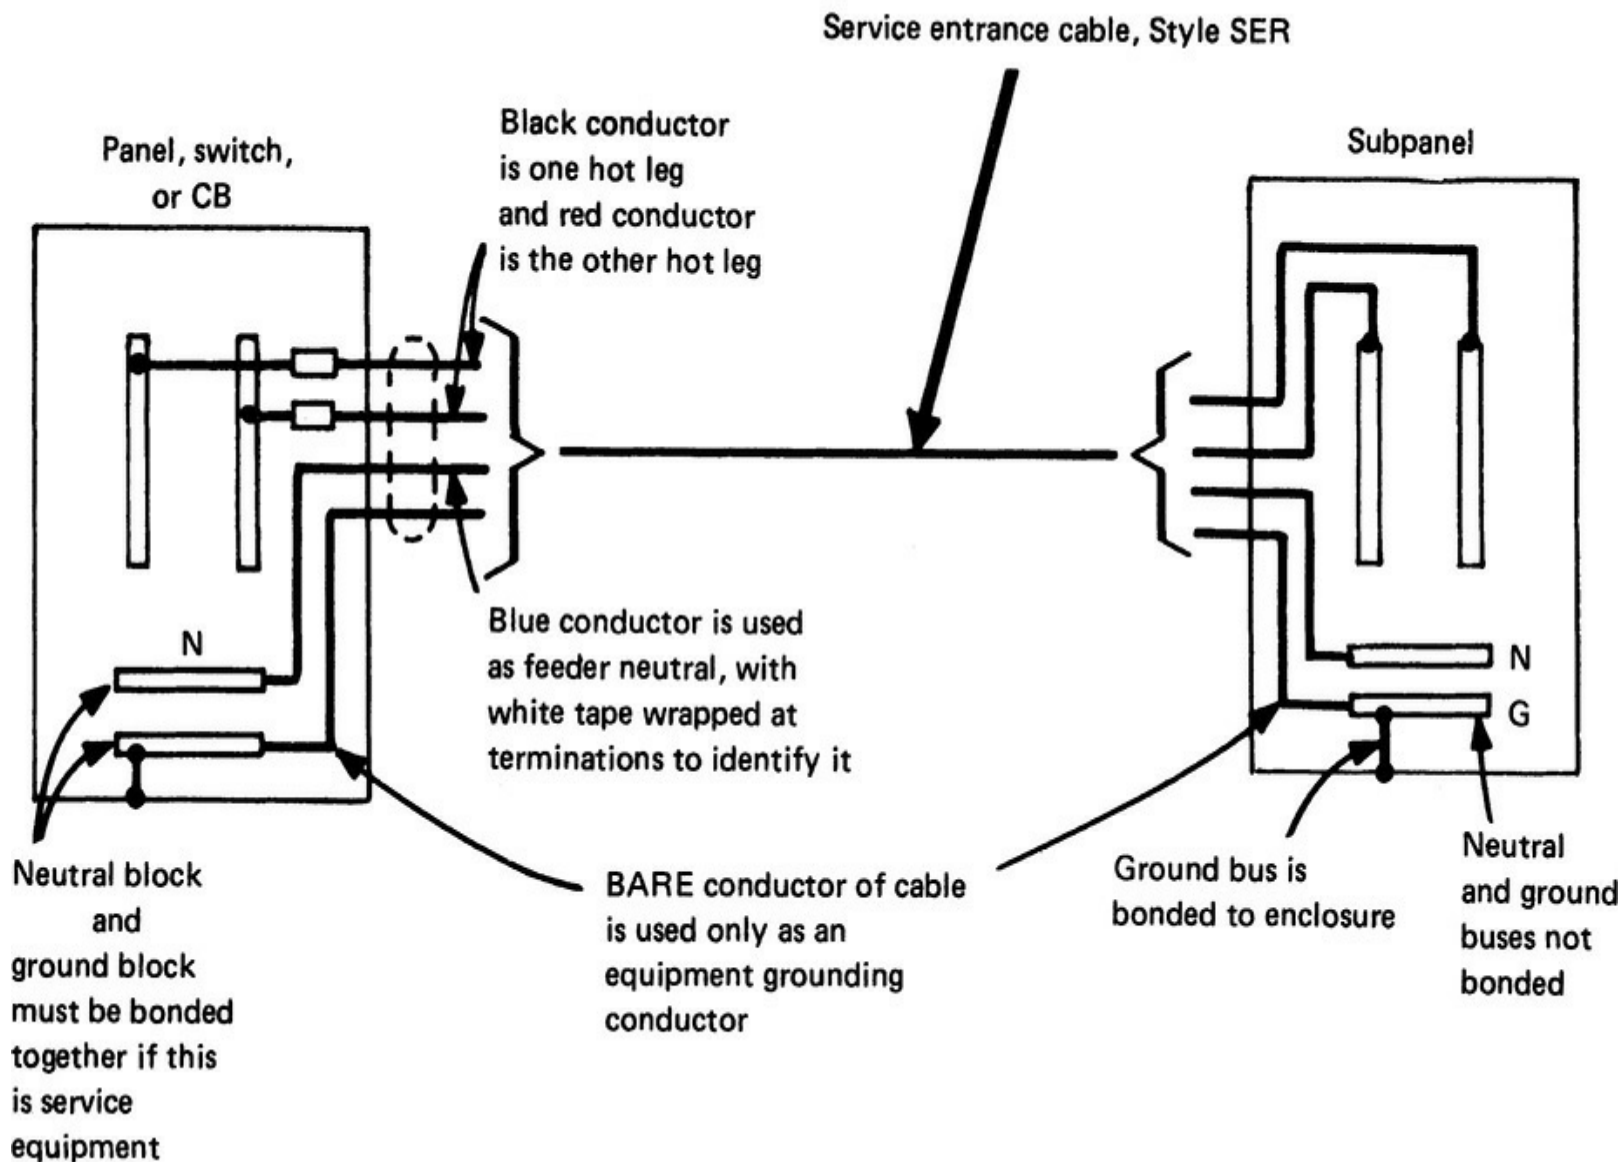

Fig. 338-5. Typical application of SE cable with a bare neutral for use as a feeder within a building. (Sec. 338.10.)

Part **(B)(3)** requires that SE cable used to supply appliances not be subject to conductor temperatures in excess of the temperature specified for the insulation involved. The insulated conductors of SE cables are 75° or 90°C, and if they are rated at 90°C, such marking will appear on the outer sheath. A cooking unit or oven that requires 90°C supply conductors would be an application for the use of SE cables, rated at 90°C. However, a review of UL listings for cooking units and ovens indicates that most such units do not require supply conductor ratings to exceed 60°C. The details in [Fig. 338-4](#) show a method of connecting cooking units where the supply conductors are required to be 75° or 90°C.

In part **(B)(4)(a)**, “Interior Installation,” Type SE cable is permitted for use as interior branch circuits or feeders, but where so used, the installation must satisfy all of the general wiring rules of Art. 300. This section requires the installation of unarmored SE cable (which is the usual type of SE cable) to satisfy Art. 334 on nonmetallic-sheathed cable (Type NM). All the rules of Art. 334 that cover *how* cable is installed must be satisfied. This notably includes the building construction limitations in 334.10, and remember the discussion at that point in this book; these are limits based on what the building code requires the minimum characteristics of the buildings to be, and not

necessarily on how the building is actually constructed. As a result, the use of SE cable as a feeder, as shown in [Fig. 338-5](#), would be a violation in any building required to be constructed of Type I or II construction. There is, however, one notable point of separation from the two articles, namely, the incorporation of the ampacity provisions in 334.80 into this article by reference has been discontinued.

The wording that replaces it restores the effective permission for this cable to be applied at the rating of its internal conductor temperature ratings (either 75°C or 90°C depending on the specific construction). This means that, for example, 4/0 AWG Type SER cable used as a feeder indoors is once again a 180 A conductor (after applying termination limitations). Since very few feeders run in the window between 180 and 200 A, this cable goes back to being the customary feeder it had been for decades, protected at the next higher standard size, or 200 A. And in instances where it carried the entire load of a dwelling occupancy, 310.15(B)(7), makes it a 200 A feeder outright.

This allowance is tempered by a crucial limitation, however, one that is squarely based on actual experimental results. Review the discussion in this book regarding 310.15(A)(3) and the performance of Type SE cable embedded in thermal insulation. To partially respond to that experience, under the 2014 **NEC**, if this cable were embedded in thermal insulation, its final ampacity would have been that of a 60°C conductor. In the case of 4/0 AWG cables embedded in insulation, under these conditions this was a 150 A cable, and no higher. However, the 2017 **NEC** has gutted that limitation, now confining it to 10 AWG and smaller, sizes almost never used.

In fact, even the previous wording actually somewhat understated the true problem for cables run in thermal insulation. By allowing derating to occur from the 90°C column for such cables, the **NEC** allows users to ignore factors that increase the retention of heat in the cable until they reach the point of reducing the ampacity below the 60°C value, which in most cases is to allow them to be ignored altogether. Meanwhile, particularly for large, heavily loaded cables, even the 60°C numbers are too high. Again, review the discussion associated with 310.15(A)(3) for detailed information on this topic. For example, 1/0 AWG aluminum SE cable has a 75° limit for terminations, which is 120 A in Table 310.15(B)(16). Since very few feeders run in the window between 120 and 125 A for actual calculated load, this cable has been sold by the mile for 125 A services and, in SER configurations, as feeder cable to apartments and commercial 3-phase, 4-wire feeder cable to stores and in restaurants, etc. If run embedded in thermal insulation, this cable is now 100 A cable, period. However, the true ampacity of this cable where actually embedded in thermal insulation is probably less than 70 A, and only a diligent application of 310.15(A)(3) stands in the way.

The ampacity issues regarding Type SE cables generally do not apply to underground applications, and the blanket application of ampacity limitations on Type UF cables in 340.80 need not be applied to Type USE cables. An exception, new as of the 2014 **NEC**, limits the reach of the final sentence in 338.10(B)(4)(b) by waiving those limitations. Note that the wording includes the term “multi-rated USE conductors.” This term is undefined, but based on the documentation connected to the change, and the reference is intended to describe Type USE cable that also has a building wire rating, such as USE-2/RHW-2 or the like.

ARTICLE 340. UNDERGROUND FEEDER AND BRANCH-CIRCUIT CABLE: TYPE UF

340.2. Definition. [Figure 340-1](#) shows a violation of the Code rule that a bare conductor in a

UF cable is for grounding purposes only. Type UF cable must be listed.

Fig. 340-1. Bare conductor in UF cable may not be used as a neutral. (Sec. 340.2.)

340.10. Uses Permitted. As called for in part (1), [Figs. 340-2](#) and [340-3](#) show details on compliance of UF cable with 300.5. Where UF comes up out of the ground, it must be protected for 8 ft up on a pole and as described in 300.5(D).

VIOLATION for cable to run under any building if not totally in raceway [300.5]

ACCEPTABLE for burial at only 12-in. depth when used for residential branch-circuit rated not more than 20 A at 120 V or less where GFCI protection is also provided [Table 300.5]

Fig. 340-2. UF cable must conform to Sec. 300.5 on direct burial cables. This includes the

requirement in 300.5(C), illustrated here, of sleeving the cable in a raceway where it runs under a building. (Sec. 340.10.)

Fig. 340-3. The second qualifier under “Location of Wiring Method or Circuit” in Table 300.5 permits a 6-in. reduction of UF burial depth. The concrete must be above the cable, without embedding it. (Sec. 340.10.)

The rules of part (1) are shown in [Fig. 340-4](#) and must be correlated to the rules of 300.5 on direct burial cables. The rule of (2) corresponds to that 300.5(I). If multiple conductors are used per phase and neutral to make up a high-current circuit, this rule requires all conductors to be run in the same trench or raceway and therefore subject to the derating factors of 310.15(B)(3). Refer to the paragraph covering 310.15(B)(3). Also see discussion under 300.5(I).

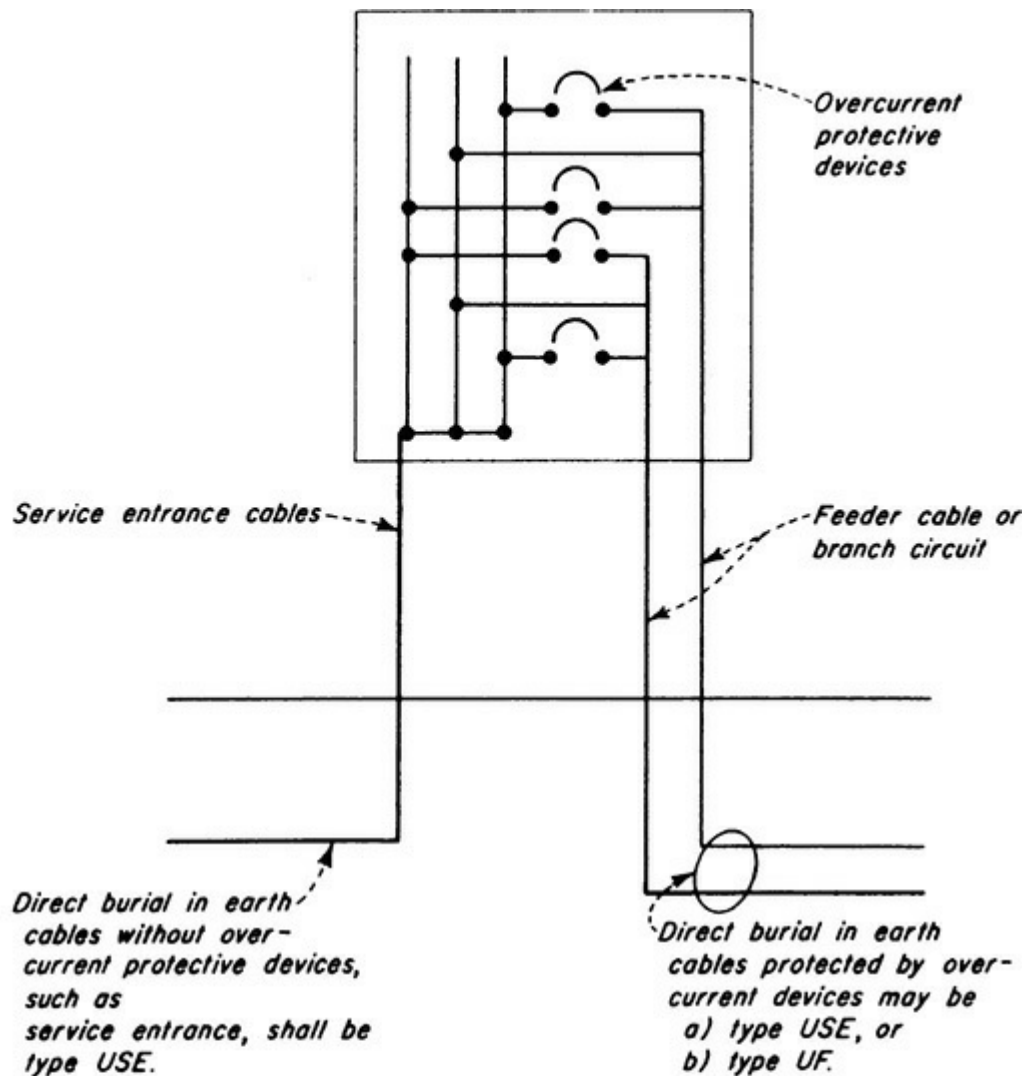

Fig. 340-4. UF cable may be used only as feeders or branch circuits. (Sec. 336.10.)

UF cable may be used underground, including direct burial in the earth, as feeder or branch-circuit cable when provided with overcurrent protection not in excess of the rated ampacity of the individual conductors. If single-conductor cables are installed, all cables of the feeder circuit, subfeeder, or

branch circuit, including the neutral cable, must be run together in close proximity in the same trench or raceway. It may be necessary in some installations to provide additional mechanical protection, such as a covering board, concrete pad, raceway, or the like, when required by the authority enforcing the Code. Multiple-conductor Type UF cable (but not single-conductor Type UF cables) may also be used for interior wiring when used in the same way as Type NM cable, complying with the provisions of Art. 334 of the Code. And UF may be used in wet locations.

The effect of the wording in part (4) where UF cable is used for interior wiring, is to require that its conductors must be rated at 90°C, with loading based on 60°C ampacity. This rule is a follow-up to the requirement that UF for interior wiring must satisfy the rules of Art. 334 on nonmetallic-sheathed cable (see 334.80). It is also subject to the construction type limitations in 334.10.

As noted in **340.12(8)**, single-conductor Type UF cable embedded in poured cement, concrete, or aggregate may be used for nonheating leads of fixed electric space heating cables, as covered in 424.43.

Application data (Category YDUX) of the UL are as follows:

This category covers underground feeder and branch circuit cable, rated 600 V, in sizes 14 to 4/0 AWG inclusive, copper, and 12 to 4/0 AWG inclusive, aluminum or copper-clad aluminum, for single and multiple conductor cables. It is designated as Type UF cable and is intended for use in accordance with Art. 340 of ANSI/NFPA 70, “**National Electrical Code**” (NEC).

Some multiconductor cable is surface marked with the suffix “B” immediately following the type letters to indicate the usage of conductors employing 90°C rated insulation.

Such cable may also be installed as nonmetallic-sheathed cable, per Section 340.10(4) of the NEC. The ampacities of Type UF cable, with or without the suffix “B,” are those of 60°C rated conductors as specified in the latest edition of the NEC.

Submersible Water Pump Cable—Indicates multiconductor cable in which 2, 3, or 4 single-conductor Type UF cables are provided in a flat or twisted assembly. The cable is listed in sizes from 14 AWG to 4/0 AWG inclusive, copper, and from 12 AWG to 4/0 AWG inclusive, aluminum or copper-clad aluminum. The cable is tag marked “For use within the well casing for wiring deep well water pumps where the cable is not subject to repetitive handling caused by frequent servicing of the pump units.” The insulation may also be surface marked “Pump Cable.” The cable may be directly buried in the earth in conjunction with this use.

This cable may employ copper, aluminum, or copper-clad aluminum conductors. Cable with copper-clad aluminum conductors is surface printed “AL (CU-CLAD)” or “Cu-Clad Al.” Cable with aluminum conductors is surface printed “AL.”

Cable employing compact-stranded copper conductors is so identified directly following the conductor size wherever it appears (surface, tag, carton, or reel) by “compact copper.” The abbreviations “CMPCT” and “CU” may be used for compact and copper, respectively.

Tags, reels, and cartons for products employing compact-stranded copper conductors have the marking: “Terminate with connectors identified for use with compact-stranded copper conductors.” For conductor termination information, see Electrical Equipment for Use in Ordinary Locations (AALZ).

This cable may be terminated at boxes and other enclosures by using nonmetallic-sheathed cable connectors (see Nonmetallic-Sheathed Cable Connectors [PXJV]).

Cable suitable for exposure to direct rays of the sun is indicated by tag marking and marking on

the surface of the cable with the designation “Sunlight Resistant.”

Only multiconductor Type UF cable may be used in cable tray, in accordance with 340.10(7).

ARTICLE 342. INTERMEDIATE METAL CONDUIT: TYPE IMC

This article covers a conduit with wall thickness less than that of rigid metal conduit but greater than that of EMT. Called “IMC,” this intermediate metal conduit uses the same threading method and standard fittings for rigid metal conduit and has the same general application rules as rigid metal conduit. Intermediate metal conduit actually is a lightweight rigid steel conduit which requires about 25 percent less steel than heavy-wall rigid conduit. Acceptance into the Code was based on a UL fact-finding report which showed through research and comparative tests that IMC performs as well as rigid steel conduit in many cases and surpasses rigid aluminum and EMT in most cases. The wiring method must be listed (Sec. 342.6).

IMC may be used in any application for which rigid metal conduit is recognized by the **NEC**, including use in all classes and divisions of hazardous locations as covered in 501.4, 502.4, and 503.3. Its thinner wall makes it lighter and less expensive than standard rigid metal conduit, but it has physical properties from differences in the alloy that give it outstanding strength. The lighter weight facilitates handling and installation at lower labor units than rigid metal conduit. Because it has the same outside diameter as rigid metal conduit of the same trade size, it has greater interior cross-sectional area (Fig. 342.1). In the past this extra space was not recognized by the **NEC** to permit the use of more conductors than can be used in the same size of rigid metal conduit. However, with the elimination of Tables 2, 3A, 3B, and 3C, as well as the revisions of Tables 4 and 5 to more correctly reflect the interior area of raceways and the dimensions of conductors, the Code does permit greater fill in IMC (see Tables C4 and C4A in Annex C).

3/4" TRADE SIZES

Fig. 342-1. Typical comparison between rigid conduit and IMC shows interior space difference. This is now recognized by Tables C4 and C4A in Annex C. (Sec. 342.1.)

342.10. Uses Permitted. The data of the UL supplement (Category DYBY) the requirements of part (A) on use of IMC, as follows:

Listing of Intermediate Ferrous Metal Conduit includes standard 10 ft lengths of straight conduit, with a coupling, special length either shorter or longer, with or without a coupling for specific applications or uses, elbows, bends, and nipples in trade sizes ½ to 4 in. incl. for installation in accordance with Art. 342 of the **National Electrical Code**.

Galvanized intermediate steel conduit installed in concrete does not require supplementary corrosion protection.

Galvanized intermediate steel conduit installed in contact with soil does not generally require supplementary corrosion protection.

In the absence of specific local experience, soils producing severe corrosive effects are generally characterized by low resistivity less than 2000 ohm-centimeters.

Wherever ferrous metal conduit runs directly from concrete encasement to soil burial, severe corrosive effects are likely to occur on the metal in contact with the soil.

Fittings for use with unthreaded intermediate ferrous metal conduit are listed under conduit fittings (Guide DWTT) and are suitable only for the type of conduit indicated by the marking on the carton.

Although literature on IMC at one time referred to Type I and Type II IMC because of slight differences in dimensions due to manufacturing methods, the **NEC** considers IMC to be a single type of product and the rules of Art. 342 apply to all IMC. Sec. 342.10, in (A), generally allows IMC above ground in all occupancies and conditions.

Note that the wording in the UL data includes the word “generally” in stating that IMC does not need additional protective material applied to the conduit when used in soil. That is intended to indicate that local soil conditions (acid versus alkaline) may require protection of the conduit against corrosion. And the UL note about corrosion of conduit running from concrete to soil must be observed. Refer to comments under 344.2 covering these conditions.

In part (B), wording of the rule intends to make clear that the galvanizing or zinc coating on the IMC does give it the measure of protection required when used in concrete or when directly buried in the earth. The last phrase, “judged suitable for the condition,” refers to the need to comply with UL regulations as included in the Guide Card information applicable to each specific raceway, advising how and when steel raceways and other metal raceways may be used in concrete or directly buried in earth.

The UL data point out that there are soils where some difficulties may be encountered, and there are other soil conditions that present no problem to the use of steel or other metal raceways. The phrase “judged suitable for the condition” implies that a correlation was made between the soil conditions or the concrete conditions at the place of installation and the particular raceway to be used. This means that it is up to the designers and/or installers to satisfy themselves as to the suitability of any raceway for use in concrete or for use in particular soil conditions at a given geographic location. Of course, all such determinations would have to be cleared with the electrical inspection authority to be consistent with the meaning of Code enforcement.

For use of IMC in or under cinder fill, part (C) gives the limiting conditions. See 344.10.

342.14. Dissimilar Metals. This section has been significantly revised based on recent testing

by NEMA as part of the 2017 **NEC** revision cycle. Interconnections between galvanized IMC and aluminum fittings, conduit elbows, etc. are still mostly permitted but not if the conditions are deemed extremely corrosive. Perhaps surprisingly, stainless steel IMC has been ruled out for contact with aluminum as well as other types of steel, and strictly limited to other stainless steel fittings, boxes, and other accessories. Similar language is now in place in other related raceway articles. The actual NEMA supporting argument for this change is reprinted in this handbook at 344.14.

342.20. Size. This is the only difference between this product and the ferrous versions of rigid metal conduit; RMC is available up to metric designator 155 (6 trade size) and IMC is only available up to metric designator 103 (trade size 4).

342.22. Number of Conductors in Conduit. The rules on conduit fill are the same for IMC, rigid metal conduit, EMT, flexible metal conduit, flexible metallic tubing, and liquidtight flexible metallic tubing—for conduits ½ in. size and larger although different tables are used. Refer to 344.20.

342.30. Securing and Supporting. The basic rule on clamping IMC is simple and straightforward (Fig. 342.3). Spacing may be increased to a maximum of 5 ft (1.5 m) where necessary because no structural member is available. But the distance must not be extended, except as permitted by the subsections. The subsections allowing wider spacing of supports are the same as those covered in 344.30 for rigid metal conduit.

Fig. 342-2. NEC warning against use of dissimilar metals does not apply to this. (Sec. 342.14.)

Fig. 342-3. All runs of IMC must be clamped in this way. (Sec. 342.30.)

Spacing between supports for IMC (greater than every 10 ft [3.0 m]) is the same as the spacing allowed for rigid metal conduit. The subparts recognize the essential equality between the strengths of IMC and rigid metal conduit.

The special support limitations for conduit nipples imposed in the 2008 **NEC** have been revoked and the text returned to that of the 2005 edition. Any nipple not over the general limit on the first point of support in length, namely 900 mm (3 ft), is considered supported by its terminating hardware and no additional support is generally required.

For the rest of the run, as before, the conduit must be “supported” (as distinguished from “secured”) at not over 3 m (10 ft) intervals, with greater support distances allowed if threaded couplings are used and the geometry of the run is such that the weight of the conduit is not imposed on a terminating enclosure. A second provision makes a very practical allowance for conduit drops from a high-bay ceiling. The support interval, if necessary due to a lack of intervening supports, can be extended to 6 m (20 ft) if threaded couplings are used and the top and bottom of the conduit run are securely fastened. This is often arranged with a tee conduit body at the equipment level, with the vertical run continuing using an empty conduit nipple ending at a threaded floor flange. The side branch of the tee is usually extended to the equipment termination with a flexible wiring method. Note, however, that an additional support must be arranged on the riser above the tee in order to comply with the provisions of both this section and also 314.23(E) with respect to the conduit body.

A somewhat related change is to recognize approved IMC mast risers with no support within 900 mm (3 ft) of the service head, for obvious reasons.

ARTICLE 344. RIGID METAL CONDUIT: TYPE RMC

344.10. Uses Permitted. UL data on rigid metal conduit are similar to those on IMC and supplement the rules of this section, as follows:

Galvanized rigid steel conduit installed in concrete does not require supplementary corrosion protection.

Galvanized rigid steel conduit installed in contact with soil does not generally require supplementary corrosion protection.

In the absence of specific local experience, soils producing severe corrosive effects are generally characterized by low resistivity (less than 2000 ohm-centimeters).

Wherever ferrous metal conduit runs directly from concrete encasement to soil burial, severe corrosive effects are likely to occur on the metal in contact with the soil.

Conduit that is provided with a metallic or nonmetallic coating, or a combination of both, has been investigated for resistance to atmospheric corrosion. Nonmetallic outer coatings that are part of the required resistance to corrosion have been additionally investigated for resistance to the effects of sunlight.

Nonmetallic outer coatings of greater than 0.010-in. thickness are investigated with respect to flame propagation detrimental effects to any underlying corrosion protection, the fit of fittings, and electrical continuity of the connection of conduit to fittings.

Conduit with nonmetallic coatings has not been investigated for use in ducts, plenums, or other environmental air spaces in accordance with the **NEC**.

Rigid metal conduit with or without a nonmetallic coating has not been investigated for severely corrosive conditions.

For nonferrous rigid metal conduits, the UL application notes state:

Aluminum conduit used in concrete, in contact with soil, or in severely corrosive conditions, requires supplementary corrosion protection.

The Listing Mark for these products includes the UL symbol together with the word “LISTED,” a control number, and the product name “Electrical Rigid Metal Conduit-Aluminum” (or “ERMC-A”), Electrical Rigid Metal Conduit-Red Brass” (or “ERMC-RB”), or “Electrical Rigid Metal Conduit-Stainless Steel” (“ERMC-SS”).

For direct earth burial of rigid conduit and IMC, the UL notes must be carefully studied and observed:

1. Galvanized rigid steel conduit and galvanized intermediate steel conduit directly buried in soil do not *generally* require supplementary corrosion protection. The use of the word “generally” in the UL instructions indicated that it is still the responsibility of the designer and/or installer to use supplementary protection where certain soils are known to produce corrosion of such conduits. Where corrosion of underground galvanized conduit is known to be a problem, a protective jacketing or a field-applied coating of asphalt paint or equivalent material must be used on the conduit. *But*, UL notes must be observed for resistance to corrosion under “severely corrosive conditions” because when steel conduits pass from concrete to direct earth burial, the juncture is classified as “severely corrosive” and nonmetallic coatings have not been investigated for these conditions. An agreement will need to be worked out with the inspector if severely corrosive effects are anticipated in any location. In the case of underground/concrete interfaces, supplementary protective coating on conduit at the crossing line can eliminate the conditions shown in [Fig. 344-1](#).

Fig. 344-1. Protective coating on section of conduit can prevent this corrosion problem. (Sec. 342.2.)

2. Aluminum conduit used directly buried in soil requires supplementary corrosion protection. Exactly what that could be in this case will require some research and the approval of the inspector. At one time UL declared that such coatings “presently used” have not been recognized for resistance to corrosion, but that statement no longer appears in the Guide Card information for this category.
3. Red brass conduit is permitted by right for underground and swimming pool applications. Note that all rigid metal conduit is required to be listed per 344.6. This may be a difficult issue on this product. An admittedly nonscientific survey of all current listees in the nonferrous rigid metal conduit category found a number of producers of aluminum conduit, a few producers of stainless steel conduit, and no producers of red brass conduit. For swimming pool applications run to a forming shell this has been a known issue for some time, which is why 680.23(B)(2)(a) specifically allows brass conduit to be approved and not listed, thereby constituting a deliberate [Chap. 6](#) amendment of the [Chap. 3](#) rule in 344.6. Some plumbing supply houses carry heavy wall red brass pipe, often in 12-ft lengths, that takes a conventional pipe thread extremely well, and is a very robust product with an extremely smooth interior that, if anything, is somewhat more difficult to bend than IMC or RMC. Lack of heavy foot pressure with excessive force on the handle won’t kink the product, but will bend the bender handle. Approval is at the discretion of the local inspector, but this product should certainly be considered unless a listed alternative becomes more available.

As indicated by the rule of part (C), care must be taken where cinder fill is used. Cinders usually contain sulfur, and if there is much moisture, sulfuric acid is formed, which attacks steel conduit. A cinder fill outdoors should be considered as “subject to permanent moisture.” In such a place conduit runs should be provided corrosion protection as described, encased in 2 in. (50 mm) of concrete, or buried in the ground at least 18 in. (450 mm) below the fill. This would not apply if cinders were not

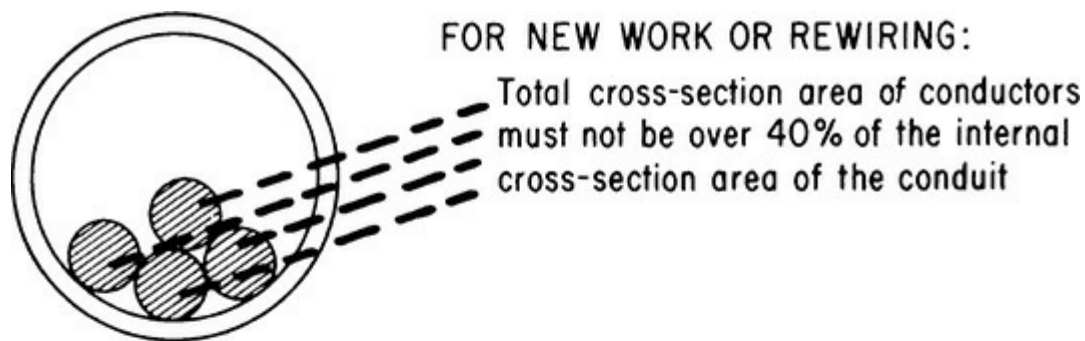

present.

344.14. Dissimilar Metals. This section has been significantly revised based on recent testing by NEMA as part of the 2017 **NEC** revision cycle. Interconnections between galvanized heavy wall conduit and aluminum fittings, conduit elbows, etc. are still mostly permitted but not if the conditions are deemed extremely corrosive. Perhaps surprisingly, stainless steel IMC has been ruled out for contact with aluminum as well as other types of steel, and strictly limited to other stainless steel fittings, boxes, and other accessories. Similar language is now in place in other related raceway articles.

The NEMA commentary on this topic is both surprising and informative: “Stainless steel is considerably more noble (or cathodic) than aluminum and is also considerably more noble than steel and zinc (galvanized steel) and would be subject to more aggressive galvanic attack in the presence of an electrolyte. Stainless steel conduit used with aluminum or galvanized fittings, accessories, outlet boxes and enclosures may result in a galvanic action, leading to corrosion.”

344.22. Number of Conductors. The basic **NEC** rule on the maximum number of conductors that may be pulled into rigid metal conduit, rigid nonmetallic conduit, intermediate metal conduit, electrical metallic tubing, flexible metal conduit, and liquidtight flexible metal conduit is contained in the single sentence of this section.

The number of conductors permitted in a particular size of conduit or tubing is covered in [Chap. 9](#) of the Code, and in Tables C1 through C12A in Annex C for conductors all of the same size used for either new work or rewiring. Tables 4 and 5 of [Chap. 9](#) cover combinations of conductors of different sizes when used for new work or rewiring. For nonlead-covered conductors, three or more to a conduit, the sum of the cross-sectional areas of the individual conductors must not exceed 40 percent of the interior cross-sectional area (csa) of the conduit or tubing for new work or for rewiring existing conduit or tubing ([Fig. 344.2](#)). Note 4 preceding all the tables in [Chap. 9](#), in the back of the Code book, permits a 60 percent fill of conduit nipples not over 24 in. (600 mm) long and no derating of ampacities is needed.

Example:
From Table C8, with the 90C conductors used at the ampacity of 75 C 500 kcmil conductors, unless equipment is marked to permit connection of 90C conductors

4 No. 500 kcmil THHN or XHHW in 3-in. rigid metal conduit

Fig. 344-2. For three or more conductors the sum of their areas must not exceed 40 percent of the conduit area. (Sec. 344.20.)

When all conductors in a rigid metal conduit are the same size, Tables C8 and C8A in App. C give the maximum allowable fill for conductors depending on conductor type up to 2000 kcmil, for metric designator 16 to 155 (trade size $\frac{1}{2}$ to 6) rigid metal conduit.

question What is the minimum size of rigid metal conduit required for six 10 THHN AWG wires?

answer Table C.8, Annex C, shows that six 10 THHN AWG wires may be pulled into a metric designator 16 (trade size $\frac{1}{2}$) rigid metal conduit.

question What size conduit is the minimum for use with four 6 RHH AWG conductors with outer covering?

answer Table C.8, Annex C, shows that a metric designator 35 (trade size $1\frac{1}{4}$) minimum conduit size must be used for from four to six RHH AWG conductors with outer covering. If they lacked the outer covering, the answer would be a metric designator 27 (trade size 1) conduit.

question What is the minimum size conduit required for four 500-kcmil XHHW conductors?

answer Table C.8 shows that metric designator 78 (trade size 3) conduit may contain four 500-kcmil XHHW (or THHN) conductors.

When all the conductors in a conduit or tubing are not the same size, the minimum required size of conduit or tubing must be calculated. Table 1, [Chap. 9](#), says that conduit containing three or more conductors of any type except lead-covered, for new work or rewiring, may be filled to 40 percent of the conduit csa. Note 6 to this table refers to Tables 4 through 8, [Chap. 9](#), for dimensions of conductors, conduit, and tubing to be used in calculating conduit fill for combinations of conductors of different sizes.

example What size rigid metal conduit is the minimum required for enclosing six 10 AWG THHN, three 4 AWG RHH (with outer covering), and two 12 AWG TW conductors ([Fig. 344.3](#))?

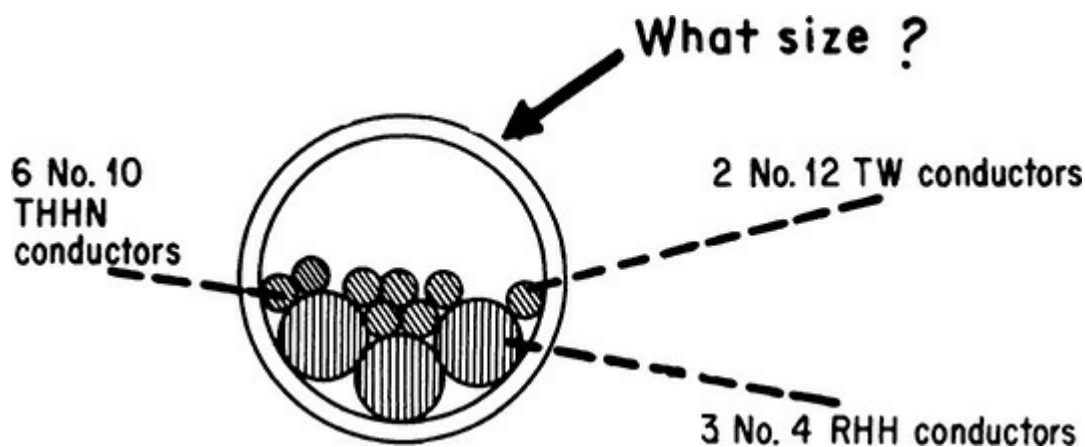

Fig. 344-3. Minimum permitted conduit size must be calculated when conductors are not all the same size. (Sec. 344.22.)

Cross-sectional areas of conductors:

From Table 5, Chap. 9:

10 AWG THHN	0.0211 sq in.
4 AWG RHH	0.1333 sq in.
12 AWG TW	0.0181 sq in.

Total area occupied by conductors:

6 10 AWG THHN	$6 \times 0.0211 = 0.1266$ sq in.
3 4 AWG RHH	$3 \times 0.1333 = 0.3999$ sq in.
2 12 AWG TW	$2 \times 0.0181 = 0.0362$ sq in.
Total area occupied by conductors	0.5627 sq in.

Referring to Table 4, Chap. 9:

The fourth column from the left gives the amount of square-inch area that is 40 percent of the csa of the sizes of conduit given in the farthest column from the left. The 40 percent column in the table on rigid metal conduits shows that 0.355 sq in. is 40 percent fill of a 1-in. conduit, and 0.610 sq in. is 40 percent fill of a 1¼-in. conduit. Therefore, a 1-in. conduit would be too small and—

A metric designator 35 (trade size 1¼) rigid metal conduit is the smallest for these 11 conductors.

example What is the minimum size of conduit for four No. 4/0 TW and four No. 4/0 XHHW conductors?

From Table 5, a No. 4/0 TW has a csa of 0.3718 sq in. Four of these come to 4×0.3718 or

1.4872 sq in.

From Table 5 we find that four No. 4/0 XHHW have a csa of 1.2788 sq in.

$$1.4872 + 1.2788 = 2.766 \text{ sq in.}$$

From Table 4, 40 percent of the csa of 3-in. rigid metal conduit is 3.000 sq in. A 2½-in. conduit would be too small. Therefore—

A metric designator 78 (trade size 3) conduit must be used.

Figure 344-4 shows how a conduit nipple is excluded from the normal 40 percent limitation on conduit fill. In this typical example, the nipple between a panelboard and a wireway contains 12 10 AWG TW wires, 6 14 AWG THHN wires, 3 8 AWG THW wires, and 2 2 AWG RHH wires (without outer covering). The minimum trade size of nipple that can be used in this case is metric designator 35 (trade size 1¼). (Nipple may be filled to 60 percent of its csa if it is not over 24 in. [610 mm] long. Area of conductors = 12×0.0243 sq in. [csa of each 10 AWG TW] plus 6×0.0097 sq in. [each 14 AWG THHN] plus 3×0.0437 sq in. [each 8 AWG THW] plus 2×0.1333 , or a total of 0.7475 sq in. If we divide this number by 0.6, the result will be the minimum area that the nipple can be sized at; $0.7475 \div 0.6 = 1.246$ sq in. The next higher sized rigid conduit raceway from Table 4, Chap. 9 is a metric designator 35 [trade size 1¼] conduit, so that is the size to select. Note that the Table 4 raceway sizes now include 60 percent columns done out, and entering the 0.7475 sq in. conductor summation in the 60 percent column shows it to be too large for the metric designator 27 [trade size 1] conduit but well within the next larger size.) And the conductors do *not* have to be derated in accordance with 310.15(B)(3)(a). If the nipple had been 25 in. long, calculation at 40 percent fill would have called for a metric designator 41 (trade size 1½) size, and all conductors would have had to be derated per 310.15(B)(3).

Fig. 344-4. Conduit nipples may be filled to 60 percent of csa and no derating is required. (Sec. 344.22.)

THWN and THHN are the smallest-diameter building wires in many common sizes. The greatly reduced insulation wall on Type THWN or THHN gives these thin-insulated conductors greater conduit fill than TW, THW, or RHH. And the nylon jacket on THWN and THHN has an extremely low coefficient of friction. THWN is a 75°C-rated wire for general circuit use in dry or wet locations; however, it is routinely being supplied in its THWN-2 variety, which has the same 90°C rating as THHN. THHN is a 90°C rated wire for dry locations only.

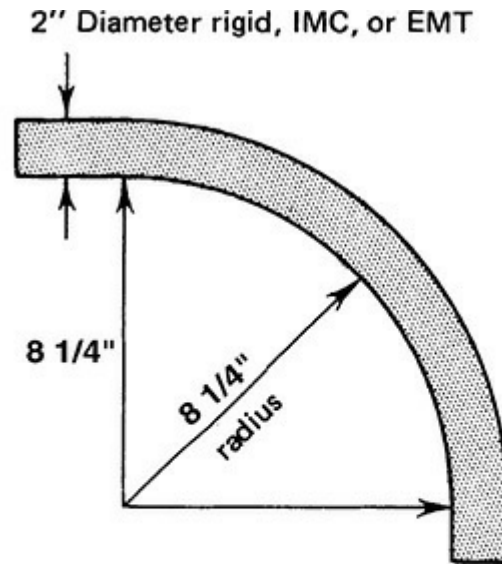

Although the same procedure applies, the tables in Annex C and the various parts of Table 4 must be correlated with the type of raceway to be used. This change of approach in the 1996 **NEC** was a major departure from the editions of the **NEC** that preceded it, but provides for more realistic fill. Remember, that spare fill capacity may be desirable in certain applications—such as long underground runs to outbuildings. The Code permits fill to 40 percent but no more. If a raceway is filled to the 40 percent maximum permitted in **Chap. 9**, a new raceway will be required if additional circuits are desired at a later date.

To fill conduit to the Code, maximum allowance is frequently difficult or impossible from the mechanical standpoint of pulling the conductors into the conduit, because of twisting and bending of the conductors within the conduit. Bigger-than-minimum conduit should generally be used to provide some measure of spare capacity for load growth; and, in many cases, the conduit to be used should be upsized considerably to allow future installation of some larger anticipated size of conductors.

344.24. Bends—How Made. The basic rule here provides general, common sense requirements regarding the bending of rigid metal conduits. The next part of the rule refers to Table 2 in **Chap. 9**. That table provides the same data that appeared in Table 344.24 in the 2002 **NEC**. Table 2 in **Chap. 9** now shows the acceptable radii, depending on the type of bend that is made.

Table 2, **Chap. 9** gives minimum bending radii for bends in rigid metal conduit, IMC, or EMT using any approved bending equipment and methods. (See **Fig. 344-5**.) However, the table headings in this rule permit sharper bends (i.e., smaller bending radii) if a one-shot bending machine or a full-shoe bender, including full-shoe hand benders, is used in making a bend for which the machine and its accessories are designed. The minimum radii for one-shot bends are given in the center column of Table 2, **Chap. 9**. The “other bends” column applies to bends made with hickies or with hydraulic

machines that do not have shoes that support the walls of the conduit or tubing throughout the bend. All bending radii apply to any amount of bend—that is, 45°, 90°, and so on.

For conduit bent using a “one-shot” or “full-shoe” bender.

For conduit bent using any other method.

Fig. 344-5. Minimum bending radii are specified to protect conductors from damage during pull-in. Note that the actual minimum code radius is applied to the centerline of the conduit, and not its inside edge. (Sec. 344.24.)

344.26. Bends—Number in One Run. There must be not more than the equivalent of four quarter bends (360°) between any two “pull points”—conduit bodies and boxes, as shown in [Fig.](#)

344-6. In previous Codes, the 360° of bends was permitted between boxes and “fittings” and even between “fitting and fitting.” Because the word *fitting* is defined in Art. 100 and the term does include conduit couplings, bushings, and so forth, there could be very many bends in an overall run, totaling far more than 360° if the equivalent of four quarter bends could be made between each pair of conduit couplings. The present wording limits the 360° of bends to conduit runs between “pull points”—such as between switchboards and panelboards, between housings, boxes, and conduit bodies—all of which are “pull points.”

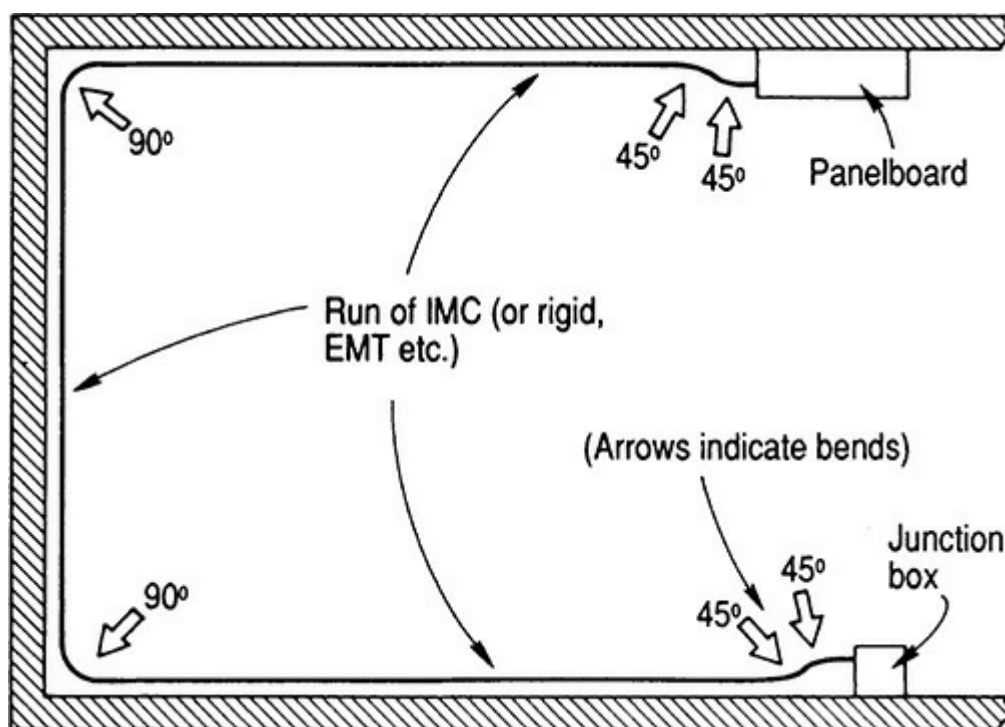

Fig. 344-6. Rigid metal conduit—like all other types of conduits—is limited to not over 360° of bends between “pull points,” such as the panelboard and junction box shown here. (Sec. 344.26.)

Note that the bends to be included in the summation include all deflections from a straight line, including a box kick at the end (about 20°), and bends of long radius, such as when conduits are joined outside of a trench and then forced in. There is no language that waives any bend of any radius, because pull force calculations show that the force to overcome a change in direction is independent of the radius; a longer radius results in more friction over the longer length involved. The sidewall bearing pressure is reduced on a longer radius bend, but that is only one of the forces to be considered.

The same concept of the number of bends permitted is given in all of the **NEC** articles on raceways—ENT, EMT, IMC, rigid metal conduit, rigid nonmetallic conduit, and so on.

344.28. Reaming and Threading. As with IMC, rigid metal conduit always requires a bushing on the conduit end using locknuts and bushing for connection to knockouts in sheet metal enclosures (Fig. 344.7). But simply because a conduit can be secured to a sheet metal KO with two locknuts (one inside and one outside—as required by 250.97), it does not mean the bushing may be eliminated. Of course, no bushing is needed where the conduit threads into a hub or boss on a fitting or an enclosure.

Fig. 344-7. Conduit terminations, other than threaded connections to threaded fittings or enclosure hubs, must be provided with bushings for protection of the conductors. (Sec. 344.28.)

344.30. Securing and Supporting. As with Art. 342, the support distances to the first support can be increased to up to 1.5 m (5 ft) on a showing that there are no readily available support points at the default point of 900 mm (3 ft). In addition, where threaded couplings are used and the supports are arranged to prevent stress in the run and as may result from bends in the run from being visited on terminations, the greater support distances in the associated table can be used. The special support limitations for conduit nipples imposed in the 2008 **NEC** have been revoked and the text returned to that of the 2005 edition. Any nipple not over the general limit on the first point of support in length, namely 900 mm (3 ft), is considered supported by its terminating hardware and no additional support is generally required. The permissions for longer distances between supports for certain run geometries, service masts, and for high-bay ceiling drops are the same as for IMC; refer to this topic in 342.30 for more information on these topics.

344.42. Couplings and Connectors. [Figure 344-8](#) shows a threadless connection of rigid metal conduit to the hub on a fitting. It is effective both mechanically and electrically if any nonconducting coating is removed from the conduit.

Fig. 344-8. Threadless connectors may be used on unthreaded end of conduit. (Sec. 344.42.)

A running thread is considered mechanically weak and has poor electrical conductivity.

Where two lengths of conduit must be coupled together but it is impossible to screw both lengths into an ordinary coupling, the Erickson coupling or a swivel-coupling may be used (Fig. 344.9). They make a rigid joint which is both mechanically and electrically effective. Also, bolted split couplings are available.

Fig. 344-9. Fittings provide for coupling conduits where conduits cannot be rotated (turned). (Sec. 344.42.)

It is not intended that conduit threads be treated with paint or other materials in order to ensure watertightness. It is assumed that the conductors are approved for the locations and that the prime purpose of the conduit is for protection from physical damage and easy withdrawal of conductors for replacement. There are available pipe-joint compounds that seal against water without interrupting electrical conductivity; see 300.6 for more information on this topic. Note also that threadless connectors and couplings, as covered in 344.42(A), must not be applied to a threaded conduit end unless listed for that application because they are tested on conduit ends that are a full diameter in size; without testing the performance of one of these items it cannot be ensured.

ARTICLE 348. FLEXIBLE METAL CONDUIT: TYPE FMC

348.12. Uses Not Permitted. UL data (Code DXUZ) supplement the Code data on use of standard flexible metal conduit—known also as “Greenfield” or simply “flex.” The UL data note:

This category covers flexible aluminum and steel conduit in trade sizes $\frac{3}{8}$ to 4 (metric designators 12 to 103) inclusive, flexible aluminum and steel conduit Type RW (reduced wall), flexible aluminum and steel conduit Type XRW (extra reduced wall) in trade sizes from $\frac{3}{8}$ to 3 (16 to 78) inclusive, for installation in accordance with Art. 348 of ANSI/NFPA 70, “**National Electrical Code**” (NEC), for conductors in circuits of 600 V, nominal, or less. This product may also be used for installation of conductors in motor circuits, electric signs, and outline lighting in accordance with the NEC.

Flexible metal conduit (steel or aluminum) should not be used underground (directly buried or in duct which is buried) or embedded in poured concrete or aggregate, or in direct contact with earth or where subjected to corrosive conditions. In addition, flexible aluminum conduit should not be installed in direct contact with masonry in damp locations.

For flexible metal conduit in 1- $\frac{1}{4}$ (35) trade size and smaller, where terminated in fittings investigated for grounding and where installed with not more than 6 ft (total length) in any ground-return path, flexible metal conduit is suitable for grounding where used on circuits rated 20 A or less. See Conduit Fittings (DWT) with respect to fittings suitable as a grounding means.

The following are not considered suitable as a grounding means:

1. The 1 $\frac{1}{2}$ (41) and larger trade sizes.
2. The 1 $\frac{1}{4}$ (35) trade size and smaller where used on circuits rated higher than 20 A, or where the total length in the ground-return path is greater than 6 ft.

To prevent possible damage to flexible aluminum conduit, flexible aluminum, and steel conduit Types RW and XRW, care must be exercised when installing connectors employing direct bearing set-screws.

PRODUCT MARKINGS

Flexible aluminum conduit is marked at intervals of not more than one ft with the letters “AL.”

Flexible aluminum conduit Type RW is marked at intervals of not more than one ft with the letters “AL” and “RW.”

Flexible steel conduit Type RW is marked at intervals of not more than one ft with the letters “RW.”

Flexible aluminum conduit Type XRW is marked at intervals of not more than one ft with the letters “AL” and “XRW.”

Flexible steel conduit Type XRW is marked at intervals of not more than one ft with the letters “XRW.”

Note that 348.12 was used to permit this wiring method in wet locations under several conditions; that permission has been revoked and now this wiring method is simply not permitted in a wet location.

348.20. Size. Part (A)(2) to this rule permits metric designator 12 (trade size $\frac{3}{8}$) flexible metal conduit to be used in lengths up to 6 ft (1.83 m) for connections to lighting fixtures. This provides correlation with 410.117(C), which includes 18 in. to 6 ft (0.45 to 1.8 m) of metal raceway for connecting recessed luminaires (generally the nonwired types). [Figure 348-1](#) shows such application, and it is permissible to use 16 AWG or 18 AWG 150°C fixture wire, as shown in [Fig. 360-1](#), for flex tubing.

complete system in a ceiling space consisting of prewired cable lengths with snap-in connectors for fixtures and switches, may use 3/8-in. flexible metal conduit.

Fig. 348-1. Flex of 3/8-in. size may be used for fixture “whip.” (Sec. 348.20.)

The usual field application of trade designator 12 (trade size 3/8) flexible metal conduit is covered in (A)(2)a, where the 1.8 m (6 ft) length (or shorter) can be used for any utilization equipment.

Part (A)(5) permits trade designator 12 (trade size 3/8) flex if it is “part of a listed assembly,” which assumes it is supplied as part of UL-listed equipment, in lengths up to 25 ft (7.5 m) as specified in 410.137(C) to connect “wired luminaire sections.”

Part (A)(3) permits flex in trade designator 12 (trade size $\frac{3}{8}$) to be used for the cable assemblies of modular wiring systems, typically in hung ceilings [so-called manufactured wiring systems covered by 604.100(A)]. This is directed specifically to ceiling modular wiring. And the equipment grounding conductor run in such flex wiring assemblies may be either bare or insulated [see 604.100(A)(2)] (Fig. 348.1).

348.22. Number of Conductors. This section specifies that Table 1 of **NEC Chap. 9** must be used in determining the maximum permitted number of conductors in $\frac{1}{2}$ through 4-in. flex. Flexible metal conduit is permitted the same conductor fill procedure, although customized to the actual inner diameter, as other types of conduit and tubing. The number of conductors permitted in metric designator 12 (trade size $\frac{3}{8}$) flex is given in Table 348.22.

348.26. Bends—Number in One Run. Figure 348-2 shows the details of this section.

FOR EXPOSED OR CONCEALED WORK . . .

. . . a run of flex or liquidtight flex from outlet to outlet or to a fitting must not contain more than the equivalent of four quarter-bends, including those bends right at the outlet or fitting.

Angle connectors for flex connection to enclosures must not be used for *concealed* flex installations. Straight connectors are OK.

Fig. 348-2. Concealed or exposed flex must not have too many bends that could damage wires on pull-in. (Sec. 348.24.)

In this section, the limitation to no more than a total of 360° of bends between outlets applies to both exposed and concealed applications of standard metal flex and liquidtight metal flex.

Without restriction on the maximum number of bends in exposed and concealed work, bends could result in damage to conductors in a run with an excessive number of bends or could encourage installation of conductors prior to conduit installation, with conduit then installed as a cable system. A limit on number of bends for exposed and concealed work conforms to the requirements for other raceway systems.

348.30. Securing and Supporting. Straps or other means of securing the conduit in place should be spaced much closer together (every $4\frac{1}{2}$ ft [1.4 m] and within 12 in. [300 mm] of each end) for flexible conduit than is necessary for rigid conduit. Every bend should be rigidly secured so that it will not be deformed when the wires are being pulled in, thus causing the wires to bind. Note that

there is some relief on the larger sizes, with an additional 300 mm (foot) to the first support for metric designator 41 and 53 (trade sizes 1½ and 2) and yet another 300 mm (foot) for larger sizes (Exception No. 2) but only where flexibility is required after installation.

Figure 348-3 shows use of unclamped lengths of flex that are short enough to comply with the main rule. The rigid raceways to which they are connected must be secured within the distances of their ends as required by their articles. The application shown does not require flexibility after installation and therefore Exception No. 2 does not apply. The raceway in front may exceed the basic 300 mm (12 in.) distance, but that is unclear from the photo. Figure 348-4 shows another example. Exception No. 3 is illustrated in Fig. 348-1. There is also a 1.8 m (6 ft) allowance for luminaire connections above hung ceilings, and the first exception allows for it to be fished between access points in finished construction. As with other flexible wiring methods, listed cable ties evaluated for support and securement are permitted, and frequently used above suspended ceilings.

Fig. 348-3. Lengths of flex not over 3 ft (900 mm) long may be used without clamps or straps where the flex is used at terminals to provide flexibility for vibration isolation or for alignment of connections to knockouts. (Sec. 348.30.)

Fig. 348-4. A length of flex not over 3 ft (900 mm) long connects conduit to pull box in modernization job, providing the flexibility to feed from fixed conduit to box. (Sec. 348.30.) Note that this run of flex already has almost 270° of bend before any bends in the rigid conduit are counted, and 300.18(A) requires raceway to be complete between pull points before wires are pulled in. Although there is no express language in the **NEC** that requires bends in succeeding raceway types joined end-to-end to adhere to the customary 360° rule, if there are several bends in the rigid conduit, the pull is likely to violate 300.17.

348.60. Grounding and Bonding. As shown in the UL data under 348.12, flex in any length over 6 ft (1.83 m) is not suitable as an equipment grounding conductor, and an equipment grounding conductor must be used within the flex to ground metal enclosures fed by the flex. 250.118 permits flex as an equipment grounding conductor *only* under the given conditions—which would be the same as shown in [Fig. 360-1](#) for flex tubing. Refer to 250.118 and to the discussion of grounding and bonding in 250.102.

The fourth paragraph of 348.60 essentially recognizes that an equipment bonding jumper used with flexible metal conduit may be installed inside the conduit or outside the conduit when installed in accordance with the limitations of 250.102. 250.118 and this rule make clear that use of flexible metal conduit as an equipment grounding conductor in itself is permitted only where a length of not over 1.8 m (6 ft) is inserted in any ground return path. The wording indicates that the total length of flex in any ground return path must not exceed 1.8 m (6 ft). That is, it may be a single 1.8 m (6 ft) length. Or, it may be two 900 mm (3 ft) lengths, three 600 mm (2 ft) lengths, or any total equivalent of 1.8 m (6 ft). If the total length of flex in any ground return path exceeds 1.8 m (6 ft), the rule requires

an equipment grounding conductor to be run within or outside any length of flex beyond the permitted 1.8 m (6 ft) that is acceptable as a ground return path in itself. This rule also includes other flexible wiring methods in the ground return path; review 250.118(5) in this book for the complete story.

It should be noted that 250.118 is not applicable to the use of flex in a hazardous location. The rules in 501.30(B) and 502.30(B) simply require bonding for flex, with only a very narrow exception given for instrumentation (Fig. 348.5).

Fig. 348-5. Flex must always be bonded in Class I and Class II hazardous locations. (Sec. 348.60.)

Effective with the 2012 edition of the UL Guide Card information [see discussion at 110.3(B) for details], there was a direct conflict between a key UL limitation on the use of a flexible metal conduit and the expressly permitted uses in 250.118(5) for this wiring method going back 42 years. There was never an upper size limitation on the use of this product as an equipment grounding conductor. The length limit of 6 ft continues to this day, along with the severe limitation on the associated circuit protection of 20 A, which also continues. The conflict has been eliminated as of the 2017 edition of the **NEC** because it has been incorporated into 250.118(5).

250.118(5)d says that an equipment grounding conductor (or jumper) must *always* be installed for a length of metal flex that is used to supply equipment “where flexibility is necessary after installation,” such as equipment that is not fixed in place, or equipment that tends to vibrate, such as motors or transformers. That wording actually modifies the conditions under which a 6-ft or shorter length of metal flex (Greenfield) may be used for grounding through the metal of its own assembly, without need for a bonding wire. Because experience has indicated many instances of loss of ground

connection through the flex metal due to repeated movement of a flex whip connected to equipment that vibrates, or flex supplying movable equipment, the last sentence requires use of an equipment bonding jumper, either inside or outside the flex in all cases where vibrating or movable equipment is supplied—for ensured safety of grounding continuity. The caption for [Fig. 348-3](#) lists an example of each possibility. Lining up connections to a pull box does not involve flexibility after installation, but vibration isolation does. The 2011 **NEC** clarified that when this wiring method is used for vibration isolation, it is employing its flexibility after the initial installation and the supplemental bonding conductor is required.

ARTICLE 350. LIQUIDTIGHT FLEXIBLE METAL CONDUIT: TYPE LFMC

350.1. Scope. This article covers *metallic* liquidtight flex. Liquidtight metal flex (often called “Sealtite” as a generic term in industry usage, although that word is the registered trade name of the liquidtight flex made by Anaconda Metal Hose Division) is similar in construction to the common type of flexible metal conduit, but is covered with an outer sheath of thermoplastic material ([Fig. 350.1](#)).

Fig. 350-1. Plastic jacket on liquidtight flex suits it to outdoor use exposed to rain or indoor locations where water or other liquids or vapors must be excluded from the raceway and associated enclosures. In lengths under 6 ft (1.8 m), UL-listed metal liquidtight flex may not require a bonding jumper depending on size and overcurrent protection. See text. (Sec. 350.60.)

350.6. Listing Requirements. Most raceways are required to be listed, as is this one, but in this case it should be noted that unlike other raceways, enormous quantities of unlisted liquidtight flexible metal conduit were sold for many decades. Frequently supply houses would never stock the listed product and it was only available by special order. And the differences in this case are substantial. Only the listed product has copper wound into its convolutions that improve its ground-return effectiveness. In addition there are chemical differences in the stability of the nonmetallic jacket that bear on how well the product holds up in outdoor environments over time. In looking at existing installations, keep in mind that lengths of this product already in use may very well be substandard.

350.10. Uses Permitted. UL data on liquidtight metal flex present a variety of restrictions on the use of LFMC. And the basic wording of 350.10(A) essentially refers the reader to the limitations placed on the use of a particular type of LFMC by its specific listing.

As noted in the UL data, liquidtight flexible metal conduit is permitted for use directly buried in the earth if it is “so marked on the product.” The rule in 350.10 extends Code recognition to direct burial of liquidtight flexible metal conduit if it is “listed and marked” for such use. Based on many years of such application, liquidtight metal flex is recognized for direct burial, but any such use is permitted only for liquidtight flex that is “listed” by UL, or some other test lab, and is “marked” to indicate suitability for direct burial, to assure the installer and inspector of Code compliance. In the past, successful applications have been made in the earth and in concrete. Standard flexible metal conduit is prohibited from being used “underground or embedded in poured concrete or aggregate.” But that prohibition is not placed on liquidtight metal flex.

350.12(2) covers issues with operating temperatures that must be kept in mind. The UL Guide Card information (DXHR) provides the following points with respect to how to apply markings that may be found on the product:

Liquidtight flexible metal conduit suitable for direct burial and in poured concrete is marked “Direct Burial,” “Burial,” “Dir Burial,” or “Dir Bur.”

Liquidtight flexible metal conduit not marked with a temperature designation or marked “60 C” is intended for use at temperatures not in excess of 60°C (140°F).

Conduit intended for use in dry or oily locations at a temperature higher than 60°C (140°F) is marked “___ C dry, 60 C wet, 70 C oil res” or “___ C dry, 60 C wet, 70 C oil resistant” with “80” or “105” inserted as the dry-locations temperature.

Conduit marked “80 C dry, 60 C wet, 60 C oil res” or “80 C dry, 60 C oil resistant” is intended for use at 80°C (176°F) and lower temperatures in air, and at 60°C (140°F) and lower temperatures where exposed to water, oil or coolants.

Conduit that has not been investigated for use where exposed to oil is marked “OIL-FREE ENVIRONMENTS ONLY.”

350.20. Size. Refer to 348.20, which has the same rules. [Figure 350-2](#) satisfies this subpart if the

No. 12 wires are stranded, as required in 430.245(B). Table 348.22 accepts three No. 12 THHN plus an equipment grounding conductor of the same size in metric designator 12 (trade size $\frac{3}{8}$) Greenfield or liquidtight.

NOTE: The 6 ft length of liquidtight is suitable as an equipment grounding conductor, without bonding.

Fig. 350-2. Both standard flexible metal conduit and liquidtight may be used here. If the connection to the motor is viewed as a vibration isolator, or the motor can be repositioned to adjust belt tension, etc., then the flexible connection will be classified as necessary after installation and an equipment grounding conductor will need to be pulled in with the circuit conductors. (Sec. 350.20.)

350.22. Number of Conductors. The maximum number of conductors must satisfy the rules of Table 1, Chap. 9. Refer to Tables C.5 and C.5(A) in Annex C for metric designators 16 to 103 (trade sizes $\frac{1}{2}$ to 4), and to Table 348.22 for metric designator 12 (trade size $\frac{3}{8}$) data.

350.26. Bends—Number in One Run. Figure 348-2 shows this rule.

350.28. Trimming. This is a new section in the 2017 edition, requiring the removal of rough edges after cutting. The panel made an interesting point, namely, that often the end ferrule furnished with the connector won't seat properly if it can't be twisted all the way in because of rough edges. And, if that happens, grounding continuity will be impaired.

350.30. Securing and Supporting. As shown in Fig. 350-3, the rule permits a length of liquidtight flexible metal conduit not over 900 mm (3 ft) long to be used at terminals where flexibility is required without any need for clamping or strapping. Obviously, the use of flex requires this permission for short lengths without support. As in the case of flexible metal conduit, relief is now available for the distance to the first support point for the larger sizes.

Fig. 350-3. Unsupported length of liquidtight flex is okay at terminations. (Sec. 350.30.)

In addition, liquidtight metal flex is specifically recognized in lengths up to 1.8 m (6 ft) for fixture “whip,” without clamping of the flex. This covers a practice that has long been common. Either standard or liquidtight metal flex may be used to carry supply conductors to lighting fixtures—such as required by 410.117(C), where high-temperature wires must be run to a fixture terminal box. As in the case of other flexible raceways, cable ties are permitted if listed for support and securement. They are frequently used above suspended ceilings.

350.42. Couplings and Connectors. As in the case of 348.42, it is a Code violation to conceal an angle connector, because the eventual outcome will be someone deciding he or she absolutely has to pull through it, and damaging insulation in the process. The 2014 **NEC** has added a clarification here that straight fittings are permitted for direct burial where marked accordingly. Angle connectors belong at the very end of a run, and where they can be disassembled and then reconnected in the field.

350.60. Grounding and Bonding. According to the rule of 250.118, where flexible metal conduit and fittings have not been specifically listed as a grounding means, a separate grounding conductor (insulated or bare) shall be run inside the conduit (or outside, for lengths not over 6 ft [1.8 m]) and bonded at each box or similar equipment to which the conduit is connected. Refer to the discussion at 250.118(5 and 6) for full details of the circumstances under which this wiring method qualifies as an equipment grounding conductor. In addition, UL has some Guide Card information because it presents some of the same information in a mirror image from that in 250.118(6), because it clearly states the types of liquidtight flexible metal conduit that are *not* to be considered as a qualified equipment grounding conductor, as follows:

1. The metric designator 41 (trade size 1½) and larger sizes.
2. The metric designators 12 and 16 (trade sizes ¾ and 1) sizes where used on circuits rated higher than 20 A, or where the total length in the ground return path is greater than 6 ft.
3. The metric designators 21, 27, and 35 (trade sizes ¾, 1, and 1¼) sizes where used on circuits rated higher than 60 A, or where the total length in the ground return path is greater than 6 ft.

As in the case of flexible metal conduit, where liquidtight flexible metal conduit requires flexibility as part of its normal usage pattern after the installation is complete, a separate equipment grounding conductor must be installed regardless of the size or length or protective ampere rating

ahead of the flexible wiring method. As noted previously, the 2011 **NEC** clarified that when this wiring method is used for vibration isolation, it is employing its flexibility after the initial installation and the supplemental bonding conductor is required.

ARTICLE 352. RIGID POLYVINYL CHLORIDE CONDUIT: TYPE PVC

352.2. Definition. Rigid polyvinyl chloride conduit wiring systems include a wide assortment of products (Fig. 352.1). This article was formerly titled “Rigid Nonmetallic Conduit” but in the 2008 **NEC**, it was reserved to the PVC variety, with the fiberglass version (Type RTRC) given its own article (Art. 355). Note that since there is now no **NEC** article to cover nonmetallic conduit in the generic sense, and only three **NEC** articles cover rigid nonmetallic conduits (352 on PVC, 353 on HDPE, and 355 on RTRC), and since 110.8 spells out that only wiring methods recognized in the **NEC** as suitable are the ones enumerated therein, all other forms of rigid nonmetallic conduit, such as styrene, fiber, tile, asbestos cement, soapstone, and others that have been used in the past for underground use are no longer recognized as suitable under the **NEC**.

Fig. 352-1. Rigid nonmetallic conduit systems are made up of a wide variety of components—conduit, fittings, elbows, nipples, couplings, boxes, straps. (Sec. 352.2.)

UL application data are detailed and divide rigid polyvinyl chloride conduit into two categories.

Note that only the first, covering Schedule 40 and 80 PVC, involve wiring methods that can be used above grade (Fig. 352.2). Schedule 80 has a very heavy wall that subtracts from the inner diameter of the raceway, leading to special wire fill calculations (Fig. 352.3). The specific UL instructions on each category are as follows:

Fig. 352-2. PVC and RTRC conduits are the only rigid nonmetallic conduits that may be used

aboveground. And when enclosing conductors run up a pole (shown here feeding a floodlight at top), the PVC conduit must be Schedule 80 PVC conduit if it is exposed to physical damage, such as possible impact by trucks or cars. If the conduit is not so exposed, it may be Schedule 40 PVC conduit. See Sec. 300.5(D). (Sec. 352.2.)

Rigid Nonmetallic, Schedule 40 and Schedule 80 PVC Conduit (DZYR)

This category covers rigid nonmetallic PVC conduit including straight conduit and elbows in trade sizes ½ to 6 (metric designators 16 to 155) inclusive, intended for installation as rigid nonmetallic raceway for wire and cable in accordance with Art. 352 of ANSI/NFPA 70, “**National Electrical Code**” (NEC). This conduit may be Schedule 40, Schedule 80, Type A or Type EB. The conduit is intended for installation and use in accordance with the following information.

Schedule 40 conduit is suitable for underground use by direct burial or encasement in concrete. Schedule 40 conduit marked “Directional Boring” (or “Dir. Boring”) is suitable for underground directional boring applications. Schedule 40 conduit is also suitable for aboveground use indoors or outdoors exposed to sunlight and weather where not subject to physical damage. Schedule 40 conduit marked “Underground Use Only” is only suitable for underground applications.

Schedule 80 conduit has a reduced cross-sectional area available for wiring space and is suitable for use wherever Schedule 40 conduit may be used. The marking “Schedule 80 PVC” identifies conduit suitable for use where exposed to physical damage and for installation on poles in accordance with the NEC.

Type A, Type EB, and Schedule 40 are intended for underground use under the following conditions, as indicated in the Certification Mark:

Type A—Installed with its entire length in concrete in any underground location.

Type EB—Installed with its entire length in concrete in trenches outside of buildings.

Schedule 40—Direct burial with or without being encased in concrete.

Where conduit emerges from underground installation, the wiring method is intended to be of a type recognized by the NEC for the purpose.

Unless marked for higher temperature, rigid nonmetallic conduit PVC is intended for use with wire rated 75°C or less including where it is encased in concrete within buildings and where ambient temperature is 50°C or less. Where encased in concrete in trenches outside of buildings it is suitable for use with wires rated 90°C or less.

Certified PVC conduit is inherently resistant to atmosphere containing common industrial corrosive agents and will also withstand vapors or mist of caustic, pickling acids, plating bath, and hydrofluoric and chromic acids.

PVC conduit and elbows (including couplings) that have been investigated for direct exposure to other reagents may be identified by the designation “Reagent Resistant” printed on the surface of the product. Such special uses are described as follows: Where exposed to the following reagents at 60°C or less: Acetic, Nitric (25°C only) acids in concentrations not exceeding ½ normal; hydrochloric acid in concentrations not exceeding 30 percent; sulfuric acid in concentrations not exceeding 10 normal; sulfuric acid in concentrations not exceeding 80 percent (25°C only); concentrated or dilute ammonium hydroxide; sodium hydroxide solutions in concentrations not exceeding 50 percent; saturated or dilute sodium chloride solution; cottonseed

oil, or ASTM 3 petroleum oil.

Schedule 40, Schedule 80, Type EB, and Type A PVC conduit are designed for connection to all PVC couplings, fittings, and boxes by the use of a suitable solvent-type cement. Instructions supplied by the solvent-type cement manufacturer describe the method of assembly and precautions to be followed.

Note: As a result of the wording and intent of **NEC** 110.3(B), all the preceding application data constitute mandatory rules of the **NEC** itself—subject to the same enforcement as any other **NEC** rules.

When equipment grounding is required for metal enclosures of equipment used with rigid nonmetallic conduit, an equipment grounding conductor must be provided. Such a conductor must be installed in the conduit along with the circuit conductors ([Fig. 352.4](#)).

For conductor fill to 40% of the cross-section area, refer to data on wire-fill capacity marked on conduit surface.

Fig. 352-3. Extra-heavy-wall PVC conduit must have conductor fill limited to its reduced csa. (Sec. 352.2.)

Equipment grounding conductor is sized from Table 250.122, based on the rating of the fuses or CB protecting the circuit conductor in the conduit. With 200-amp protection for the 3/0 conductors here, the equipment grounding conductor must be at least a No. 6 copper or No. 4 aluminum.

Fig. 352-4. Equipment grounding conductor must be used “within” the rigid nonmetallic conduit. (Sec. 352.60).

352.10. Uses Permitted. This section applies to use of the conduit for circuits operating at any voltage (up to 1000 V and at higher voltages). The rules make rigid nonmetallic conduit a general-purpose raceway for interior and exterior wiring, concealed or exposed in wood or masonry

construction—under the conditions stated. The Schedule 80 variety is acceptable where there would be a strong likelihood of damage to a less robust conduit.

Rigid nonmetallic conduit may be used aboveground to carry high-voltage circuits without need for encasing the conduit in concrete. That permission is also given in 300.37. Aboveground use is permitted indoors and outdoors.

Part (G) covers underground applications of all the types of rigid nonmetallic conduit—for circuits up to 1000 V, as regulated by 300.5; and for circuits over 1000 V, as covered by 300.50 (Fig. 352.5). Directly buried nonmetallic conduit carrying high-voltage conductors does not have to be concrete-encased if it is a type listed for use without concrete encasement. If concrete encasement is required, it will be indicated on the UL label and in the listing.

Fig. 352-5. All UL-listed rigid nonmetallic conduits are acceptable for use underground. PVC Schedule 40 and Schedule 80 do not require concrete encasement. Other types must observe UL and NEC rules on concrete encasement. (Sec. 352.10.)

Figure 352-6 shows both underground and aboveground application. Referring to the circled numbers: (1) The burial depth must be at least 18 in. (450 mm) for any circuit up to 1000 V. The buried conduit may be Schedule 40 or Schedule 80 (either without concrete encasement) or Type A or Type EB (both require concrete encasement). Refer to the opening coverage here and 300.5. (2) The concrete encasement where the conduit comes up from its 18-in. (450-mm) depth was required at one time by the NEC, but is no longer required. (See 300.5.) (3) The radius of the bend must comply

with Table 2, Chap. 9 (minimum 18 in. [457.2 mm] if done in the field with a bending box; 330.2 mm [13 in.] if done in the factory with some form of one-shot bender). The conduit aboveground, on a pole or on a building wall, must be Schedule 80 if the conduit is exposed to impact by cars or trucks or to other physical damage. If the conduit is not exposed to damage, it may be Schedule 40.

Numbers in circles refer to text.

Fig. 352-6. Schedule 80 PVC conduit may run up pole from earth to aboveground use. (Sec. 352.10.)

In many cases where nonmetallic conduit is used to enclose conductors suitable for direct burial in the earth, inspectors and engineering authorities have accepted use of any type of conduit—PVC, polyethylene, styrene, and so on—without concrete encasement and without considering application of Code rules to the conduit. The reasoning is that because the cables are suitable for direct burial in the earth, the conduit itself is not required at all and its use is above and beyond Code rules. But temperature considerations are real and related to effective, long-time operation of an installation. Temperature effects must not be disregarded in any conduit-conductor application.

New as of the 2008 **NEC** was the recognition of a foam-core PVC product. This conduit is significantly lighter than the customary solid product. It was referred to in the 2008 **NEC** as “nonhomogeneous” PVC and it was implicitly permitted underground as both a direct-burial wiring method and where encased in concrete. As of the 2011 edition, it is no longer mentioned. The intent is to fully recognize it for all applications where conventional PVC is used. It is tested to the exact same product standard as the conventional product. The lack of mention now simply reflects that it is PVC conduit and can be used in accordance with this article.

Although it is generally prohibited from supporting “equipment,” part **(H)** correlates with 314.23(E) Exception and recognizes the use of rigid nonmetallic conduit to support nonmetallic

conduit bodies, provided the conduit body is no larger than the largest conduit that is providing the support.

Probably the most important use of part **(I)** will be the use of PVC to enclose MV-105 conductors that have a 105°C temperature rating but that are being operated so as to not exceed 90°C. This is often done to increase reliability and to extend the expected project life of a job.

352.12. Uses Not Permitted. It should be noted that nonmetallic conduit is not permitted in ducts, plenums, and other air-handling spaces. See 300.21 and the comments following 300.22.

Figure 352-7 shows a difference in application rules between rigid nonmetallic conduit and metal conduit with respect to supporting equipment. Part **(B)** allows limited use of rigid nonmetallic conduit for support of nonmetallic conduit bodies that do *not* contain devices or fixtures, as described in 352.10(H). This provision correlates with 314.23(F).

Fig. 352-7. This is okay for rigid metal conduit but not for rigid nonmetallic conduit. (Sec. 352.12.)

Part **(D)** requires care in use of the conduits so that they are not exposed to damaging temperatures. In using nonmetallic conduits, care must be taken to ensure temperature compatibility between the conduit and the conductors used in it. For instance, a conduit that has a 75°C temperature rating at which it might melt and/or deform must not be used with conductors which have a 90°C temperature rating and which will be loaded so they are operating at their top temperature limit. There is available PVC rigid conduit listed by UL and marked to indicate its suitability for use with all 90°C-rated conductors, thereby suiting the conduit to use with 90°C-rated conductors. The UL data described in 352.2 give the acceptable ambient temperatures and conductor temperature ratings that correlate to these **NEC** rules. Conductors with 90°C insulation may be used at the higher ampacities of that temperature rating only when the conduit is concrete encased, or marked with evidence of suitability for this temperature exposure (Fig. 352.8).

Fig. 352-8. UL data indicate that this violates Sec. 352.12(E) unless it is marked as suitable for such applications. (Sec. 352.12.)

352.22. Number of Conductors. Refer to 344.22.

352.24. Bends—How Made. Refer to 344.24 and the discussion in this chapter in 352.10. The radius of field bends should be based on the “One Shot and Full Shoe” column in [Chap. 9](#), Table 2 provided bending equipment identified for the purpose is used properly. Usually the conduit is heated with a special electric blanket or placed in a bending box designed for this purpose. A blow torch is most certainly not appropriate and most inspectors, seeing the tell-tale scorch marks, will fail a job where this has been done. Larger conduits must have closure plugs placed in the ends prior to heating, which results in heated compressed air providing interior support to the conduit until the bend has been cooled and set. Smaller size conduits can also be bent cold using special removable interior springs that support the walls while the conduit is bent, using a full-shoe rigid conduit bender if necessary.

352.26. Bends—Number in One Run. Refer to 344.26.

352.28. Trimming. See [Fig. 352-9](#).

Fig. 352-9. PVC conduit is designed for connection to couplings and enclosures by an approved cement, but leaving rough edges in the conduit end is a clear violation of Sec. 352.28. (Sec. 352.28.)

352.30. Securing and Supporting. In this section, Table 352.30(B), giving the maximum distance between supports for rigid nonmetallic conduit, permits greater spacing than some previous **NEC** editions. For each size of rigid nonmetallic conduit, a single maximum spacing between supports, in feet, is given for all temperature ratings of conductors used in rigid nonmetallic conduit raceways ([Fig. 352.10](#)).

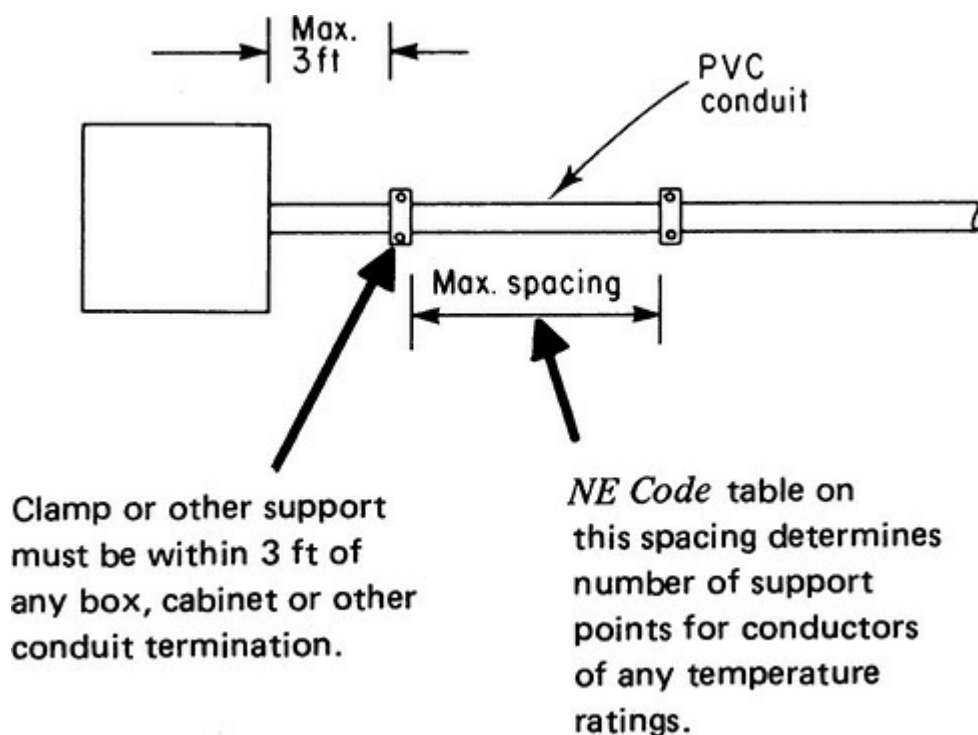

Fig. 352-10. Support rules on nonmetallic conduit are simple and direct. (Sec. 352.30.)

The wording in the paragraph of part (B) here is similar to subparts in Code articles covering other raceways and cables. This wording specifically recognizes holes in framing members as providing support for rigid nonmetallic conduit.

The special support limitations for conduit nipples imposed in the 2008 **NEC** have been revoked and the text returned to that of the 2005 edition. Any nipple not over the general limit on the first point of support in length, namely 900 mm (3 ft), is considered supported by its terminating hardware and no additional support is generally required.

352.44. Expansion Fittings. In applications in which the conduit installation will be subject to constantly changing temperatures and the runs are long, consideration must be given to expansion and contraction of PVC conduit. In such instances an expansion coupling should be installed near the fixed end of the run to take up any expansion or contraction that may occur. The normal expansion range of these fittings is about 6 in. (150 mm). The coefficient of linear expansion of PVC conduit is given in Table 352.44 of the **NEC**, and exceeds the expansion coefficient of steel by a factor of five. Without properly applied expansion fittings an aboveground installation subject to the usual range of outdoor temperatures will fail. If the job is installed on a cold winter day, and the conduit cannot freely move when the hot weather arrives, the result will look like an accordion. If the same job is installed on a hot day, come the winter months the conduit will contract to the point of pulling out of glue joints and exposing the conductors within.

In addition, when PVC conduit is exposed to direct sun, it absorbs even more heat than the surface wired over. A leading maker of PVC conduit recommends that at least 140°F be used as the upper temperature design parameter for this reason. If the minimum temperature were 0°F, that change in temperature would cause a 100 ft (30 m) length of conduit to expand and contract through a range of almost 6 in. (150 mm). The wiring system must be arranged with this in mind. Of course, some parts of the system will handle this movement without difficulty. For example, a service riser running straight up from a meter socket and ending at a weatherhead, if properly supported with clamps designed to allow movement, can expand and contract at will.

Caution is in order when one end of a straight length of PVC conduit is securely held, such as when it emerges from concrete embedment, and connects to an enclosure. This section does not require an expansion fitting if the expected expansion and contraction does not exceed 6 mm ($\frac{1}{4}$ in.). If that dimension is distributed over both ends of the conduit run, the result is reasonable. However, if the $\frac{1}{4}$ in. occurs entirely at one end, that degree of movement is easily enough to break anchor points and crack nonmetallic enclosures on a cold day.

Expansion couplings are normally used where conduits are exposed. In underground or slab applications such couplings are seldom used because expansion and contraction can be controlled by *bowing* the conduit slightly. However, the rule of Sec. 300.5(J) now mandates that ground movement be addressed in underground installations. The informational note indicates methods—expansion joints in vertical risers—that may be used to satisfy the rule. Conduits left exposed for an extended period of time without expansion fittings during widely variable temperature conditions should be examined to see if contraction has occurred and compromised the glue joints.

ARTICLE 353. HIGH-DENSITY POLYETHYLENE CONDUIT: TYPE HDPE

CONDUIT

353.1. Scope. This article covers the requirements for the installation and use of Type HDPE conduit. It is a tubular raceway of circular cross section, and is available in discrete lengths, or in continuous lengths on a reel. It is available from metric designator 16 (trade size ½) up to and including metric designator 155 (trade size 6). This type of nonmetallic raceway has been used by utilities in various jurisdictions across the country for years. Its high durability and flexibility of application regardless of soil conditions makes it a very good choice for underground installations of electrical conductors. 353.2 provides a definition and 353.6 mandates the use of listed HDPE only.

353.6. Listing. As with the case for all raceway wiring methods, this wiring method must be listed, and with this comes important information from the UL Guide Card information:

This category covers plastic types of rigid, nonmetallic high-density polyethylene (HDPE) conduit, including straight conduit, elbows, and other bends, in sizes ½ to 6 (metric designators 16 through 155) inclusive, intended for installation underground as raceway for wire and cable in accordance with Art. 353 of ANSI/NFPA 70, “**National Electrical Code**” (NEC). This conduit may be HDPE Schedule 40, Schedule 80, EPEC A, or EPEC B. This conduit is intended for installation and use in accordance with the following information.

The conduit is intended for underground use under the following condition, as indicated in the Certification Mark: Direct burial with or without being encased in concrete (HDPE Schedule 40, Schedule 80, EPEC A, EPEC B). The conduit is intended for use in ambient temperatures of 50°C or less.

Unless marked otherwise, HDPE conduit is intended for use with wire rated 75°C or less, or when directly buried or encased in concrete in trenches outside of buildings, it may be used with wire rated 90°C or less.

Where conduit emerges from underground installation, the wiring method is intended to be of a type recognized by the NEC for the purpose.

HDPE conduit is designed for joining by threaded couplings, drive-on couplings, or a butt-fusing process. Instructions supplied by the solvent-type cement manufacturer describe the method of assembly and precautions to be followed.

353.10. Use Permitted. Part (1) indicates that Type HDPE is available in both individual cut-lengths or it may be supplied on a reel. It is suited for use in severely corrosive environments, cinder fill, and underground in direct contact with earth or concrete.

Part (6) includes similar recognition for conductors with insulation ratings that exceed those of the HDPE conduit, under the condition that they are not operated at such a temperature. Refer to the discussion at 352.10(I) for more information on this topic.

353.12. Uses Not Permitted. It must not be used above 50°C, either by reason of a high ambient temperature, or high operating temperatures of the enclosed conductors, or both. Polyethylene is flammable, and for that reason it is generally limited to direct burial applications. If not specifically prohibited, it is permitted above grade if encased in a concrete envelope not less than 50 mm (2 in.) thick. It is not permitted to be exposed, and it must not be used inside buildings.

353.22. Number of Conductors. Refer to 344.22.

353.24. Bends—How Made. NEC Table 354.24 specifies the minimum bending radius for this material, which is more restrictive than most tubular raceways. The table begins with a 250 mm

(10 in.) radius for metric designator 16 (trade size ½) conduit, and rises to a 1.5 m (5 ft) minimum radius for the trade size 4 product. There is no table entry as of the 2014 **NEC** for metric designator 129 or 155 (trade size 5 or 6) conduit, so the manufacturer's directions need to be consulted for these sizes.

353.26. Bends—Number in One Run. Refer to 344.26.

353.48. Joints. All joints must be made by an approved method. The 2008 **NEC** added a note at this location suggesting the three methods of successfully splicing this wiring method, including heat fusion or electrofusion along with mechanical fittings.

ARTICLE 354. NONMETALLIC UNDERGROUND CONDUIT WITH CONDUCTORS: TYPE NUCC

This is the same product as Type HDPE conduit, and it follows the same installation rules, but conductors are preinstalled and shipped with the product by the manufacturer. Note that even though conductors arrive with the product preinstalled, it is still classified as a raceway, and the 360° maximum bends-in-the-run rule continues to apply. In this form, the upper size limit is metric designator 103 (trade size 4) conduit, also using the special bend radius Table 354.24.

ARTICLE 355. REINFORCED THERMOSETTING RESIN CONDUIT: TYPE RTRC

355.2. Definition. This is the fiberglass entry in the nonmetallic conduit market. At one time it was only permitted for below-grade applications, but advances in chemistry have resulted in materials that meet above-grade fire resistance tests and it is now permitted for use in buildings where concealed in walls, floors, and ceilings, and also where exposed if identified for the application. It is stiffer than PVC and has a much lower coefficient of thermal expansion (about 45 percent of the value for PVC). Although the **NEC** uses the same support distance table as for PVC conduit, it does allow for longer support intervals if the product is listed for larger distances. It is more difficult to bend in the field, although an extensive range of different bend angle sweeps is available to accommodate field installation issues. It must not be used above 50°C unless listed for a higher temperature. The article is, in effect, a carbon copy of Art. 352 with only one significant difference: it has its own thermal expansion table, with a coefficient of expansion appreciably less (about 45 percent) of that for rigid PVC conduit. The “XW” variety of this conduit (see below) is its counterpart to Schedule 80 PVC. The UL Guide Card information (Guide Card DYJC) follows:

This category covers reinforced thermosetting resin conduit and fittings intended for installation in accordance with Art. 355 of ANSI/NFPA70, “**National Electrical Code**” (**NEC**).

Reinforced thermosetting resin conduit is certified in trade sizes ½ through 6 (metric designators 16 through 155) inclusive, in IPS and ID dimensions, and in trade sizes ¾ through 6 (metric designators 21 through 155) inclusive, in XW dimensions as marked on the product. Certification includes straight conduit, elbows, and other fittings, unless otherwise noted.

Reinforced thermosetting resin conduit has been investigated for use at –40°C (–40°F) to 110°C (230°F).

Reinforced thermosetting resin conduit is designed for connection to couplings, fittings, and boxes by use of a suitable epoxy-type cement or drive-on bell and spigot. Instructions supplied by the epoxy-type-cement manufacturer describe the method of assembly and precautions to be followed.

The conduit is designated “EB” (Encased Burial) or “DB” (Direct Burial), which refers to specific wall thicknesses. EB conduit is suitable for encasement in concrete. DB conduit is suitable for encasement in concrete and direct burial. Conduit marked “Below Ground” (or “BG”) has been investigated for underground use only—for direct burial, with or without being encased in concrete.

Conduit marked “Above Ground” (or “AG”) has been investigated for use aboveground, underground, and for direct burial with or without encasement in concrete. This conduit has been investigated for concealed or exposed work where not subject to physical damage. The conduit is designated “SW” (Standard Wall) or “HW” (Heavy Wall), which refers to specific wall thicknesses.

XW-type reinforced thermosetting resin conduit, which refers to specific wall thicknesses, is certified as suitable for use where exposed to physical damage in accordance with the **NEC** and is suitable for use wherever IPS and ID conduit may be used. The marking “AG, XW, RTRC” identifies conduit suitable for aboveground use and where exposed to physical damage in accordance with the **NEC**.

Reinforced thermosetting resin conduit, elbows, and other fittings investigated for direct exposure to reagents are identified by the designation “Reagent Resistant” and are marked to indicate the specific reagents.

ARTICLE 356. LIQUIDTIGHT FLEXIBLE NONMETALLIC CONDUIT: TYPE LFNC

356.2. Definition. This is a flexible nonmetallic raceway of circular cross section, available in three forms. Type LFNC-A has a smooth, seamless inner core and cover bonded together, with reinforcement between the core and cover layers. Type LFNC-B has a smooth inner surface together with reinforcement within the conduit wall. This is its most usual form. Type LFNC-C has a corrugated inner and outer surface, with no reinforcement in the wall. It is generally limited to 6 ft (1.8 m) lengths unless a longer length is required for the amount of flexibility called for at the point of use. However, the “B” style does not carry this length limitation.

356.10. Uses Permitted. Liquidtight flexible nonmetallic conduit may be used exposed or concealed and also may be used for direct burial in earth if “listed and marked for the purpose.” This extends similar permission to liquidtight flexible *nonmetallic* conduit that was given for liquidtight flexible *metallic* conduit in the 1987 **NEC**. And 356.10 recognizes this nonmetallic flex for “concealed” as well as exposed locations. This product [356.10(6)] is also authorized to be produced as a listed prewired assembly in the metric designator 16 through 27 (trade size ½ through 1) sizes. The 2014 **NEC** removed the over 600-V prohibition from 356.12, thereby making a formerly specialized application for neon sign work in 600.32(A) completely unrestricted in this article. Note that this application is not, as yet, correlated with the permissible wiring methods for over 1000-V work in 300.37 or for motors in 430.223. Note that the former limitation for uses longer than 6 ft to the “B” style product [in (5)] was lifted in the 2017 **NEC**, and so any of the three styles

can now be used for long runs as long as the support rules in 356.30 are met. Supposedly the relevant product testing for all three styles is the same.

356.20. Size. Although metric designator 16 (trade size ½) trade size is the smallest recognized size of liquidtight flexible nonmetallic conduit for general use, Part (A)(1) notes that metric designator 12 (trade size ¾) liquidtight flexible metal conduit may be used for motor leads. This was added to coordinate with 430.245(B) for motors with detached junction boxes. The other part allows 1.8 m (6 ft) lengths for utilization equipment connections and where “part of a listed assembly for tap connections to luminaires as required in 410.117(C).” The upper size limit is metric designator 103 (trade size 4).

ARTICLE 358. ELECTRICAL METALLIC TUBING: TYPE EMT

358.10. Uses Permitted. As is the case with most other raceways, the **NEC** only recognizes the use of *listed* EMT. EMT is a general-purpose raceway of the same nature as rigid metal conduit and IMC. Although rigid metal conduit and IMC afford maximum protection for conductors under all installation conditions, in many instances it is permissible, feasible, and more economical to use EMT to enclose circuit wiring. Because EMT is lighter than conduit, however, and is less rugged in construction and connection details, the **NEC** restricts its use (Art. 358) to locations (either exposed or concealed) where it will not be subjected to severe physical damage or (unless suitably protected) to corrosive agents.

EMT distribution systems are constructed by combining wide assortments of related fittings and boxes. Connection is simplified by employing threadless components that include compression, indentation, and set-screw types.

Some questions have been raised about the acceptability of EMT directly buried in soil. These questions are even more difficult following substantial changes in content and organization of this material in the 2017 **NEC**. At first glance, the answer appears now to be an unqualified “yes” for galvanized steel EMT. Sec. 358.10(A) now gives permission for use “in concrete, in direct contact with the earth, or in areas subject to severe corrosive influences.” The sentence then concludes with a reference to 358.10(B); the question immediately arises, does this phrase modify the entire sentence or just the last of the three items? The way the sentence is structured, including the use of the coordinating conjunction “or” suggests all three topics are indeed being referred to 358.10(B)(1), since that rule, after the permissive opening, identifies the three topics in exactly the same way as (A). The bottom line appears to be that it can be buried without additional corrosion protection beyond the galvanizing, provided the inspector approves it as suitable for the local soil conditions. However, the UL Guide Card (FJMX) information for this product is as yet unchanged. In comparing At this point it is useful to compare the UL listing information on EMT and galvanized steel rigid conduit. The relative acceptability of the different steel raceways will come down to the limitations placed on these listed products by the testing laboratories and local experience with soil conditions. In the UL listing on “Electrical Metallic Tubing,” a note says that “galvanized steel electrical metallic tubing in a concrete slab below grade level *may* require supplementary corrosion protection.” (That word *may* leaves the decision up to the designer and/or installer, subject to final review by the inspector.)

The next note says, “In general, galvanized steel electrical metallic tubing in contact with soil requires supplementary corrosion protection.” That sentence virtually requires that direct burial use

include supplementary corrosion protection. Now compare the equivalent sentence from the Guide Card information on rigid ferrous metal conduit, “Galvanized rigid ferrous metal conduit installed in contact with soil does not generally require supplementary corrosion protection.” The identical wording goes with IMC, and both sentences create a presumption of acceptability for the heavy wall products that is not there for EMT. Further, UL does not evaluate supplementary corrosion protection on EMT for this use. Although EMT may be available with supplementary protection, the Guide Card information on this topic reads: “Galvanized electrical metallic tubing that is provided with a metallic or nonmetallic coating, or a combination of both, has been investigated for *resistance to atmospheric corrosion*” (emphasis supplied). This means that inspectors are entirely on their own if they recognize any form of supplementary protection with respect to the corrosive influences of soil. And supplementary corrosion protection must always be applied unless there is a solid local record of positive experience, which is very unusual. On balance, EMT should not be used for direct burial absent a solid local track record of benign soil conditions.

The first paragraph of Part B also addresses stainless steel EMT. Intriguingly, the UL information specifically indicates that this product, along with its galvanized steel counterpart, does not need supplementary protection in concrete either on grade or above grade. However, there is no mention one way or another as to how the stainless steel product would perform below grade. That, then would be the inspector’s call, but in most cases a stainless product would probably survive soil burial.

Part (B), in the second paragraph, addresses aluminum EMT, and here there is no question; supplementary protection must be provided for both within concrete and also for direct burial. And this does line up perfectly with the UL Guide Card information on that topic.

358.14. Dissimilar Metals. This section was added in the 2017 cycle based on recent testing by NEMA as part of the 2017 NEC revision cycle, and the fact that stainless steel EMT is now on the market. Interconnections between galvanized heavy wall conduit and aluminum fittings, conduit elbows, etc. are still mostly permitted but not if the conditions are deemed extremely corrosive. Perhaps surprisingly, and similar to other comparable raceways, stainless steel IMC has been ruled out for contact with aluminum as well as other types of steel, and strictly limited to other stainless steel fittings, boxes, and other accessories. The actual NEMA supporting argument for this change is reprinted in this handbook at 344.14.

358.20. Size. The whole concern and discussion regarding the differences of actual cross-sectional area between the various raceways has been rendered moot. That is, in recognition of the differences between actual csa from one conduit or tubing, the table in [Chap. 9](#) covering csa—Table 4—and the tables covering maximum number of conductors of all the same size and insulation within a given size of raceway—now Tables C1 and C1A—have been completely rearranged and revised. The procedure remains the same, but the permitted fill is raceway-specific. And conductor dimensions have been corrected.

358.22. Number of Conductors. Conductor fill for EMT is the same as described under 344.22 for rigid metal conduit.

358.24. Bends—How Made. Refer to 344.24.

358.26. Bends—Number in One Run. [Figure 358-1](#) shows EMT run from a panelboard to a junction box (JB) along the wall—with a total of exactly 360° of bend (from the panel: 45°, 45°, 90°, 90°, 45°, 45°). Note that assigning two opposing 45° angles to ordinary box kicks is unduly

restrictive. Opposing 10° angles, so that two such kicks equal about a 45° bend, is more realistic and reasonable.

Fig. 358-1. EMT, like other conduit runs, is limited to not over 360° of bends between raceway ends. (Sec. 358.26.)

358.28. Reaming and Threading. Here, the rules clarify Code intent. Threading of electrical metallic tubing is prohibited, but integral couplings used on EMT shall be permitted to be factory threaded. Such equipment has been used successfully in the past and has been found satisfactory. The revised Code rule recognizes such use. But it should be noted that this applies to EMT using *integral threaded fittings*, that is, fittings which are part of the EMT itself as part of the manufacturing process. A listing still exists on this product, but apparently it has not been in actual production for many years.

358.30. Securing and Supporting. [Figure 358-2](#) shows this rule applied to an EMT layout. As stated in the basic rule of this section, EMT must be supported every 10 ft (3.0 m) and within 3 ft (900 mm) of each “outlet box, junction box, device box, cabinet, conduit body, or other tubing terminations.” Prior to the 1993 **NEC**, this section referred to “each outlet box, junction box, cabinet, and fitting.” If the word *fitting* is taken to include couplings, then a strap must be used within 3 ft (900 mm) of each coupling. The definition of *fitting*, given in Art. 100, includes locknuts and bushings. That wording was changed to provide a “laundry list” of enclosures that are covered by this rule. The intent was to clarify that supports are not required within 3 ft (900 mm) of EMT couplings.

Fig. 358-2. EMT must be clamped within 3 ft (900 mm) of every enclosure or "fitting." (Sec. 358.30.)

As permitted by Exception No. 1, clamps on unbroken lengths of EMT may be placed up to 5 ft (1.5 m) from each termination at an outlet box or fitting where structural support members do not *readily* permit support within 3 ft (900 mm). This exception allows the first clamp to be up to 5 ft (1.5 m) from a termination of EMT at an outlet box. This is like the comparable permission for heavy-wall steel conduits but with an important difference. The EMT between the support 5 ft back and the termination must be unbroken, without coupling. Exception No. 2 allows EMT to be fished; although this may seem odd, it has been done successfully where there is room to stage the unbroken length required.

Part (B), following the two exceptions, makes clear that no additional means of support or securing are needed where framing provides support for horizontal runs at least every 10 ft (3.0 m); however, in addition, the EMT must be secured within 3 ft (900 mm) of every termination. The special support limitations for conduit nipples imposed in the 2008 **NEC** have been revoked and the text returned to that of the 2005 edition. Any nipple not over the general limit on the first point of support in length, namely 900 mm (3 ft), is considered supported by its terminating hardware and no additional support is generally required.

358.42. Couplings and Connectors. Couplings of the raintight type are required wherever electrical metallic tubing is used on the exteriors of buildings. (See 225.22 and 230.53.) Note that the ability of conventional compression connectors and couplings to be actually raintight has been questioned and UL has revised the product standard, greatly toughening the rain tests on fittings that

claim wet location suitability. The result was that every standard compression connector failed. Do not assume that because you are holding a compression connector, you have a fitting that meets the current test requirements for wet locations; look for specific labeling on the product carton. Wet-location suitable fittings now have special designs, usually including internal nonmetallic glands, to pass the new tests. One manufacturer developed a connector with a ferrule similar to what plumbers use to attach brass supply tubes to angle stops under sinks and toilets. This ferrule must engage steel EMT instead of soft brass, however, and the torque specification that comes with the fitting is impressive. It requires a crow-foot open-end wrench extended from a torque wrench, with the wrench reading adjusted for the extra reach of the crow foot, in order to properly seat this fitting.

314.17 requires that conductors entering a box, cabinet, or fitting be protected from abrasion. The end of an EMT connector projecting inside a box, cabinet, or fitting must have smooth, well-rounded edges so that the covering of the wire will not be abraded while the wire is being pulled in. Where ungrounded conductors of size 4 AWG or larger enter a raceway in a cabinet, the EMT connector must have an insulated throat (insulation set around the edge of the connector opening) to protect the conductors. See 300.4(G). For conductors smaller than 4 AWG, an EMT connector does *not* have to be the insulated-throat type. Using THW conductors, a circuit of 4 AWG conductors (a 2- or 3-wire circuit) requires a metric designator 27 (trade size 1) EMT (Table C.1, Annex C, **NEC**). Therefore, for THW or TW wire, there is no requirement for insulated-throat EMT connectors in the metric designator 16 and 21 (trade size ½ and ¾) sizes. A circuit, say, of three 1 AWG THW wires would call for metric designator 35 (trade size 1¼) EMT, which would require use of insulated-throat connectors—or noninsulated-throat connector with a nonmetallic bushing on the connector end. In the larger sizes, the economics on the makeups can be significantly different. A metric designator 103 (trade size 4) insulated-throat EMT connector might cost \$18, whereas a noninsulated-throat connector in that size might cost \$10 and \$2 for a plastic bushing ([Fig. 358.3](#)).

Fig. 358-3. Different-cost makeups for 4-in. (102-mm) EMT satisfy Code rules on EMT termination. (Sec. 358.42.)

When an EMT connector is used—either with or without an insulated throat to satisfy 300.4(G)—there is no requirement in Art. 358 that a bushing be used on the connector end. Note, however, that a bushing is required for rigid metal conduit and for IMC as covered in 344.46 and 342.46.

ARTICLE 360. FLEXIBLE METALLIC TUBING: TYPE FMT

360.2. Definition. This section defines this **NEC** raceway. The rule indicates that flexible metallic tubing is a *raceway*. Use of that term makes clear that all rules applying to “raceways”

within the Code apply to Type FMT as well. The rule further indicates that flexible metallic tubing is intended for use where “not subject to physical damage” and gives use above suspended ceilings as an example. Although this wording does not limit its use to air-handling ceilings, it does raise some questions for electrical inspectors with respect to accepting flexible metallic tubing as a general-purpose raceway.

360.6. Listing Requirements. This rule makes it a violation of the Code to use any flexible metallic tubing that is not specifically listed for use with electrical conductors. Ensure that any flexible metallic tubing is listed and marked as Type FMT, which indicates its suitability for use with electrical conductors.

360.10. Uses Permitted. This section limits the use of flexible metallic tubing to branch circuits. In addition, branch-circuit conductors can only be installed in “dry locations”—either concealed or accessible—with systems rated no more than 1000 V. This product has particular utility for making connections in an air-handling ceiling because it completely excludes the transmission of air and it has no nonmetallic elements that could be a source of smoke or fumes. For these reasons it is permitted not just in other spaces for environmental air [300.22(B)], but in actual ductwork for connections, as covered in 300.22(B).

360.12. Uses Not Permitted. Here the Code states those applications for which Type FMT is not permitted. When the proposal was made to add flexible metallic tubing to the Code as a suitable raceway, it was indicated that it had been designed for certain specific applications and not for general use. It was specifically intended for use as the fixture whip on recessed fixtures where high-temperature wire is run from the branch-circuit junction box to the hot wiring compartment in lighting fixtures, an application long filled by flexible metallic conduit ([Fig. 360.1](#)). Today the cold-lead applications have largely disappeared with integrally wired thermally-protected luminaires, but this wiring method works equally well for conventional connections in hung ceilings. It should be noted that the limitation given in part **(6)** of this section limits the use of this raceway to lengths not exceeding 6 ft (1.8 m), which has the effect of effectively limiting this use of this product to the application for which it was originally intended—fixture whips.
